Abstract We first advance a mathematical novelty that the three geometrically and topologically distinct objects mentioned in the title can be exactly obtained from the Jordan frame vacuum Brans I solution by a combination of coordinate transformations, trigonometric identities and complex Wick rotation. Next, we study their respective accretion properties using the Page–Thorne model which studies accretion properties exclusively for $r \geq r_{\text{ms}}$ (the minimally stable radius of particle orbits), while the radii of singularity/throat/horizon $r < r_{\text{ms}}$. Also, its Page–Thorne efficiency $\epsilon$ is found to increase with decreasing $r_{\text{ms}}$ and also yields $\epsilon = 0.0572$ for Schwarzschild black hole (SBH). But in the singular limit $r \rightarrow r_s$ (radius of singularity), we have $\epsilon \rightarrow 1$ giving rise to 100% efficiency in agreement with the efficiency of the naked singularity constructed in [10]. We show that the differential accretion luminosity $\frac{dL_\infty}{d\ln r}$ of Buchdahl naked singularity (BNS) is always substantially larger than that of SBH, while Eddington luminosity at infinity $L_{\text{Edd}}^\infty$ for BNS could be arbitrarily large at $r \rightarrow r_s$ due to the scalar field $\phi$ that is defined in $(r_s, \infty)$. It is concluded that BNS accretion profiles can still be higher than those of regular objects in the universe.

1 Introduction

Astrophysical observations suggest that almost all black holes (BH) are surrounded by gas clouds with accretion disks of various sizes, extending from about ten to hundred parsecs [1]. However, BHs need not be the only accreting objects in the sky. There could be other categories of hypothetical objects such as naked singularity (NS) and wormholes (WH) that are not ruled out either by theory or by experiment to date. On the contrary, there has been a recent surge of interest in the study of their observational signatures, which include, but not limited to, the phenomena of accretion [2–15], gravitational lensing [16–31], shadow cast on the background of the thin accretion flow [32–41] and gravitational waves [42–48]. These studies offer a wealth of information about these objects but the individual spacetimes describing them are chosen either absolutely freely or constructed artificially and as a rule they cannot be analytically derived from one another by mathematical algorithms. We shall show here that there could be a novel exception to this rule – some famous static spherically symmetric asymptotically flat NS and WH solutions can indeed be derived from one another by a combination of coordinate transformations, trigonometric identities and complex Wick rotation. The natural question then is to ask if these solutions, despite being mathematically non-trivially connected, can nevertheless be observationally distinguishable. To answer this question, we shall investigate the diagnostic of their accretion properties. Among other things, the two major takeaways from the present investigation are: (1) the possibility of conversion of NS into an everywhere regular asymptotically flat WH solution and vice versa, while both lead to Schwarzschild BH (SBH) as a special cases. (2) While BH is undoubtedly the most favored candidate for the accreting astrophysical object, the profiles of other competing objects such as those of NS and regular traversable WH cannot be observationally ruled out as yet.

To elaborate what we mean, consider vacuum Jordan frame (JF) Brans–Dicke theory in the JF with the scalar field $\phi$ playing the role of spin−0 gravity. Originally Brans [49] listed four separate classes of matter-free solutions (I–IV) in the Machian JF of which only the first two are asymptotically flat. JF Brans I solution represents a NS due to the appearance of a curvature singularity at a finite non-zero coordinate radius. The solution can also be interpreted as a singular non-traversable WH connecting two asymptotically flat spacetimes across the singularity for a narrow range of
the Brans–Dicke coupling constant $\omega$ [50]. JF Brans I solution never represents BHs for finite values of $\omega$, as has been recently argued by Faraooni et al. [51]. However, JF Brans I solution yields JF Brans II solution under some redefinitions and complex Wick rotations (see Sect. 2), the latter truly being a twice asymptotically flat everywhere regular traversible WH [52]. Although geometrically and topologically quite different, JF Brans I and II are then seen to be not strictly independent solutions as one can be derived from the other - an intriguing fact that seemingly went unnoticed by Brans himself and later researchers. Both Brans I and II are characterized by the same number of constants and reduce to SBH in the general relativity (GR) limit $\omega \to \infty$.\(^1\) The collapse of vacuum JF Brans I solution was shown by numerical simulation to lead to SBH with the scalar field radiated away [56,57].

In the conformally rescaled Einstein frame (EF), the equations are just those of GR with $\omega$ with the transformed scalar field $\phi$ playing the role of a material source term in the GR equations. Clearly, $\phi$ in JF and $\phi$ in EF play completely different roles. Both JF Class I and II solutions can be expressed in terms of a single arbitrary constant $\gamma$ in the EF (see Sect. 2) but they still carry forward their JF characteristics into the EF. As long as $\gamma$ is kept real and $< 1$, the JF Brans I NS converts in the EF to Buchdahl NS (BNS) [58], rediscovered a decade later now famously known as the Janis–Newman–Winnicour (JNW) solution [59]. Under some other transformations including Wick rotation, BNS converts in the EF to a regular, twice asymptotically flat traversible WH, which we call the Ellis-Bronnikov wormhole (EBWH) characterized by a real $\gamma$. We shall assume that accretion is taking place only on the attractive positive mass side ($0 < r' < \infty$) and so by the term EBWH in this paper, we shall mean only this form of the metric, i.e., Eqs. (36–39). This coordinates can be extended to cover the full-patch ($-\infty < \ell < +\infty$), which then assumes the more familiar form of EBWH [60,61] but we shall not use this form for our purposes. Like their JF predecessors, the two EF re-incarnations, BNS and EBWH, are also not independent solutions – one can be obtained from the other, to be shown in Sect. 2. However their passages to SBH differ: The BNS yields the SBH at the value $\gamma = 1$, while EBWH yields the SBH at the value $\gamma = i$ [46]. In either case, the scalar field $\phi$ vanishes. This means that, for collapse from EBWH to SBH, the constant $\gamma$ has to suddenly jump from a real value to an imaginary value $-i$ at the end of collapse auguring a topology change from a centerless and horizonless WH to a BH with a singular center ($r = 0$) covered by a horizon.

A caveat should be mentioned before proceeding further. Our analysis presupposes the existence or stability of the considered solutions though these issues are not the object of this paper. The existence of NS is forbidden by the Penrose cosmic censorship conjecture (unproven) and the EBWH has been shown to be unstable under general perturbations collapsing into a SBH (see, e.g., [62–65]). On the other hand, under a restricted class of scalar field perturbations that vanish at the throat, EBWH has been shown to be stable [66]. Another recent new idea is that, due to curved spacetime, observation of instability or otherwise of EBWH could be perception-dependent depending on the location of the observer – while one observer perceives instability, another observer might perceive stability and conversely (see, for details, [67]).

The purpose of this paper is to explicitly show how the above famous solutions, Brans I, BNS, EBWH and SBH, are connected with one another and to study the kinematic and emissivity properties of accretion around the last three objects. We then wish to investigate how, despite being connected across the real/imaginary divide of $\gamma$, the profiles differ from each other. We shall employ Page–Thorne model [68] for accretion and assume for numerical illustration a toy model of a central object with mass $15 M_\odot$ and accretion rate $M = 10^{18} g s^{-1}$, which could be identified with BNS, EBWH or SBH respectively.

In Sect. 2, we explain the diagram showing the conversions among different solutions and Sect. 3 shows the massless corollaries. Section 4 describes the thin accretion disk with its kinematic and emissivity formulas belonging to the Page–Thorne model. Section 5 analyses the accretion profiles of three objects, the BNS, EBWH and SBH. Section 6 calculates the Eddington luminosity caused by the scalar field in the BNS and EBWH spacetimes. Section 7 concludes the paper. We take $c = 1, 8\pi G = 1$ unless specifically restored.

### 2 Conversions among different solutions

The diagram below transparently tells the whole story of inter-connectibility of metrics. The arrows are pointed both ways to indicate that the transformation for going from one to the other metric can be reversed to return to the starting metric.

#### 2.1 JF Brans I $\leftrightarrow$ EF BNS (or JNW)

The field equations obtained by varying the vacuum (matter free) JF Brans–Dicke action

---

\(^1\) The limit is not as simple as it looks, there are conceptual twists and turns, see e.g., [53–55].
metric is invariant under inversion the second asymptotically flat region with the radial markar diverge at that radius and is naked because the surface is not covered by a horizon. When \( \lambda = 1 \) or \( C = 0 \), we recover SBH in isotropic coordinates and the surface then becomes a regular horizon.

The Arnowitt-Deser-Misner (ADM) mass \( M \) is given by

\[
M = \frac{1}{16\pi} \int_S \sum_{i,j=1}^3 (\partial_j g_{ij} - \partial_i g_{ij}) n^i dS,
\]

where \( S \) is a 2-surface enclosing the active gravitational region and \( n^i \) is the unit outward normal. The Keplerian mass \( M_{\text{Kepler}} \), which is also called the tensor mass \([56,57]\), is obtained from the post–post-Newtonian (PPN) expansion of the metric. In the case of the JF Brans I solution \( \text{(4)} \), they yield, respectively

\[
M_{\text{ADM}} = \frac{m(C + 1)}{\lambda}, \quad M_{\text{Kepler}} = \frac{m}{\lambda}.
\]

Under the conformal transformation

\[
\tilde{g}_{\rho\sigma} = p g_{\rho\sigma}, \quad p = \frac{1}{16\pi} \tilde{\phi},
\]

and a redefinition of the Brans–Dicke scalar

\[
d\tilde{\phi} = \left( \omega + \frac{3}{2} \right)^{1/2} d\phi.
\]

Then the action \( \text{(1)} \) in the Einstein frame \( (\tilde{g}_{\rho\sigma}, \tilde{\phi}) \) becomes

\[
S_{\text{EF}} = \int d^4 x (-\tilde{g})^{1/2} \left[ \tilde{R} + \tilde{\phi} \right] \phi, \phi, \sigma \right].
\]

The field equations are

\[
\tilde{R}_{\rho\sigma} = -\phi, \phi, \sigma,
\]

\[
\square^2 \phi = 0.
\]

The right hand side represents ordinary matter if \( \phi, \phi, \sigma > 0 \) and ghost matter if \( \phi, \phi, \sigma < 0 \) (that violates Null Energy Condition). The solutions of Eqs. \( \text{(14)} \) and \( \text{(15)} \) can be obtained, using the transformations \( \text{(11)} \) and \( \text{(12)} \) on the Brans I metric \( \text{(4)} \), which we call here the Buchdahl solution \([58]\) in isotropic coordinates:\footnote{There is a bit of history here. Originally, it was Fisher [69], who derived the solution for the canonical real scalar field \( \phi \) so that the stress tensor is positive, \( \phi, \phi, \sigma > 0 \). Since then it has been rediscovered under different parametrizations by other authors such as Bergman and Leinik [70], Buchdahl [58] and Janis–Newman–Winnicour (JNW) [59], to name a few. The equivalence of the last two are shown in [71,72]. However, to avoid confusion, we refer to the solution only as Buchdahl solution for its simple form. On the other hand, the WH solution of Eq. \( \text{(14)} \) is threaded by a phantom scalar field, or imaginary \( \phi \), so that the stress tensor is negative, \( \phi, \phi, \sigma < 0 \). To our knowledge, the WH solution was simultaneously discovered by Ellis [60] and Bronnikov [61] in 1973. (These solutions are sometimes called the “Anti-Fisher” solution for change of sign before the stress term.) That is why, to be historically correct, we call them EBWH (Sect. 2c).}

\[
d\tau_{\text{BNS}}^2 = - \left( 1 + \frac{m}{2\tau} \right)^{-2\gamma} \left( 1 - \frac{m}{2\tau} \right)^{2\gamma} dt^2
\]
The expression for $\lambda^2$, of course, continues to be the same as Eq. (8), and using this, we can rewrite Eq. (17) as

$$
\phi_{\text{BNS}} = \left[2(1 - \gamma^2)^{1/2} \ln \left[1 - \frac{m}{2r}\right]\right].
$$  

The solution is valid for $r > m/2$ and the coordinate frame $\tilde{R}$ is given by

$$
\tilde{R} = \frac{2m^2 r^4 (1 - \gamma^2)}{(r - m^2)^{2(2 - \gamma)} (r + m^2)^{2(2 + \gamma)}},
$$  

- For $0 < \gamma < 1$ in Eq. (19), $\phi$ is real so that $\phi, \phi, r, \phi, \sigma > 0$ and $\tilde{R} > 0$ from Eq. (20). There appears a singularity at $r_s = m/2$, where all the curvature scalars diverge as inherited from its predecessor JF Brans I solution (4). We call this singularity, which is not covered by a horizon, the BNS. Note that the BNS is precisely the famous JNW NS written only in a different form [72].
- For $1 < \gamma < \infty$ in Eq. (19), $\phi$ becomes imaginary so that $\phi, \phi, r, \phi, \sigma < 0$ and $\tilde{R} < 0$ from Eq. (20) characteristic of WHs threaded by ghost matter, which we call EBWH.
- For $\gamma = 1$ in Eq. (19), one has $\phi, \phi, r, \phi, \sigma = 0$, and $\tilde{R} = 0$ from Eq. (20) recovering $SBH$ in isotropic coordinates.

The ADM mass $M$ for the Buchdahl metric (16) is given by

$$
M_{\text{ADM}} = M = mg.
$$  

This mass coincides also with the Keplerian mass $M_{\text{Kepler}}$ as may be found by the PPN expansion of the metric components (16), as well as with the ADM mass, $M_{\text{ADM}}$, i.e., for the Buchdahl NS,

$$
M_{\text{Kepler}} = M_{\text{ADM}} \Rightarrow r_s = \frac{M}{2\gamma}.
$$  

Under a coordinate transformation

$$
\rho = r \left(1 + \frac{m}{2r}\right)^2,
$$  

one has

$$
1 - \frac{2m}{\rho} = \left(1 - \frac{m}{2r}\right)^2.
$$

and so Buchdahl solution (16, 19) transform to another form of JNW NS [73]

$$
d\tau_{\text{INW}}^2 = -(1 - \frac{2m}{\rho})^{\gamma} dt^2 + (1 - \frac{2m}{\rho})^{-\gamma} d\rho^2 + \rho^2 (1 - \frac{2m}{\rho})^{-1}\gamma \left[\frac{\theta^2 + \sin^2 \theta d\psi^2}{d\sigma^2}\right],
$$  

$$
\phi_{\text{INW}} = [2(1 - \gamma^2)]^{1/2} \ln \left(1 - \frac{2m}{\rho}\right).
$$

Here also, when $\gamma = 1$, we recover $SBH$ in standard coordinates with the NS now appearing at $r = 2m$. We shall however calculate accretion properties using the isotropic form, which is the Buchdahl metric (16, 19).

2.2 JF Brans I $\leftrightarrow$ JF Brans II

To obtain the non-singular solution, we need to first remove the above mentioned singularity from the $Brans I$ solution (4–8). We can do it by the following operations on it:

$$
r \rightarrow \frac{1}{r}, \quad m \rightarrow \frac{2\hbar}{\Lambda}, \quad \lambda \rightarrow -i\Lambda, \quad \alpha_0 \rightarrow \epsilon_0, \quad \beta_0 \rightarrow \epsilon_0 + 2 \ln \frac{m}{2},
$$  

where $m$ and $\Lambda$ are real. Using the identity

$$
tan^{-1}(x) = \frac{i}{2} \ln \left(\frac{1 - ix}{1 + ix}\right),
$$

we arrive at the JF Brans II metric and the scalar field as follows

$$
d\tau_{\text{Brans II}}^2 = -e^{2\alpha(r)} dt^2 + e^{2\beta(r)} [dr^2 + r^2 (d\theta^2 + \sin^2 \theta d\psi^2)],
$$

where

$$
\alpha(r') = \epsilon_0 + \frac{2}{\Lambda} \tan^{-1} \left(\frac{2r'}{m}\right),
$$

$$
\beta(r') = \delta_0 - \frac{2(C + 1)}{\Lambda} \tan^{-1} \left(\frac{2r'}{m}\right)
$$

$$
- \ln \left(\frac{4r'^2}{4r'^2 + m^2}\right),
$$

$$
\psi_{\text{Brans II}}(r') = \varphi_0 \exp \left[\frac{2C}{\Lambda} \tan^{-1} \left(\frac{2r'}{m}\right)\right],
$$

$$
\Lambda^2 = C \left(1 - \frac{\omega C}{2}\right) - (C + 1)^2 > 0.
$$

Asymptotic flatness at $r' = \infty$ requires that

$$
\epsilon_0 = -\frac{\pi}{\Lambda}, \quad \delta_0 = \frac{\pi(C + 1)}{\Lambda}.
$$

The story is now quite different – there is a drastic change. The above solution (29–33) has been listed by Brans [74], which we call Brans II solution, but we see that the Brans
I and II are not independent – one can be derived from the other by the transformations in (27). However, though not independent, Brans I and II solutions are by no means equivalent as the former is singular, while the latter is a regular WH [52]. It should be mentioned that the WH interpretation does not take away the WH’s ability to explain the weak field tests of usual solar or stellar gravity in the Keperian positive mass (\(\frac{2\pi}{\Lambda}\)) on one side of the WH [75]. Here we have shown the passage, Brans I \(\rightarrow\) Brans II, while the reverse passage (Brans II \(\rightarrow\) Brans I) was shown by Bhadra and Sarkar [76].

2.3 JF Brans II \(\leftrightarrow\) EBWH

JF Brans II solution was interpreted as a traversible twice asymptotically flat WH in [77]. We may go over to the EF and see that the same interpretation of WH holds [77]. After redefining the constants in JF Brans II (29–33) as

\[
\begin{align*}
2C\frac{A}{\Lambda} & \rightarrow 4\delta, \quad \frac{2(C + 2)}{\Lambda} \rightarrow 4\gamma, \quad -2\pi\frac{A}{\Lambda} \rightarrow \epsilon, \\
2\pi(1 + C)\frac{A}{\Lambda} & \rightarrow \zeta,
\end{align*}
\]

and going over to the EF via using (11,12), we obtain a solution that we claim to be just the everywhere regular EF EBWH describing the positive mass mouth. This is given by

\[
d\tau_{EBWH}^2 = -P(r')dt'^2 + Q(r')[dr'^2 + r'^2(d\theta^2 + \sin^2 \theta d\psi^2)],
\]

where

\[
\begin{align*}
P(r') &= \exp[2\epsilon + 4\gamma \tan^{-1}(2r'/m)], \\
Q(r') &= \left(1 + \frac{m^2}{4r'^2}\right) \exp[2\zeta - 4\gamma \tan^{-1}(2r'/m)], \\
\phi_{EBWH}(r') &= 4\delta \tan^{-1}(2r'/m), \quad 2\delta^2 = 1 + \gamma^2,
\end{align*}
\]

where the coordinate patch covers only one mouth or half-patch, \(0 < r' < \infty\). Asymptotic flatness requires that \(\epsilon = -\pi\gamma\) and \(\zeta = \pi\gamma\). We shall call the metric (36–39) simply EBWH without the prefix EF and use it for calculation since accretion is taking place only around the positive mass mouth. The constraint equation \(2\delta^2 = 1 + \gamma^2\) comes from the EF field equations when the solution is put into them. This EF EBWH has a throat radius

\[
r_{th} = \frac{M}{2\gamma}\left[\gamma + \sqrt{1 + \gamma^2}\right].
\]

The passage from \(d\tau_{EBWH}^2\) to the SBH \(d\tau_{SBH}^2\) of mass \(M\) in isotropic coordinates is possible under a combination of inversion and Wick rotation

\[
r \rightarrow \frac{m^2}{4\rho}, \quad \gamma = i,
\]

and use of the identity

\[
\tanh^{-1}(x) = \frac{1}{2} \ln\left(\frac{1 + x}{1 - x}\right).
\]

These reduce \(d\tau_{EBWH}^2\) to

\[
d\tau_{SBH}^2 = -\left(1 - \frac{m}{\rho}\right)^2 dt^2 + \left(1 + \frac{M}{2\rho}\right)^4 [d\rho^2 + \rho^2(d\theta^2 + \sin^2 \theta d\psi^2)].
\]

Let us extend the coordinates to cover both mouths by transforming the radial variable \(r' \rightarrow \ell\) by

\[
\ell = r' - \frac{m^2}{4r'},
\]

so that the solution (36–39) goes over into

\[
\begin{align*}
d\tau_{EBWH}^2 &= -F(\ell)dt^2 + F^{-1}(\ell)[d\ell^2 + (\ell^2 + m^2) \\
&\quad \times (d\theta^2 + \sin^2 \theta d\psi^2)], \\
F(\ell) &= \exp\left[-2\pi\gamma \tan^{-1}\left(\frac{\ell + \sqrt{\ell^2 + m^2}}{m}\right)\right],
\end{align*}
\]

\[
\phi_{EBWH}(\ell) = 4\delta \tan^{-1}\left(\frac{\ell + \sqrt{\ell^2 + m^2}}{m}\right),
\]

\[
2\delta^2 = 1 + \gamma^2,
\]

where \(\ell\) now covers the two-sided domain, \(-\infty < \ell < +\infty\). The throat now appears at \(\ell_{th} = m\gamma\). Now use the identity

\[
\tan^{-1}\left(\frac{\ell}{m}\right) = \tan^{-1}\left(\frac{\ell}{m}\right) - \frac{\pi}{2}.
\]

Then the metric (45–48) yields precisely the familiar form of the solution obtained independently by Ellis [60] and Bronnikov [61], hence the terminology EBWH:

\[
\begin{align*}
F_{EBWH}(\ell) &= \exp\left[-\pi\gamma + 2\gamma \tan^{-1}\left(\frac{\ell}{m}\right)\right], \\
\phi_{EBWH}(\ell) &= 2\delta \left[\frac{\pi}{2} + \tan^{-1}\left(\frac{\ell}{m}\right)\right],
\end{align*}
\]

\[
2\delta^2 = 1 + \gamma^2.
\]

2.4 BNS \(\leftrightarrow\) EBWH

Using the coordinate transformation

\[
\ell = r + \frac{m^2}{4r},
\]

the BNS (16, 19) can be expressed as

\[
d\tau_{BNS}^2 = -f(\ell)dt^2 + \frac{1}{f(\ell)}[d\ell^2 + (\ell^2 - m^2) \\
&\quad \times (d\theta^2 + \sin^2 \theta d\psi^2)].
\]
\[ f(\ell) = \left( \frac{\ell - m}{\ell + m} \right)^{\gamma}, \]
\[ \phi_{\text{BNS}}(\ell) = \sqrt{2(1 - \gamma^2)} \ln \left[ \frac{\ell - m}{\ell + m} \right]. \]

In this form, it is exactly the Ellis solution [58] that has been discussed also by Bronnikov and Shikin [78]. The singularity has now been shifted to \( \ell = m \).

To remove the singularity, we analytically continue the BNS by means of Wick rotation of the parameters while maintaining the positivity of the ADM mass \( M = m \gamma \). We choose
\[ m \to -im, \quad \gamma \to i \gamma. \]

This results in just the EBWH with the metric
\[ d\tau_{\text{EBWH}}^2 = -f(\ell)dt^2 + \frac{1}{f(\ell)}(dt^2 + (\ell^2 + m^2) \times (d\theta^2 + \sin^2 \theta d\psi^2)), \]
\[ f(\ell) = \exp \left[ -2\gamma \cot^{-1} \left( \frac{\ell}{m} \right) \right], \]
\[ \phi_{\text{EBWH}}(\ell) = \sqrt{2(1 + \gamma^2)} \cot^{-1} \left( \frac{\ell}{m} \right), \]
which can be expressed in the original form (49–51) by using the identities
\[ \cot^{-1}(x) + \tan^{-1}(x) = \frac{\pi}{2}, \quad x > 0 \]
\[ = -\frac{\pi}{2}, \quad x < 0. \]

To recapitulate, the BNS (53–55) reduces to SBH for \( \gamma = 1 \), NS for \( \gamma < 1 \) and for \( \gamma > 1 \), a non-traversable WH due to the presence of singularity at \( \ell = m \). The NS can be regularized by the complex transformations (56) to obtain the EBWH, which also leads to SBH but for \( \gamma = i \).

3 Massless corollaries

These are rather curious cases.

(i) When \( m = 0 \) in the EBWH (36–39), the spacetime becomes flat, as expected. But when \( m \neq 0 \) but \( \gamma = 0 \), we obtain what is known as a symmetric massless EBWH, because the ADM mass is individually zero on each side. However, the integrated scalar field energy is of equal and opposite signs on two sides, so they also add to zero. This means the individual sides exhibit gravitational action on light [29]. The massless EBWH does not accrete matter since \( r_{\text{ms}}^{\text{EBWH}} \to \infty \) (see Sect. 5). However, it can bend light rays around its throat and can thus be detected by observation of gravitational lensing. This massless object has been considered as a candidate for a possible halo object in our galaxy [79, 80].

The metric (57–59) at \( \gamma = 0 \) reduces to
\[ d\tau_{\text{EBWH},M=0}^2 = -dt^2 + \frac{dR^2}{1 - \frac{m^2}{R^2}} + R^2 \times (d\theta^2 + \sin^2 \theta d\psi^2), \]
\[ \phi_{\text{EBWH},M=0} = \sqrt{2} \left[ \frac{\pi}{2} + \tan^{-1} \left( \frac{\ell}{m} \right) \right]. \]

This metric can mimic a BH in producing gravitational waves as analyzed in [42]. The metric (62, 63) represents a geodesically complete manifold on which \( \ell \in (-\infty, \infty) \) and the throat appears at \( \ell_{\text{th}} = 0 \). Light bends towards the source in the sector \( 0 < \ell < \infty \) (attractive gravity) and bends away from the source in the sector \(-\infty < \ell < 0 \) (repulsive gravity).

Using the transformation
\[ R = \sqrt{\ell^2 + m^2}, \]
the metric (62, 63) in standard coordinates becomes
\[ d\tau_{\text{EBWH},M=0}^2 = -dt^2 + \frac{dR^2}{1 - \frac{m^2}{R^2}} + R^2 \times (d\theta^2 + \sin^2 \theta d\psi^2), \]
\[ \phi_{\text{EBWH},M=0} = \sqrt{2} \left[ \frac{\pi}{2} + \tan^{-1} \left( \frac{R^2 - m^2}{R^2} \right) \right] \]
and the throat shifts to \( R_{\text{th}}^{\text{EBWH},M=0} = m \). The two-way light bending angle is (see, for details, [20, 22])
\[ \alpha_{\text{EBWH},M=0}(R_0) = \frac{\pi m^2}{4R_0^2} + \frac{9\pi m^4}{64R_0^4} + \cdots \]
where \( R_0 > m \) is the closest approach distance and shows deflection towards the throat.

(ii) The BNS at \( \gamma = 0 \) has the metric (\( m/2 < r < \infty \)):
\[ d\tau_{\text{BNS},M=0}^2 = -dt^2 + \left( 1 - \frac{m^2}{4r^2} \right)^2 \left[ dr^2 + r^2 \times (d\theta^2 + \sin^2 \theta d\psi^2) \right], \]
\[ \phi_{\text{BNS},M=0} = \sqrt{2} \ln \left[ \frac{1 - \frac{m}{2r}}{1 + \frac{m}{2r}} \right] \approx -\frac{m}{r}, \]
and the ADM mass \( M = m \gamma = 0 \) (\( m \neq 0 \)), while the massless NS at \( r = m/2 \) is made purely of the scalar charge \( m \) (it is still called naked since curvature scalars diverge at \( r = m/2 \) and there is no horizon). This metric does not accrete matter as \( r_{\text{ms}}^{\text{BNS}} \) is imaginary at \( \gamma = 0 \) but it can nonetheless cause light bending which, following the method in [20], is
\[ \alpha_{\text{BNS},M=0}(R_0) = -\frac{\pi m^2}{4R_0^2} + \frac{9\pi m^4}{64R_0^4} + \cdots \]
so the leading order term shows the deflection away from the singularity at \( r = m/2 \) and is exactly negative to that of EBWH. This is in stark qualitative contrast between two
massless objects having implications for gravitational lensing observables, which will be examined in detail elsewhere.

4 Thin accretion disk formulas

Below we briefly describe the developments in Harko et al. [5]. The accretion disc is formed by particles moving in circular orbits around a compact object, with the geodesics determined by the space–time geometry around the object, be it a WH or BH. For a static and spherically symmetric geometry the metric is given in a general form by

\[
d\tau^2 = g_{tt} dt^2 + g_{rr} dr^2 + g_{\theta\theta} d\theta^2 + g_{\phi\phi} d\phi^2. \tag{71}
\]

At and around the equator, the metric functions \(g_{tt}, g_{rr}, g_{\theta\theta}\) and \(g_{\phi\phi}\) only depend on the radial coordinate \(r\), and the thinness of the disk is defined by \(|\theta - \pi/2| \ll 1\).

4.1 Kinematic formulas

These are the angular velocity \(\Omega\), the specific energy \(\tilde{E}\), and the specific angular momentum \(\tilde{L}\) of particles moving in circular orbits in a static and spherically symmetric geometry and are given by:

\[
\frac{dt}{d\tau} = \frac{\tilde{E}}{-g_{tt}}, \quad \frac{d\phi}{d\tau} = \frac{\tilde{L}}{g_{\phi\phi}} \tag{72}
\]

and

\[
g_{rr} \left(\frac{dr}{d\tau}\right)^2 = -1 + \frac{\tilde{E}^2 g_{\phi\phi} + \tilde{L}^2 g_{tt}}{-g_{tt} g_{\phi\phi}}. \tag{73}
\]

The last expression provides an effective potential term

\[
V_{\text{eff}} (r) = -1 + \frac{\tilde{E}^2 g_{\phi\phi} + \tilde{L}^2 g_{tt}}{-g_{tt} g_{\phi\phi}}. \tag{74}
\]

Existence of circular orbits in the equatorial plane demands that \(V_{\text{eff}} (r) = 0\) and \(V_{\text{eff}, r} (r) = 0\), where the comma in the subscript denotes a derivative with respect to the radial coordinate \(r\). These conditions allow us to write

\[
\tilde{E} = \frac{g_{tt}}{\sqrt{-g_{tt} - g_{\phi\phi} \Omega^2}}, \quad \tilde{L} = \frac{g_{\phi\phi} \Omega}{\sqrt{-g_{tt} - g_{\phi\phi} \Omega^2}},
\]

\[
\Omega = \frac{d\phi}{dt} = \frac{-g_{tt,r}}{g_{\phi\phi, r}}. \tag{75}
\]

We assume thin accretion disk with height \(H\) much smaller than the characteristic radius \(R\) of the disk, \(H \ll R\). The thin disk is assumed to be in hydrodynamical equilibrium stabilizing its vertical size, with the pressure and vertical entropy gradient being negligible in the disk. The efficient cooling via the radiation over the disk surface is assumed preventing the disk from collecting the heat generated by stresses and dynamical friction. The thin disk has an inner edge defined by the marginally stable orbit or innermost stable circular orbit (ISCO) radius \(r_{\text{ms}}\) defined by the solution of \(d^2V_{\text{eff}}/dr^2|_{r=r_{\text{ms}}} = 0\), while the orbits at higher radii are Keplerian. In steady-state accretion disk models, the mass accretion rate \(\dot{M}_0\) is assumed to be a constant and the physical quantities describing the orbiting matter are averaged over a characteristic time scale, e.g., the total period of the orbits over the azimuthal angle \(\Delta\phi = 2\pi\), and over the height \(H\) \([68,81,82]\).

In the above steady-state thin disk model, the orbiting particles have \(\Omega, \tilde{E}\) and \(\tilde{L}\) that depend only on the radii of the orbits. Accreting particles orbiting with the four-velocity \(u^\mu\) form a disk of an averaged surface density \(\Sigma\). Page and Thorne \([68]\), using the rest mass conservation law, showed that the time averaged rate of rest mass accretion \(d\dot{M}_0/dt\) is independent of the radius: \(\dot{M}_0 \equiv d\dot{M}_0/dt = -2\pi r u^t \Sigma = \text{const.}\) (Here \(u^t\) is the radial component of the four-velocity). We omit other technical details of the model (for which, see \([68]\)) but quote only the relevant formulas below.

4.2 Emissivity formulas

These consist of the flux \(F(r)\), temperature \(T(r)\) and the luminosity of the radiant energy \(L(\nu)\) over the disk that can be expressed in terms of \(\tilde{E}, \tilde{E}, \tilde{L}\) of the compact sphere \([68,81,82]\)

\[
F (r) = -\frac{\dot{M}_0}{4\pi \sqrt{-g}} \frac{\Omega_{,r}}{(\tilde{E} - \tilde{E} \tilde{L})^2} \int_{r_{\text{ms}}}^r (\tilde{E} - \tilde{E} \tilde{L}) \tilde{L}_{,r} dr. \tag{76}
\]

The accreting matter in the steady-state thin disk model is supposed to be in thermodynamical equilibrium. Therefore the radiation flux emitted by the disk surface will follow Stefan-Boltzmann law:

\[
F (r) = \sigma T^4 (r), \tag{77}
\]

where \(\sigma\) is the Stefan-Boltzmann constant. The observed luminosity \(L(\nu)\) has a redshifted black body spectrum \([83]\)

\[
L (\nu) = 4\pi d^2 I (\nu) = \frac{8\pi \hbar c \cos j}{c^2} \int_{r_{\text{ms}}}^{r_{\text{f}}} \int_0^{2\pi} \frac{\nu^3 r dr d\phi}{\exp \left[ \frac{\hbar \nu c}{k_B T} \right] - 1}. \tag{78}
\]

Here \(\hbar\) is Planck’s constant, \(I (\nu)\) is the Planck distribution function, \(k_B\) is the Boltzmann constant, \(v_e\) is the emission frequency, \(d\) is the distance to the source, \(j\) is the disk inclination angle perpendicular to the line of sight, and \(r_{\text{ms}}\) and \(r_{\text{f}}\) indicate the position of the innermost and outermost edge of the disk, respectively. We take \(r_{\text{f}} \rightarrow \infty\), since we expect that the flux over the disk surface vanishes at \(r \rightarrow \infty\) for any kind of general relativistic compact object described by asymptotically flat geometry. We take \(j = 0^\circ\) so that the disk is face-on. The observed photons are redshifted to the
frequency \( \nu \) related to the emission frequency \( \nu_e \) related by
\[
\nu_e = (1 + z)\nu,
\]
where the red-shift factor is given by [3]
\[
1 + z = \frac{1 + \Omega r \sin \varphi \sin j}{\sqrt{-8M - \Omega^2 \sin^2 \varphi}}.
\]

Following Page–Thorne model, an important characteristic of the accretion disk is the efficiency \( \epsilon \), which quantifies the ability by which the accreting body converts particle mass into radiation. It is measured at infinity and is defined as the ratio between the rate of energy of the photons emitted from the disk surface and the rate with which mass-energy is transported to the central accreting body. If all photons reach asymptotic infinity, the efficiency is given by the specific energy \( \bar{E} \) of accreting particles measured at \( r = r_{\text{ms}} \) such that [84]
\[
\epsilon = 1 - \bar{E}_{\text{ms}}.
\]

We shall use the above formulas to numerically compute the kinematic and emissivity properties.

### 5 Analyses of accretion profiles: BNS, EBWH and SBH

We shall henceforth be considering Eqs. (16–19) for BNS, Eqs. (36–39) for EBWH and Eq. (43) for SBH for the ensuing calculations. Note that we assume a toy model for the mass of the accreting central object to be \( M = 15M_\odot \) with the accretion rate \( \dot{M}_0 = 10^{18} \text{ g s}^{-1} \) for illustration.

#### 5.1 Behavior of kinematic profiles

For the reality of the BNS, it is necessary that \( 0 < \gamma < 1 \), while for the EBWH, \( 1 < \gamma < \infty \), the intervals being mutually exclusive. The SBH with a vanishing scalar field \( \phi \) corresponds to \( \gamma = 1 \) in BNS and \( \gamma = i \) in the EBWH. To derive the kinematic properties, consider Eq. (74) for the generic effective potential \( V_{\text{eff}} \). For the solutions under consideration, we explicitly derive \( r_{\text{ms}} \) in isotropic coordinates as under [using \( m = \frac{M}{\gamma} \) in (16) where \( M \) is the \( M_{\text{ADM}} \) defined in (21)]:

\[
r_{\text{rms}}^{\text{BNS}} = \frac{M}{2\gamma} \left[ 3\gamma + \sqrt{5\gamma^2 - 1 + \sqrt{2\gamma}} \right]
\]
\[
\times \left( 7 - \frac{1}{\gamma^2} - \frac{3 - 15\gamma^2}{\gamma \sqrt{5\gamma^2 - 1}} \right)^{\frac{1}{2}},
\]

\[
r_{\text{rms}}^{\text{EBWH}} = \frac{M}{2\gamma} \left[ 3\gamma + \sqrt{5\gamma^2 + 1 + \sqrt{2\gamma}} \right]
\]
\[
\times \left( 7 + \frac{1}{\gamma^2} + \frac{3 + 15\gamma^2}{\gamma \sqrt{5\gamma^2 + 1}} \right)^{\frac{1}{2}},
\]

which is a well known value. The kinematic formulas including the potential \( V_{\text{eff}} \) in Eq. (74) valid at an arbitrary radius \( r \) are as under:

\[
\bar{E}_{\text{BNS}} = \left[ \frac{4\gamma^2 + M(M - 4\gamma r)}{4\gamma^2 + M(M - 8\gamma r)} \right]^{\frac{1}{2}} \left( 1 - \frac{M}{2r} \right)^\gamma
\]
\[
\times \left( 1 + \frac{M}{2r} \right)^{-\gamma},
\]

\[
\bar{E}_{\text{EBWH}} = \left[ \frac{-M^2 + 4Mr\gamma^2 + 4r^2\gamma^2}{-M^2 + 8Mr\gamma^2 + 4r^2\gamma^2} \right]^{\frac{1}{2}} \times \exp \left( -\pi \gamma - 2\gamma \tan^{-1} \left( \frac{2\gamma r}{M} \right) \right),
\]

The marginally stable radii in isotropic coordinates yield the ratio \( r_{\text{rms}}^{\text{EBWH}}(\gamma \rightarrow \infty) / r_{\text{rms}}^{\text{NS}} = 1.0579 \). The demand for the reality of the expression for \( r_{\text{rms}}^{\text{BNS}} \) in Eq. (82) further reduces the BNS range \( 0 < \gamma < 1 \) to the range \( \frac{1}{\sqrt{3}} < \gamma < 1 \), which then corresponds to the \( 2.5 < r_{\text{rms}}^{\text{BNS}} / M < 4.949 \) and the singular radii \( 0.5 < r_{\text{rms}}^{\text{NS}} / M < 1.118 \). These clearly show that \( r_{\text{rms}}^{\text{BNS}} < r_{\text{rms}}^{\text{NS}} \). The EBWH range is \( 1 < \gamma < \infty \), which corresponds to minimally stable radii \( 5.495 > r_{\text{rms}}^{\text{EBWH}} / M > 5.236 \) and the throat radii \( 1.207 > r_{\text{th}}^{\text{EBWH}} / M > 1 \), indicating that \( r_{\text{rms}}^{\text{EBWH}} < r_{\text{th}}^{\text{EBWH}} \). The idea here is to show that marginally stable orbits for BNS (or for EBWH) do not come close the NS since the allowed radial intervals are disjoint, not overlapping around a common value \( r_{\text{rms}}^{\text{BNS}} / M \sim r_{\text{rms}}^{\text{NS}} / M \), so it is not possible that the \( r_{\text{rms}}^{\text{BNS}} \) could approach \( r_{\text{rms}}^{\text{NS}} \). As a result, we do not find arbitrarily large increase in the accretion luminosity, unlike what happens in the NS [10] at \( r_{\text{rms}} \rightarrow r_{\text{NS}} = 0 \), the central singularity. That is why we shall calculate the profiles only from \( r_{\text{rms}} \) upwards as shown in the relevant figures. The distinction between the two singularities probably signals the generic difference between the BNS and NS in [10] – the former singularity is removable while that the latter is not. Further, in the former, \( r = 0 \) is the central singularity, whereas in the latter the center is a regular point.

Note once again that singularity appears at \( r_{\text{rms}}^{\text{BNS}} \) for the horizon at \( \tilde{r}_{\text{rms}}^{\text{SBH}} = \frac{M}{2r} \) and the throat at \( \tilde{r}_{\text{th}}^{\text{EBWH}} = \frac{M}{2r} \left( \gamma + \sqrt{1 + \gamma^2} \right) \). Eq. (85) yields \( \tilde{E}_{\text{BNS}} \rightarrow 0 \) as \( \tilde{r}_{\text{rms}}^{\text{BNS}} \rightarrow 0 \).
Table 1  The $r_{\text{ms}}$ and the efficiency $\epsilon$ for EBWH, BNS and SBH. Note that $\gamma = 1$ in BNS and $\gamma = i$ in EBWH respectively yield SBH quantities, while $\gamma = 0$ yields the values for massless BNS and EBWH respectively.

| $\gamma$   | EBWH |         | BNS |         |
|------------|------|---------|-----|---------|
|            | $r_{\text{ms}}/M$ | $\epsilon$ | $r_{\text{ms}}/M$ | $\epsilon$ |
| 0          | $\infty$ | - | Imaginary | - |
| 0.45       | - | - | 2.809 | 0.0790 |
| 0.5        | - | - | 3.732 | 0.0693 |
| 0.7        | - | - | 4.609 | 0.0603 |
| 0.9        | - | - | 4.877 | 0.0578 |
| 1          | - | - | 4.949 | 0.0572 |
| 1.25       | 5.404 | 0.0534 | - | - |
| 1.5        | 5.354 | 0.0538 | - | - |
| 2          | 5.303 | 0.0542 | - | - |
| 2.5        | 5.279 | 0.0544 | - | - |
| $i$        | 4.949 | 0.0572 | - | - |

Fig. 2  The effective potential $V_{\text{eff}}$ for EBWH ($\gamma > 1$), BNS ($\gamma < 1$) and SBH ($\gamma = -i$ from EBWH, and $\gamma = 1$ from BNS).

$M_{\odot}$, which in turn yields $\epsilon \rightarrow 1$ or 100% efficiency in exact accordance with the result obtained in [10] about the efficiency of their NS by integrating the spectral luminosity.\(^3\)

However, according to Page–Thorne model, some illustrative values of $\epsilon$ are: For SBH it is 0.0572 or 5.72% at $r_{\text{ms}}^{\text{SBH}}/M = 4.949$, for EBWH it is 5.42% at $r_{\text{ms}}^{\text{EBWH}}/M = 5.303$ and for BNS it is 7.9% at $r_{\text{ms}}^{\text{BNS}}/M = 2.809$, as in Table 1. These results qualitatively accord with those in [6].

The kinematic profiles are presented in the Figs. 2, 4 and 5. The effective potential $V_{\text{eff}}(r)$ for the three objects described by a EBWH and BNS are shown in Fig. 2. The specific angular momentum of the orbiting particle is chosen to be $\hat{L} = 4M$. From an examination of the plots for EBWH (top panel, left hand), it turns out that the potential barrier peak is highest at the SBH limit ($\gamma = i$), while it is depressing

\(^3\) We are thankful to the anonymous second referee for pointing out the result in [10].
with the decrease in the value of $\gamma$. For BNS (top panel, right hand), it is seen that the picture is just the opposite. The barrier peak is lowest at the SBH limit ($\gamma = 1$), while the barrier is rising indefinitely with the decrease in the value of $\gamma$, finally diverging at $r_s = \frac{M}{2\gamma}$ indicative of NS. A strict comparison between the accretion profiles of EBWH, BNS and SBH is impossible since they are defined within mutually exclusive intervals of $\gamma$. However, the profiles of EBWH and BNS may be individually compared with those of SBH, which is a unique limit having a vanishing scalar field $\phi$. This comparison in potential profiles of BNS and EBWH are shown for fixed relevant values of $\gamma$ and compared with those of SBH (bottom panel). The BNS profiles show maxima at a height much higher than those for the other objects, which characterizes NS.

The specific energy $\tilde{E}(r)$ of the orbiting particles as a function of the radial coordinate $r$ (in cm) for the three objects are displayed in Fig. 4. The profiles of SBH appear between the higher profile of BNS and lower ones due to EBWH (bottom panel). The behavior of the specific angular momentum $\tilde{L}(r)$ of orbiting particles are shown in Fig. 5. The overall pattern for EBWH is that $\tilde{L}(r)$ decreases from above to a minimum and then increases again (top panel, left hand). For the BNS, similar behavior is exhibited only for $\gamma \leq 0.5$, whereas for higher values of $\gamma$, $\tilde{L}(r)$ increases but eventually approaches the previous minimum but from below (top panel, right hand). Patterns similar to that for potential are also seen for relevant values of $\gamma$ (bottom panel).

### 5.2 Behavior of emissivity profiles

Using relevant values of $\gamma$, the Figs. 6, 7 and 8 show the emissivity profiles, all of which nearly coincide at large $r$. Figure 6 shows the time averaged flux $F(r)$ as a function of the radial coordinate $r$ radiated by the disk for EBWH (top panel, left hand) shows that the flux peaks highest for SBH ($\gamma = i$) than that of EBWH for different real $\gamma$. This behavior is qualitatively just the opposite in the case of BNS, where its maximum appears far above that of the SBH, ~ 6 times higher (top panel, right hand). Comparison of the radiation flux profiles are also seen between BNS and EBWH for respective admissible values of $\gamma$ (bottom panel). It can be observed that the EBWH profiles appear (top panel, left hand) somewhere in between those of BNS and SBH. Figure 7 shows temperature distribution $T(r)$ as a function of the radial coordinate $r$ of the accretion disk for EBWH (top panel, left hand), BNS (top panel, right hand), and comparison in the temperature distribution $T(r)$ is seen between BNS and EBWH for respective admissible values of $\gamma$ (bottom panel). The qualitative features are the same as that of
The specific angular momentum $\tilde{L}(r)$ for EBWH, BNS and SBH for different values of $\gamma$ for flux, as expected, since it is connected to radiation flux by Stefan-Bolzmann law. Figure 8 shows the luminosity spectra $\nu L(\nu)$ of the accretion disk for EBWH (top panel, left hand), BNS (top panel, right hand). The luminosity profiles of these objects are compared with that of SBH for relevant values of $\gamma$ (bottom panel). The overall patterns show that SBH profile dominates over that of EBWH but the BNS profiles dominate over both. Indeed, in the case of a NS, the $r_{ms}$ comes closer to the central singularity, which leads to a considerable increase in the luminosity of the disk though it does not lead to 100% efficiency.

Joshi et al. [10] defined a differential luminosity reaching an observer at infinity as

$$\frac{dL_{\infty}}{d\ln r} = 4\pi r^2 \sqrt{-g} \tilde{E} F, \quad (89)$$

where $\tilde{E}$ is the specific energy and $F$ is the radiation flux emitted by the disk. Figures 9 and 10 show differential luminosity for BNS, EBWH and SBH, respectively. We obtain the same SBH Page–Thorne profile as obtained in [10]. The most significant difference between BNS and SBH (Fig. 9) appears near $r_{ms}$, where the differential luminosity of BNS is always noticeably larger than SBH (but not infinitely large).

In contrast, differential luminosity of EBWH is always lower than that of SBH. However, a very important observable – the Eddington luminosity at infinity shows infinite magnitude as the singular radius $r_s$ is approached, which we discuss next.

6 Eddington luminosity of the disk

The Eddington luminosity, often called the Eddington limit, is the maximum luminosity that an accreting disk around an astrophysical body can achieve, when there is balance between the force of radiation acting outward and the gravitational force acting inward establishing a hydrostatic equilibrium. This luminosity for the case of a boson star was pointed out in [83]. The hydrostatic equilibrium leads to Eddington luminosity given by $L_{\text{Edd}} = 4\pi M m_p/\sigma_T = 1.3 \times 10^{38} (M/M_\odot)$ erg/s, where $m_p$ is the proton mass, and $\sigma_T$ is the Thompson cross section [85]. Since the accretion disk in general has a radius dependent mass distribution, $M = M(r)$, the Eddington luminosity becomes a radius

4 We thank the anonymous first referee for drawing our attention to this property of the disk.
dependent quantity as well, \( L_{\text{Edd}}(r) \propto M(r) \). A similar effect can also occur in the case of accretion disk around the NS and WHs considered in the present paper. Except SBH, our solutions for BNS and EBWH are sourced by the scalar fields (Eqs. (19) and (39) respectively) that can be described by a energy-momentum tensor yielding a mass distribution \( M(r) \) along the equatorial plane of the disk [6], given by:

\[
M(r) = 4\pi \int_{r_s}^r T_{00} r^2 dr = 2\pi \int_{r_s}^r g' \varphi_x \varphi_r r^2 dr,
\]

where \( r_s \) stands for the radius of NS \( r_s = M/2\gamma \) [see Eq. (22)] or the throat radius \( r_{th} \) of WHs [see Eq. (40), prime dropped], as the case may be. No Eddington luminosity for SBH since there is no scalar field (in virtue of no-hair theorem). By using the the scalar field from the metrics (16,19) and (36,39) respectively, we obtain

\[
M_{\text{BNS}}(r) = \frac{\pi}{2} \left( 1 - \gamma^2 \right) M^2 \int_{r_s}^r \frac{1}{r^2} \left( 1 - \frac{M}{2\gamma r} \right)^{2(\gamma - 2)} dr,
\]

\[
M_{\text{EBWH}}(r) = \frac{8\pi \delta^2 M^2}{\gamma^2} \int_{r_s}^r \frac{1}{r^2} \left( 1 + \frac{M^2}{4\gamma^2 r^2} \right)^{-4} dr.
\]

\[
\times \exp \left[ 2\pi \gamma - 4\gamma \tan^{-1} \left( \frac{2\gamma r}{M} \right) \right] dr.
\]

The corresponding coordinate-dependent Eddington luminosity can be obtained as

\[
L_{\text{Edd}}^\text{BNS}(r) = 1.37 \times 10^{33} \times (1 - \gamma^2) M^2 \int_{r_s}^r \frac{1}{r^2} \left( 1 - \frac{M}{2\gamma r} \right)^{2(\gamma - 2)} \left( 1 + \frac{M}{2\gamma r} \right)^{-2(\gamma + 2)} dr
\]

\[
= 1.37 \times 10^{33} M^2 \times r_{\text{BNS}}(r), \tag{92}
\]

\[
L_{\text{Edd}}^\text{EBWH}(r) = \frac{1.09 \times 10^{34} \times (1 + \gamma^2) M^2}{\gamma^2} \int_{r_s}^r \frac{1}{r^2} \left( 1 + \frac{M^2}{4\gamma^2 r^2} \right)^{-4} dr
\]

\[
\times \exp \left[ 2\pi \gamma - 4\gamma \tan^{-1} \left( \frac{2\gamma r}{M} \right) \right] dr.
\]

\[
= 1.37 \times 10^{33} M^2 \times r_{\text{EBWH}}(r) \tag{93}
\]

Figure 11 shows the dependence of the dimensionless Eddington luminosity \( L_{\text{edd}}(r)/L_{\text{edd}} \) for a BNS with \( M = 15M_\odot \), for different values of \( \gamma \). It is seen that with the increase of \( \gamma \) Eddington luminosity decreases sharply, down
to zero in the case of SBH (since it does not have a scalar field). Behavior in Fig. 12 for EBWH is similar to BNS in Fig. 11. At small $\gamma$, Eddington luminosity reaches highest values. Comparing the two plots in Figs. 11 and 12, we find that values of $\gamma$ close to 1 ($\gamma = 0.9$ in the case of BNS and $\gamma = 1.5$ in the case of EBWH), the Eddington luminosity of EBWH is always higher than BNS. However, a completely different picture is observed with decreasing $\gamma$ in the case of BNS. It can be seen from the Fig. 11 that for local observers, the Eddington luminosity of EBWH is higher than BNS, but for asymptotic observers, objects such as BNS will be much brighter than EBWH.

The Eddington critical luminosity is the luminosity attained at the critical radius at which the outward radiation force balances gravity causing expansion layers of the star. Observation of X-ray bursts lead to the theoretical expectation that the emerging luminosity observed at infinity should be approximately equal to the Eddington critical luminosity. The Eddington luminosity at infinity of a NS with a thin surface is given by [6]

$$L_{\infty}^{\text{NS}} = \frac{4\pi m_p M}{\sigma T} \left[ \frac{16\gamma^2 r^2}{(M^2 - 4\gamma^2 r^2)^2} \left( 1 - \frac{M}{2\gamma r} \right)^{3\gamma} \left( 1 + \frac{M}{2\gamma r} \right)^{-3\gamma} \right] \bigg|_{r=r_s}.$$  

For the BNS, we obtain

$$L_{\infty}^{\text{BNS}} = \frac{4\pi m_p M}{\sigma T} \left[ \frac{16\gamma^2 r^2}{(M^2 - 4\gamma^2 r^2)^2} \left( 1 - \frac{M}{2\gamma r} \right)^{3\gamma} \left( 1 + \frac{M}{2\gamma r} \right)^{-3\gamma} \right] \bigg|_{r=r_s}.$$  

When $r_s = \frac{M}{2\gamma}$, we find $L_{\infty}^{\text{BNS}} \rightarrow \infty$. This shows that the Eddington luminosity of BNS can reach arbitrarily higher values than that of regular astrophysical objects.

For the EBWH we obtain

$$L_{\infty}^{\text{EBWH}} = \frac{4\pi m_p M}{\sigma T} \left[ \frac{16\gamma^2 r^2}{(M^2 + 4\gamma^2 r^2)^2} \right] \exp \left\{ -3\pi \gamma + 6\gamma \tan^{-1} \left( \frac{2\gamma r}{M} \right) \right\} \bigg|_{r=r_{th}}.$$  

(96)
The emission spectra $\nu L(\nu)$ of the accretion disk with inclination $i = 0^\circ$ for EBWH, BNS and SBH for different values of $\gamma$ and after putting $r_{\text{th}} = (\frac{M}{2\gamma})(\gamma + \sqrt{1 + \gamma^2})$, we get

$$L_{\text{\,\,\,\,Edd}}^\infty_{\text{EBWH}} = 5.2 \times 10^{38} \frac{M^3}{M_\odot} \left(\gamma + \sqrt{1 + \gamma^2}\right)^2 \times \exp \left[-3\pi\gamma + 6\gamma \tan^{-1}\left(\gamma + \sqrt{1 + \gamma^2}\right)\right],$$

which is in general finite. It can be verified that $L_{\text{\,\,\,\,Edd}}^\infty_{\text{SBH}} = 0$ at $r_{\text{hor}} = \frac{M}{\gamma}$ from Eq. (95) at $\gamma = 1$ or from Eq. (96) at $\gamma = i$ [using Eqs. (41) and (42)]. This is consistent with the fact that SBH has no scalar field exterior.

### 7 Conclusions

In the foregoing work, we first showed how the NS in the BNS (or JNW) could be removed by a novel combination of coordinate transformations, trigonometric identities and complex Wick rotation converting it to a regular traversible EBWH. The diagram in Fig. 1 succinctly explains how Brans I metric in the JF and BNS, horizonless EBWH, SBH in the EF are connected among one another [46,50,76,86,87]. This interesting non-trivial connectivity does not seem to have been widely noticed as yet, to our knowledge.\footnote{In this context, we draw attention to a long standing debate in GR about the conformally connected JF and EF, viz., which frame is the physical one, and about the equivalence of the geometrical and physical properties of the gravitating systems in the two frames. Although we studied accretion properties exclusively in the EF, we showed earlier [88] on the basis of second order light deflection that there are non-equivalent predictions coming from the two frames, JF and EF. Going a step further, predictions of lensing observables in the two frames also...}

differ, thus they are not invariant quantities, which is lucidly demonstrated in [89]. A precise lensing measurement can easily distinguish between the two theories, supporting one and ruling out the other. The basis for this conclusion is the fundamental fact that ordinary coordinate transformations do not change curvature properties, while conformal transformations do change them leading to corresponding changes in

Footnote 5 continued

the numerical values of observables. A simple example is that a flat spacetime can be changed to a non-flat spacetime by conformal transformation, hence physically observable predictions from them should be distinct, although light motion in both spacetimes is defined by the same invariant equation, \( dt^2 = d\tilde{t}^2 = 0 \). We thank the anonymous first referee for raising this important issue.
5.72\% efficiency at $r_{ms}^{\text{SBH}}/M = 4.949$ deduced as corollaries from BNS ($\gamma = 1$) and EBWH ($\gamma = i$), and for BNS ($\gamma = 0.45$), it is around 8\% at $r_{ms}^{\text{BNS}}/M = 2.809$ as exhibited in Table 1. These results accord well with those in [6].

It is of interest to note from Eq. (85) that $E_{\text{BNS}}^{\text{BNS}} \rightarrow 0$ as $r \rightarrow r_{s}^{\text{BNS}} = M/\sqrt{3E}$, so that $\epsilon \rightarrow 1$ or 100\% efficiency, which agrees with the conclusion in [10] arrived at by integrating the spectral luminosity, but this happens only in the singular limit $r \rightarrow r_{s}^{\text{BNS}}$, not covered by the Page–Thorne model. Marginally stable orbits in BNS cannot come close the NS. The demand that the expression for $r_{ms}^{\text{BNS}}$ in Eq. (82) be real further reduces the original BNS range $0 < \gamma < 1$ to the range $\frac{1}{\sqrt{3}} < \gamma < 1$, which then corresponds to the radial ranges $2.5 < r_{ms}^{\text{BNS}}/M < 4.949$ and the singular radii $0.5 < r_{s}^{\text{BNS}}/M < 1.118$. These clearly show that the intervals are disjoint, not allowing even a nearly common value $r_{ms}^{\text{BNS}}/M \sim r_{s}^{\text{BNS}}/M$, so it is not possible that minimally stable orbits could gradually zero in onto the singularity. As a result, an arbitrarily large increase in the emissivity properties at the singular radius $r_{s}^{\text{BNS}}$ cannot be attained within the Page–Thorne model unlike that in [10]. This happens probably due to the generic difference between the BNS of a self-consistent theory and the matched NS in [10] – the former singularity is removable by combinations of non-trivial transformations, while that in the latter is irremovable. Further, in the BNS, $r_{s}^{\text{BNS}} = M/\sqrt{3}$, the center $r = 0$ is a regular point, where scalar curvatures are finite. In the other NS [10], there is central singularity $r_{s}^{\text{NS}} = 0$, where scalar curvatures diverge.

Apart from the above differences, the BNS is an EF version of Brans–Dicke NS threaded by a massless scalar field. This scalar field $\phi$, defined in the entire open interval $(r_{s}, \infty)$, gives rise to a very important observable, the Eddington luminosity, $L_{\text{Edd}}^{\text{BNS}}(\epsilon)$. The analyses in Sect. 6 lead us to conclude that naked curvature singularity can exhibit arbitrarily large Eddington luminosity at infinity $L_{\text{Edd}}^{\infty}$ as $r \rightarrow r_{s}$, which are consistent with the results obtained by Kovács and Harko [6]. Interestingly, the gravity fields of massless ($M = 0$) BNS and EBWH do not at all accrete matter since $r_{ms}$ is imaginary or infinitely large respectively, as is shown in Table 1, but both deflect light [see Eqs. (67) and (70)] since the Keplerian mass sensed by the photons is non-zero ($m \neq 0, \gamma = 0$). These cases are important since massless EBWH has actually been modeled as galactic halo objects in the Milky Way [79,80].

The overall conclusion is that the three objects considered here are in principle distinguishable by their accretion properties. In particular, though not all naked singularities, like BNS here and that in [10], have the same efficiency, BNS may still exhibit profiles noticeably higher than those of non-singular objects in the universe.
