**Abstract:** *Colletotrichum* is one of the most important plant pathogenic genera of fungi due to its scientific and economic impact. *Colletotrichum* spp. can infect a wide range of hosts, causing losses in crops of major importance worldwide, such as soybean. In the past, soybean anthracnose was mainly caused by *C. truncatum*, but during the last decade, other species have been identified at an increasing rate, becoming one of the most important limiting factors to soybean production in several regions. To gain a better understanding of the evolutionary origin of soybean anthracnose, we compared the repertoire of effector candidates of four *Colletotrichum* species pathogenic to soybean and eight pathogens of other hosts. Our results show that the four species infecting soybean belong to two lineages and do not share any of the lineage specific effector candidates identified. These results strongly suggest that two *Colletotrichum* lineages have acquired the capability to infect soybean independently. This study also provides, for each lineage, a set of candidate effectors encoding genes that may have important roles in pathogenicity towards soybean offering a new resource useful for further research on soybean anthracnose management.

**Keywords:** anthracnose; genome sequencing; pathogenicity factors, *Colletotrichum truncatum*, *Colletotrichum orchidearum*, *Glomerella*, *Glycine max*.

1. **Introduction**

With 257 accepted species classified into species complexes (s.c.) or singletons [1], *Colletotrichum* is considered among the ten most destructive genera of phytopathogenic fungi [2], responsible for losses in many important cultivated crops [3–7]. Several species of *Colletotrichum* have been reported as pathogenic to soybean, being the *C. orchidearum* and *C. truncatum* s.c. found as the complexes with most of the available data associated with symptomatic soybean plants worldwide [8]. While *C. truncatum* is associated with soybean since 1917 [9], *C. musicola*, *C. plurivorum* and *C. sojae*, members of the *C. orchidearum* s.c. were only described in the past 5 years [10–12], however this species complex is misidentified at least since 2003 [8].

A dispute for survival and adaptation marks the evolutionary battle between plants and pathogens throughout history [13–15]. This arms race can be partially described by the “zig-zag” model [13], where the first layer of defense of plants recognizes molecular patterns associated with pathogens (PAMPs) or damage-associated molecular patterns (DAMPs) and active a pattern triggered immune response (PTI) [13,16,17]. On the other
Hand, pathogens can overcome this layer of defense releasing effectors, that are secreted proteins that cause alterations in structure or processes of the host cell, suppressing the defense responses or enhancing access to nutrients, promoting the colonization of the host by the pathogen [18]. The recognition of effectors or effector targets by resistance (R) genes of the host will then trigger the second layer of defense, called effector-triggered immunity (ETI), being a stronger response than PTI that can lead to a hypersensitive reaction (HR) [14,18]. With the advance of molecular studies, it was shown that the division among PTI and ETI is blurred [19–21], and now an integrated plant immune system has been proposed, where a crosstalk between plant immune receptors is essential to both, PTI and ETI achieve its maximum immune response [22].

Over the past few years, the genomes of at least 43 species of Colletotrichum have been sequenced [23–47] (http://www.colletotrichum.org/genomics/), including C. truncatum, C. musicola, C. plurivorum and C. sojae [45]. The availability of genome sequences from multiple species of Colletotrichum enables unprecedented insights into genome composition [48]. An understanding of the pathogenicity mechanisms of Colletotrichum and the way that they adapt to their hosts can be a powerful tool in developing sustainable control strategies [49–51]. It is known that the evolution through adaptation of pathogens to different hosts can involve sets of effectors, that can specialize to infect a specific host [52–56], therefore the evolutionary trajectory of host-pathogen interactions can help to clarify the mechanisms underlying the threat of pathogens to crops [57].

The identification of effector candidates is the first step into the functional characterization of these molecules. Until now, several studies on effectors of different species of Colletotrichum such as C. higginsianum [58,59] C. orbiculare [60,61] C. lentis [62–64], C. graminicola [65–67] C. simmondii, C. fiorinae, C. nymphaeae, C. salis [30], C. lindemuthianum [68], C. falcatum [69], C. fruticola, C. siamense, C. aenigma, C. tropicale, C. viniferum [44] have been published. On the other hand, comparative genomic studies of Colletotrichum spp. that infect soybean have not been performed and the number of candidate effectors of C. truncatum, C. plurivorum, C. musicola and C. sojae, and how many are unique to these species is unknown. A compilation of candidate effectors of those species may help to identify determinants of host specificity in the Colletotrichum-soybean interaction as well as better understanding the mechanisms underlying soybean infection.

To gain a better understanding of the evolutionary origin of soybean anthracnose, we analyzed the repertoire of Lineage Specific Effector Candidates (LSECs) defined as secreted proteins that have no homology to any other protein or that have homology to proteins from other members of the same genus, species or species complex [30]. We analyzed the proteomes of four species of Colletotrichum pathogenic to soybean and compared these with eight closely related species of Colletotrichum non-pathogenic to this host providing a useful platform for future works regarding soybean anthracnose.

2. Results

2.1 Among the selected Colletotricchum species, only C. truncatum and members of the C. orchidearum s.c. are pathogenic to soybean

The pathogenicity of 10 Colletotrichum species selected for comparative genomic analyzes (Table 1) were tested on soybean.

| Strain     | Species       | Species complex | Host       | Origin | *   |
|------------|---------------|-----------------|------------|--------|-----|
| MAFF 240422| C. orbiculare | C. orbiculare   | Cucumis sativus | Japan  | [38]|
| LFN0074    | C. musicola   | C. orchidearum  | Glycine max | Brazil | [45]|
| LFN00145   | C. plurivorum | C. orchidearum  | Glycine max | Brazil | [45]|

**Table 1: Colletotrichum strains used in the pathogenicity test and comparative genomics analysis**
Assays confirmed that only *C. truncatum* and the three species belonging to the *C. orchidearum* s.c., *C. musicola*, *C. plurivorum* and *C. sojae* cause anthracnose symptoms in soybean, of which *C. truncatum* is the most virulent to the tested soybean cultivar (Monsoy IPR07739) than the three species belonging to the *C. orchidearum* s.c. (Figure 1). *Colletotrichum gloeosporioides*, *C. higginsianum*, *C. tofieldiae*, *C. orchidophilum*, *C. fioriniae* and *C. nymphaeae* were not pathogenic to soybean (Figure 1).

![Phylogenetic relationships of Colletotrichum species](image1.png)

*Figure 1. Evolutionary relationships of Colletotrichum species. (a) Bayesian inference phylogenetic of the strains used in this study. The tree was reconstructed from concatenated nucleotide alignments of the act (actin), chs-1 (chitin synthase), and gapdh (glyceraldehyde 3-phosphate dehydrogenase) genes. For each locus the alignment was performed with MAFFT v7.450 (Katoh and Standley 2013), exported to MEGA7 (Kumar et al. 2016) and the best-fit substitution model was calculated. Thicker branches represent nodes with bayesian posterior probability equal to 1.00. The scale bar represents the number of expected substitutions per site. (b) Level of virulence of Colletotrichum species to soybean. Tuckey’s test was applied on transformed data ((X+1)^0.5). Equal letters do not differ in the average of virulence among Colletotrichum strains in the Tuckey test with p-value = 0.05%. Species belonging to the *C. orchidearum* species complex (s.c) are represented by yellow bars, while *C. truncatum* is represented by the pink bar.*

2.2 The majority of candidate effectors of Colletotrichum species are conserved

To better understand the evolution of the two main *Colletotrichum* s. c. that infect soybean worldwide (*C. truncatum* s. c. and *C. orchidearum* s. c.) [8] we conducted in silico analyses (Figure S1) to check if the representative species of those complexes (*C. truncatum*, *C. musicola*, *C. plurivorum* and *C. sojae*) share a unique set of effector candidates.

The proteomes of the 12 *Colletotrichum* species (Table 1) were assigned to 32,018 orthogroups, of which 7,428 are shared among all the proteomes analyzed (Figure 3B). Comparative analysis identified 66 orthogroups comprising 338 genes of *Colletotrichum* spp. common only to the four species infecting soybean, of which only one orthogroup is fully secreted; and 764 orthogroups (2454 genes) shared only between the species belonging to the *C. orchidearum* s.c., of which eight orthogroups are secreted. While 1,214 (1,695 genes); 1,103 (1,126 genes); 760 (771 genes) and 943 (952 genes) orthogroups were specific to *C. truncatum*, *C. musicola*, *C. plurivorum* and *C. sojae*, respectively (Figure 3C).

![Figure 2](https://example.com/figure2.png)

**Figure 2.** Comparative genomic analysis of *Colletotrichum* species pathogenic and not pathogenic to soybean. Species highlighted in yellow represent the *C. orchidearum* species complex (s.c.), and striped yellow bars correspond to each species belonging to the *C. orchidearum* s.c. (*C. musicola*, *C. plurivorum* and *C. sojae*); while *C. truncatum* is represented in pink. (a) Heatmap showing the percentage of overlapping proteins shared in pairwise comparisons (values correspond to percentage of proteins encoded by the species reported in the y axis that show similarity with those reported by the species reported in the x axis). (b) UpsetR plot of the protein clustering analysis of 12 *Colletotrichum* species. Bars on the upper side represent the number of orthogroups shared by the
species highlighted by the black dots reported on the bottom side. The number of genes corresponding to the orthogroups is in parentheses. (c) Species compared in this study, the bars on the right side of the species name represent the total number of orthogroups in each proteome. L1 (lineage 1); L2 (lineage 2).

The proteomes of the four soybean infecting species of *Colletotrichum* were scanned for the presence of signal peptides, transmembrane (TM)-domains, and glycosylphosphatidylinositol (GPI)-anchors. For further analyses, the secretome of each *Colletotrichum* species was defined based on those proteins with a predicted signal peptide, and absence of TM domains [50] and GPI-anchors. The secretomes of the four species vary between 9-10%, being 1,638; 1,485; 1,495; and 1,447 proteins for *C. truncatum*, *C. musicola*, *C. plurivorum* and *C. sojae* respectively (Table 2).

Table 2. Secretome size of the four species of *Colletotrichum* that infect soybean, compared in this study.

| Species       | Proteome | Signal peptide | Absence of TM/GPI anchor | % of secreted proteins |
|---------------|----------|----------------|---------------------------|------------------------|
| *C. truncatum*| 15,901   | 2,116          | 1,638                     | 10                     |
| *C. plurivorum*| 15,153   | 1,989          | 1,495                     | 10                     |
| *C. sojae*    | 16,124   | 1,931          | 1,447                     | 9                      |
| *C. musicola* | 16,826   | 1,871          | 1,485                     | 9                      |

Our results revealed that most of the effector candidates of the four *Colletotrichum* species pathogenic to soybean are present in other microorganisms, corresponding to 80% of *C. truncatum*, 84% of *C. musicola*, 83%, of *C. plurivorum* and 85% of *C. sojae*. While around 15% of the effector candidates of each species are shared only among the *Colletotrichum* genus (Figure 3). LSECs, with no similarity inside or outside the genus *Colletotrichum* were identified, among those, 11 *C. orchidearum*-LSECs in *C. plurivorum*, 13 *C. orchidearum*-LSECs in *C. musicola*; and 16 *C. orchidearum*-LSECs in *C. sojae*. We also identified 40 *C. truncatum*-LSECs, 15 *C. musicola*-LSECs, eight *C. plurivorum*-LSECs and nine *C. sojae*-LSECs. Host-LSECs shared only between the four *Colletotrichum* species that infect soybean were not identified (Figure 3, Table S1). All the sets of s.c. and species-LSECs aforementioned were assigned to their corresponding orthogroups based on the similarity analysis of the proteins (Table S1).

The absence of similarity to proteins with a known function is a common characteristic to effector proteins [72]. All the LSECs were scanned with RunIprScan to identify conserved domains and submitted to a BLAST against the non-redundant database Pathogen Host interactions-base (PHI-base) to check the similarity with known genes of other microorganism species. All LSECs of the four *Colletotrichum* spp. pathogenic to soybean do not have any known domain or similarity in PHI-base (Table S1).
Figure 3. Effector candidates of *Colletotrichum* species pathogenic to soybean. Effector candidates of *C. musicola*, *C. plurivorum*, *C. sojae* and *C. truncatum* with similarity outside the genus *Colletotrichum* are represented in dark green, while effector candidates with similarity with other species of the genus are represented in orange. *C. orchidearum*-Lineage Specific Effector Candidates (LSECs) are represented in yellow and species-LSECs are represented in dark red. Total numbers of candidate effectors are represented in the bars.

We scanned the *C. orchidearum* s.c. LSECs for characteristics commonly observed in effector proteins, such as a high percentage of cysteines (cysteine-rich), with >2% of cysteines in their amino acid sequences [73], repeat-containing proteins [74] and the predicted translocation to different subcellular compartments of the plant cell, such as the chloroplast or mitochondria when they have a transit peptide, to the plant cell nucleus, when they possess nuclear localization signals (NLS) [75] or are delivered to the plant apoplast [76]. All *C. orchidearum*-LSECs, have at least one of the above-mentioned characteristics, from those, six; five; and five LSECs were predicted as effectors by EffectorP 2.0 tool for *C. musicola*, *C. plurivorum*, and *C. sojae*. Among the species-LSECs, 11 *C. musicola*, seven of *C. plurivorum* and eight of *C. sojae* have at least one of these characteristics, of which five, two and three were predicted to be effectors by EffectorP 2.0 tool. Among the *C. truncatum*-LSECs, 34 were predicted to have at least one of those characteristics, being 16 of them predicted by EffectorP 2.0 (Table 3, Table S1).
Table 3. Predicted *C. orchidearum* s.c. and species-LSECs of the four species of *Colletotrichum* pathogenic to soybean, containing characteristics commonly associated with effector proteins in fungi, and the total number of protein sequences predicted as effectors by EffectorP 2.0.

| Species       | LSECs | RCP | SL (NLS) | SL (other) | Apoplast | CR | EffectorP |
|---------------|-------|-----|----------|------------|----------|----|-----------|
| *C. musicola* | 13    | 5   | 0        | 0          | 9        | 7  | 6         |
| *C. plurivorum* | 11  | 5   | 1        | 0          | 7        | 6  | 5         |
| *C. sojae*    | 16    | 3   | 2        | 2          | 11       | 8  | 5         |

LSECs: Lineage Specific Effector Candidates; RCP: repeat-containing proteins; SL: subcellular localization; NLS: nuclear localization signal; CR: cysteine-rich proteins (>2%); NA: not applicable.

### 2.3 *C. truncatum* LSECs are expressed and have evolutionary evidence

To confirm the expression of *C. truncatum*-LSECs *in vitro* and in soybean during the infection by *C. truncatum*, samples were collected for RNA sequencing at 12; 48 and 120 hpi, and 21 cDNA libraries were sequenced. A total of 1,202,535,286 raw reads were generated by Illumina HiSeq4000 sequencing. Overall, from 0.02 to 7.56% of the paired-end reads were mapped to the *C. truncatum* genome. 18 *C. truncatum* LSECs have evidence of expression *in planta* and/or *in vitro*. From those, nine are evolutionarily conserved in 18 *C. truncatum* genomes pathogenic to soybean. Another eight *C. truncatum* LSECs are conserved but are not expressed (Figure 4).
Figure 4. The distribution of 58 LSECs in 18 strains of *Colletotrichum truncatum* and evidence of expression of *C. truncatum* (CMES1059). 18 genomes of *C. truncatum* pathogenic to soybean were scanned for presence/absence of the 58 *C. truncatum*-LSECs using BLAST. Red squares indicate the presence of LSECs by the blasting with coverage >90% and identity >60%. Green squares indicates evidence of expression of LSECs in soybean and/or in vitro.

3. Discussion

The availability of four representative *Colletotrichum* genomes of the *C. truncatum* s.c. and *C. orchidearum* s.c. [45] reported as the most distributed s.c. associated with soybean worldwide [8], along with the genomes of several *Colletotrichum* species associated with other hosts [23–46], allowed us to investigate the evolutionary origin of soybean anthracnose, by looking at the repertoire of effector candidates of each species and comparing them with the proteomes of eight additional *Colletotrichum* species non-pathogenic to soybean.
Effectors proteins produced by plant pathogens are secreted proteins, many of which translocated to the apoplast or cytoplasm of the host, where they alter the host defense responses to allow colonization by the pathogen [18,77]. Prediction of effector proteins from proteomes of *Colletotrichum* species has revealed different sets of effector candidates [30,44,62,68]. The evolution of effector proteins rely on the arms-race between plants and pathogens, with the aim of escape detection and evolve the capability of cause disease in different hosts [48], therefore the pathogenicity to specific hosts and/or cultivars can be a result of the evolution of effector proteins from a common ancestor [78,79], as shown for the hemibiotrophic pathogen *Phytophthora infestans* [14], *Venturia* spp. [80] and *Ceratocystis* spp. [81]. Our results revealed effector candidates for the four species pathogenic to soybean. Most of the *C. orchidearum* s.c. and species-LSECs are predicted to be secreted to the plant apoplast, while only a few genes are predicted to be localized to the plant cell nucleus or other subcellular compartments (Table 3, Table S1). These results suggest that the initial contact with the host is determinant for the capability of *Colletotrichum* species to infect soybean.

Initial pathogenicity tests revealed that among the tested *Colletotrichum* isolates, only the four *Colletotrichum* species previously associated with soybean [9–12] were pathogenic to the evaluated soybean cultivar. The three species that belong to the *C. orchidearum* s.c. showed a similar level of virulence, and lower than the level of virulence of *C. truncatum*. In another study, the virulence of one isolate of *C. plurivorum* was compared with five isolates of *C. truncatum*, and overall, the isolate was less virulent than at least one isolate of *C. truncatum* in soybean pods, stems and cotyledons, moreover, the authors reported that pod twisting symptoms were only caused by *C. plurivorum*, when the same stage of soybean development was compared after inoculation with *C. truncatum* [82].

While *C. truncatum* has been associated with soybean since 1917 [9], *C. musicola*, *C. plurivorum* and *C. sojae* were detected in soybean fields only recently [10–12]. Studies have revealed that the *C. orchidearum* s.c. has been misidentified at least since 2003, being *C. truncatum* and *C. orchidearum* s.c. the most associated with soybean until now [8]. Our results show that the four species that infect soybean belong to two lineages and do not share any of the identified LSECs. Moreover, the estimated divergence time of the *C. truncatum* s.c. occurred around 22.9 million years ago (mya), while the *C. orchidearum* s.c. diverged 4.8 mya [83], both of them before the domestication of soybean, that occurred 3000 years ago in China [84]. This evolutionary evidence, along with experimental data and the absence of host-LSECs shared only among the four species of *Colletotrichum* that infect soybean, strongly suggests that the two main *Colletotrichum* lineages associated with soybean have acquired the capability to infect soybean independently. Currently, *C. truncatum* is the most important species associated with soybean anthracnose worldwide [85,86], therefore, we checked if the *C. truncatum*-LSECs are conserved in 18 additional *C. truncatum* genomes pathogenic to soybean. Our results revealed that 17 *C. truncatum* genes have evolutionary evidence of being conserved among the species. This suggests that those effectors might play a role in the virulence of *C. truncatum* to soybean, as microorganisms do not keep useless genes due the high fitness costs of maintaining effector alleles [57,87]. Additionally to *in silico* prediction based genome sequences, an initial list of effector candidates can be narrowed down based on their expression [72]. 18 *C. truncatum*-LSECs have evidence of expression in soybean and/or *in vitro*. The low coverage of RNAseq data was a limiting factor for the analysis of gene expression, therefore LSECs without evidence of expression should not be excluded from the initial dataset and be further investigated.

The identification of sets of LSECs of the *C. orchidearum* s.c. and *C. truncatum* open the field to perform evaluations of the functional role of these genes in soybean infection. Besides cultural and chemical control strategies that have already been described for soybean anthracnose, recent outbreaks of the disease have been reported by researchers and producers [82,88,89], suggesting that the control strategies used are not always effective. This may be a consequence of different *Colletotrichum* species present in soybean fields,
that allied to the suggestion of separate evolution of these species, may imply directly in
disease management strategies, as the correct identification of the causal agent is crucial
to an efficient control strategy [90,91].

4. Materials and Methods

4.1 Fungal strains used

To gain insights into the repertoire of effector candidates of Colletotrichum species
pathogenic to soybean, we selected 12 Colletotrichum proteomes and correspondent strains
(Table 1). Four of them are pathogenic to soybean, including C. musicola, C. plurivorum and
C. sojae, members of the C. orchidearum s.c. and C. truncatum. Eight additional proteomes,
isolated from multiple hosts, were included in the analysis: C. orbiculare, C. gloeosporioides
Sensu Lato, C. higginsianum, C. tofieldiae, C. graminicola, C. orchidophilum, C. fioriniae and C.
nymphaeae (Table 1).

4.2 Pathogenicity assays

Pathogenicity assays were performed to confirm the capability of the selected strains
to cause soybean anthracnose. Except for C. graminicola and C. orbiculare, all the strains
were retrieved from culture collections to perform the tests (Table 1). Seeds of the soybean
cultivar IPRO7739, from Monsoy company, were superficially disinfected with NaClO (1%) for 1 min, then rinsed three times in sterile distilled water (SDW). Disinfected seeds
were placed in Petri dishes containing 100 g of sterile sand, soaked with 10 mL of SDW. Each Petri dish contained 5 seeds and were incubated at 25°C for 32 h until germination.

Colletotrichum strains were grown on potato dextrose agar (PDA) culture medium
and incubated at 25°C for 15 days. Conidia suspensions were prepared by washing and
filtering the cultures and were adjusted to a final concentration of 1×10^6 conidia/mL. Each
pre-germinated seed was inoculated with 5 μL of conidial suspension of each Colletot-
trichum strain as described previously [92]. Water was used as a negative control. Inocu-
lated seedlings were initially incubated in the dark at 25ºC for 4 h and then transferred to
100 mL pots filled with sterilized vermiculite and randomly distributed in a greenhouse
for 7 days when the severity of anthracnose was evaluated using an adapted diagram-
matic scale that ranges from 0 to 5 [93]. Severity data were analyzed with the post-hoc
Tuckey method at 0.05 significance level, using the ExpDes R package (v.1.2.0).

4.3 Identification of specific effector protein candidates (SECs) of soybean pathogenic
Colletotrichum species

The proteomes of four species of Colletotrichum pathogenic to soybean, and eight ad-
ditional non-pathogenic Colletotrichum species were included in the analysis (Table 1). A
phylogeny of the genus Colletotrichum was constructed based on publicly available DNA
sequences of three nuclear loci belonging to the 12 selected species: actin (ACT), glyceralde-
hyde-3-phosphate dehydrogenase (GAPDH) and chitin synthase (CHS). The analyses were run
from random trees for 5,000,000 generations and sampled every 1000 generations. The predicted proteomes of the 12 Colletotrichum spp. were clustered based on similarity with
OrthoFinder (v. 2.3.5) [94] and the clusters of proteins were analyzed with the R package
UpsetR (v. 1.4.0) [95] to identify unique and shared orthogroups between the species and
species complexes.

The prediction of effector candidates of soybean pathogenic species of Colletotrichum
was made using the proteomes predicted by Rogério et al., (2020). The initial secretome
was predicted with SignalP (v.5.0) [96], then sequences containing transmembrane (TM)
domains and glycoprophosphatidylinositol (GPI)-anchors were identified using THMMM
(v.2.0) [97] and PredGPI [98] respectively, and those proteins that are predicted to have a
signal peptide cleavage site, no transmembrane domains and no GPI-anchors were considered as the initial set of effector candidates for each species of *Colletotrichum*.

The set of effector candidates of each *Colletotrichum* species was submitted individually to a sequence of BLAST searches using an e-value threshold of 1E-5 and classified into shared (proteins with homology to proteins from other members of the genus *Colletotrichum*), species-complex specific (those that had homology only within other species from the same s. c.), host-specific (shared only between the four species that infect soybean) and species-specific (those that had no homology to any other protein either within or outside of the same genus) LSECs [30]. The final set of predicted LSECs was scanned with RunIPrScan to identify conserved domains and submitted to a BLAST against the non-redundant database of NCBI and Pathogen Host interactions-base (PHI-base) to check the similarity with known genes of other microorganism species; being those proteins with similarity outside the genus *Colletotrichum* considered conserved among microorganisms.

Species-specific and species complex LSECs were characterized. For the prediction of subcellular localization within the plant cell, mature protein sequences were submitted to LOCALIZER [75], and to the prediction of apoplastic LSECs, the proteins were submitted to ApoplastP [76]. The percentage of cysteines was identified in Geneious (v. 2020.10.4) and repeat-containing proteins were predicted using T-REKs [99].

4.5 Genome assembly and gene evolution

To check if *C. truncatum*-LSECs are conserved among the species, Illumina reads of 18 *C. truncatum* strains available in NCBI (Table 4) were trimmed with Trim Galore (v.0.4.5). Forward and reverse reads were merged using Flash (v.1.2.7) [100]. Assemblies of combined and uncombined reads were performed with SPAdes v.3.13.1 using the *C. truncatum* CMES1059 strain genome as a reference.

### Table 4. *Colletotrichum truncatum* strains used in the evolutionary analysis

| Strain | Species | Species complex | Host       | Origin | Accession N°|
|--------|---------|-----------------|------------|--------|-------------|
| MT1-01 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095339  |
| MT2-05 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095348  |
| MT3-01 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095353  |
| MT3-21 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095343  |
| MT4-05 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095347  |
| MT4-13 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095341  |
| MT5-12 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095345  |
| MT5-26 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095349  |
| MT5-32 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095350  |
| GO2-03 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095352  |
| GO2-06 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095344  |
| GO2-12 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095346  |
| GO4-07 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095355  |
| GO4-08 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095338  |
| GO4-17 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095351  |
| GO5-11 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095354  |
| GO5-14 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095340  |
| GO5-25 | *C. truncatum* | *C. truncatum* | Glycine max | Brazil  | SRX7095342  |
4.6 Evidence of expression of C. truncatum by RNAseq

To confirm evidence of gene expression of C. truncatum in planta, five pre-germinated seeds of soybean cultivars IPRO7739 and IPRO8372 were inoculated with C. truncatum (CMES1059) strain as described in 4.2. Hypocotyls fragments of 0.5 cm of five randomly selected plants were collected and pooled together at 12; 48 and 120 hpi. To confirm evidence of expression of C. truncatum in vitro, 100mL of potato dextrose liquid culture was inoculated with C. truncatum conidia in 250mL Erlenmeyer flasks at 25ºC, shaken at 150 rpm. After 120 hpi micelia was collected by filtration and washed with ADE. Harvested plant tissue and fungal micelia was flash-frozen in liquid N\textsubscript{2} and stored at -80ºC until RNA extraction. Three biological replicates of the experiment were performed. The collected material was ground using mortar and pestle and total RNA was purified using PureLink RNA Mini Kit (Invitrogen, USA) following the manufacturer’s instructions. Total RNA was treated with RNAse-free DNase (Life Technologies) to remove DNA contamination. The quantity of total RNA was estimated using Qubit 2.0 fluorometer (Life Technologies) and RNA integrity was checked using Agilent TapeStation 4200 (Agilent Technologies).

Total extracted RNA was sent to Genewiz (South Plainfield, USA) for Illumina sequencing. In total, 21 libraries derived from all the treatments were prepared using NEBNext Ultra RNA Library Prep Kit for Illumina (NEB) using manufacturer’s instructions. Sequencing libraries were validated on the Agilent TapeStation (Agilent technologies) and quantified in Qubit 2.0 fluorometer (Invitrogen) and by quantitative PCR (Kapa Biosystems). Libraries were sequenced using Illimina HiSeq4000 (2x150 bp).

The quality of reads was accessed using FastQC (v.0.11.7) and clean reads were obtained by removing reads containing adapters with CutAdaptors (v.1.9.1). Paired-end clean reads were mapped against the C. truncatum CMES1059 reference genome [45] using HISAT (v. 2.1.0). Alignments from each library were processed with StringTIE (v.1.3.5) to quantify expression values of transcripts.

Supplementary Materials: The following are available online at www.mdpi.com/xxx/s1. Figure S1: In silico analysis workflow for the prediction of effector candidates in C. truncatum, C. musicola, C. plurivorum and C. sojae. Table S1: Lineage Specific Effector Candidates (LSECs) of C. truncatum, C. musicola, C. plurivorum and C. sojae.
