Abstract

Background: Risk factors of esophageal stricture after ESD are inconsistent and incomprehensive, the present study aimed to identify a robust model to predict postoperative stricture.

Methods: This retrospective study included 273 individuals underwent ESD for early esophageal cancer from January 1, 2014 to October 30, 2020 in Beijing Friendship Hospital. Univariate Cox proportional hazard regression was used to estimate potential factors of stricture after ESD, followed by multivariate Cox proportional hazard regression to identify significant independent predictors after adjusting for covariates. Nomogram building based on multivariate Cox regression model was used to evaluate accuracy and discrimination by ROC curves and calibration curves respectively.

Results: Stricture was identified in 28 patients (10%). The other patients were enrolled in non-stricture group (n=243). Multivariate Cox proportional hazard model demonstrated that operation time (HR 1.01, 95%CI: 1.00-1.01, \( P < 0.01 \)), upper segment of esophagus (HR 6.48, 95%CI: 2.07-20.33, \( P < 0.01 \)), middle segment of esophagus (HR 3.42, 95%CI: 1.36-8.64, \( P < 0.01 \)), >3/4 circumferential lumen of esophagus (HR 6.32, 95%CI: 2.20-18.13, \( P < 0.01 \)), postoperative fever (HR 6.17, 95%CI: 1.75-21.77, \( P < 0.01 \)), were independent predictive factors for postoperative stricture. The predictive accuracy of the nomogram was estimated by the AUC of ROC curves was 0.93, 0.87, 0.87 at 1 year, 2 years, and 3 years respectively.

Conclusion: Longer operation time, >3/4 of the circumferential lumen of esophagus, located at upper and middle esophageal segment, and postoperative fever were independent risk factors of esophageal stricture after ESD.

Background

Early esophageal cancer is expected to undergo en bloc resection using endoscopic submucosal dissection (ESD), making the 5-year survival rate high as 92.0% (95% CI, 83.1-95.9)[1, 2]. Stricture formation is one of the major adverse effects associated with ESD, causing serious dietary deficiencies that reduce the quality of life and necessitate multiple endoscopic balloon dilatation (EBD) sessions that incur high medical costs[3]. Multivariate logistic analysis revealed that more than 3/4 of the circumferential extension is a reliable risk factor[4]. But little consensus has been achieved in longitudinal resection length >50mm, the depth of infiltration more than lamina propria (m2), muscular injury and clip number and so on[5-7]. Postoperative symptoms and laboratory tests were seldom incorporated into models. The aim of this study is to more comprehensively analyze the independent risk factors associated with postoperative stricture and provide a robustly ready-to-use clinical prediction model to select high-risk people.

Materials And Methods

Patients
This was a retrospective cohort study consecutively collected 361 cases completed ESD for early esophageal cancer from 1st January 2014 to 30th October 2020 at Beijing Friendship Hospital, Capital Medical University in China. Exclusion criteria included: (1) not high-grade intraepithelial neoplasia (HGIN)/squamous cell carcinoma (SCC) confirmed by histopathology; (2) additional treatment due to positively cutting edge of resected specimen, such as surgery treatment, radiotherapy and chemotherapy; (3) missing the gastroscopy review or other essential information.

**Information and materials**

Information of patient characteristics (age, sex, drinking history, smoking history, body mass index (BMI), family history), lesion characteristics (infiltration depth) and treatment process (operation time, hospital stay, glucocorticoid prevention, postoperative fever, blood test) was collected from medical record. Endoscopic images of lesions (lesion location, longitudinal lesion length, proportion of esophageal circumference, number of clips, postoperative stricture) was collected from picture archiving and communication system (Qingdao Medicon Digital Engineering Co., Ltd., Medicare I-EndoCenter, Qingdao, China).

Esophageal stricture was defined as an esophageal diameter <11 mm, rather than the inability to pass the gastroscope (which had a diameter of 9.8-11.0 mm)[8]. Classify dysphagia severity into the following four grades: score 0=able to eat a conventional diet; score 1 (mild)=able to eat some solid meals; score 2 (moderate)=able to eat semisolid but not solid foods; score 3 (severe) =able to consume liquids only; score 4=aphagia[9]. Score 2 and above was defined as both dysphagia and esophageal stricture.

The upper segment of esophagus was defined as the cervical and upper thoracic segments, 15-25cm away from the incisors; the middle segment of the esophagus was defined as mid-thoracic esophagus, 25-30cm away from the incisors; the lower segment of esophagus was defined as the lower thoracic esophagus and the abdomen, below 30cm from the incisors[10]. Operation time was defined as duration of anesthesia. Postoperative fever was defined as axillary body temperature exceeding 37.3°C within 48 hours after ESD. White blood cell (WBC) was tested on the second day after ESD. Deep muscle layer injury, subcutaneous emphysema, mediastinal emphysema, and esophageal fistula were defined as perforation. Some patients with large resected area were prescribed to oral glucocorticoid (Tianjin Lisheng Pharmaceutical Co., Ltd., Prednisone acetate, Tianjin, China) to prevent stricture, with a dose of 30 mg/day on the third day after ESD, tapered gradually (30, 30, 25, 25, 20, 15, 10, and 5 mg for 7 days each) and then discontinued 8 weeks later[11].

**Esophageal ESD**

A complete description of the ESD (Olympus, Co., Ltd., GIF-Q260J/GIF-Q180, Tokyo, Japan) procedure has been reported[12]. Mark margin of the lesion with dual knife, inject Meilan hyaluronate sodium saline into submucosa, cut the periphery, gradually peel off the lesion along the submucosa, and intermittently give hemostatic forceps to stop bleeding. Careful observation of no active bleeding on the wound, indwelling gastric tube after operation.
**Study endpoints**

Endoscopic review was performed 3th month and 9th month after ESD and once a year thereafter or when a patient complained of dysphagia associated with semisolid foods. The primary endpoint was esophageal diameter <11 mm or dysphagia confirmed. The second endpoint was scarring confirmed or the last gastroscopy review.

**Statistical analysis**

The student t test was used to compare the differences between continuous variables with normal or approximate normal distribution, which were presented as the mean and standard deviations (SD). Other continuous variables were presented as the median and quartile, and the categorical variables were presented as counts and percentages. Chi-square (c2) test was for unordered categorical variables. The Mann-Whitney test were used to compare ordinal categorical variables or continuous variables that not meet Student's test. Univariate Cox regression analysis was used to evaluate the effects of clinically significant variables. Statistically significant factors obtained from the univariate Cox regression analysis were then entered into a forward LR multivariate Cox proportional hazard regression to identify independent risk factors after adjusting for other covariates. The risk factors for stricture formation were estimated by calculating the hazard ratios (HR) and the 95% confidence intervals (95%CI). The statistical tests above were evaluated by SPSS software version 22.0.

Kaplan-Meier cumulative incidence plots were created by Graphpad Prism (v.9.1.1.225). Package “rms” “survivalROC” in R Software 4.0.5 (www.r-project.org) was used for nomogram building based on multivariate Cox proportional hazard regression model. Receiver operating characteristic curves (ROC) were used to present the predictive accuracy of nomograms graphically. We performed calibration for established nomograms and applied 1,000 repetitions by 4 groups (n=55) of bootstrap sample corrections to internally validate the nomograms. The area under the curve (AUC) for validation was applied to evaluate the accuracy of the nomogram. Two-sided and a value of \( P<0.05 \) was considered statistically significant all above.

**Results**

**Clinical Characteristics**

Retrospectively collect 361 patients performed ESD for early esophageal carcinoma in Friendship hospital endoscopy center from January 1st, 2014 to October 30th, 2020. A total of 90 individuals were excluded, 271 patients were eligible into the study, stricture was identified in 28 patients (10%) and the rest in non-stricture group (243, 90%) (Figure 1). The median follow-up time was 116 (96-191) days.

The baseline characteristics (age, sex, drinking and smoking history, BMI, family history) had no statistical difference between two groups (\( P>0.05 \)). Infiltration depth of lesion and perforation were not significantly different (\( P>0.05 \)). Whereas lesion location, involved esophageal circumference, lesion
length, operation time, number of clips, hospitalization stay, glucocorticoid prevention, postoperative fever and WBC count had significantly statistic difference between the two groups (P<0.05) (Table 1).

**Predictive factors for postoperative stricture**

Univariate Cox proportional hazard regression showed that operation time, longitudinal lesion length, lesion location, proportion of esophageal circumference, perforation, postoperative fever, glucocorticoid prevention and WBC count may be clinically risk factors of postoperative stricture (Table 2). Forward LR multivariate Cox proportional hazard regression analysis on the basis of the former demonstrated that operation time (for 1-minute increase) (HR 1.01, 95%CI: 1.00-1.01, P<0.01), upper segment of esophagus (HR 6.48, 95%CI: 2.07-20.33, P<0.01), middle segment of esophagus (HR 3.42, 95%CI: 1.36-8.64, P<0.01), >3/4 circumference involved (HR 6.32, 95%CI: 2.20-18.13, P<0.01), postoperative fever (HR 6.17, 95%CI: 1.75-21.77, P<0.01), could be independent predictive factors for postoperative stricture (Table 2). The Kaplan-Meier curves showed that the stricture cumulative incidence was higher among more than 3/4 circumference of esophagus group (c2=49.14, P<0.01; Figure 2A), located upper and middle segment of esophagus group (c2=5.03, P=0.03; Figure 2B) and postoperative fever group (c2=20.36, P<0.01; Figure 2C).

**Nomogram for the prediction of esophageal postoperative stricture**

We developed a predictive nomogram from the multivariate Cox proportional hazard regression model (Fig 3A). Calibration curves generated by 1,000 repetitions of bootstrap sample corrections (4 groups, n=55) were illustrated good for 1 year, 2 years and 3 years respectively (Fig 3B-D). ROC curves were drawn to estimate the predictive accuracy of the nomogram, and the AUC was 0.93, 0.87, 0.87 at 1 year, 2 years, and 3 years respectively (Fig 3E-F).

**Discussion**

Evidence of this study showed that more than 3/4 circumferential esophageal lumen, lesions near upper esophagus, postoperative fever and operation time were the independent risk factors of esophageal stricture after ESD. >3/4 luminal circumference was consistent with the vast majority of previous studies, while the conclusion of other three risk factor varied from literature to literature[7,13].

Nomograms as estimators have shown promising potential in clinical trial design and interpretation and have been widely adopted in prognostic models[14-16]. To our knowledge, this is the first study providing a nomogram to predict postoperative stricture risk. ROC curves and calibration curves suggested that the nomogram is a powerful tool in individual risk assessment. Refractory stricture is mostly formed within 1 year after ESD, so that there was little difference between the risk predictions for 2 years and 3 years in the nomogram chart and calibration curves. We also took glucocorticoid prevention effect to stricture into consideration. The incidence (38%,15/39) of esophageal stricture in patients with resection lesion >3/4 circumference was obviously lower than the 88-100% incidence of stricture in other studies[13,17]. So we
speculated that oral small glucocorticoid had not a statistic effect on the prevention due to not enough sample size in our study[11,18,19].

Lesions in the upper and middle segment of esophagus ($P<0.01$) were independent risk factors for postoperative stricture. This might be related to esophagus anatomy that the diameter of upper and middle segment smaller than lower segments besides narrow sites[20]. In addition, the symptoms of dysphagia caused by the narrowing of stricture in the upper segment appeared earlier and more obviously. Similar report suggested that lesion in the cervical segment is an independent risk factor for postoperative stricture[21]. But in our study only one lesion located in the cervical esophagus, so we classified it as the upper segment of esophagus.

Influential factors of longer operation time for ESD included location, gross type, tumor depth, ulcerative findings, lesion size, endoscopist experience and so on[22]. The more difficult it was to remove the lesion, the longer the operation time needed. Multivariate regression analysis was used to eliminate the mixed interference of factors such as large circumferential ratio, location, clip number and perforation. And all the endoscopists performing ESD in our center are experienced chief professor. The longer time surgery took, the more frequent intraoperative hemorrhage and endoscopic electrocoagulation, leading to extensive fibrosis and scar formation related to postoperative stricture.

It was demonstrated that postoperative fever was an independent factor for esophageal stricture in our study, which was never analyzed in previous study. Some literature illustrated fever is a common phenomenon during the first 48 hours after surgery, which is mostly non-infectious[23,24]. This is regulated by pyrogenic cytokines such as serum interleukin-1, interleukin-6, tumor necrosis factor, and interferon-gamma. The more tissue damage, the greater the cytokine release[24]. We speculated that patients after esophageal ESD suffered fever maybe for major invasive procedures so that they were more likely to develop postoperative stricture.

This study has a number of strengths. Complete collection of detailed clinical data and outcomes, and use of multivariable, time-varying analyses to quantify independent risk factors for esophageal stricture with a relatively large sample size so far. A nomogram tool was established to select the population for early prevention based on Cox regression model. By the way, fever within 48 hours after ESD could be a simple and effective predictor in addition to the circumference ratio, which was not found in previous studies.

This study has several limitations. First, it took place in single hospital in Beijing, China, potentially limiting generalizability to other places and we lack enough data to do external validation of the nomogram model so far. Second, our study was a retrospective cohort study, there were inevitably problems of recall bias and a small part of missing data such as tumor infiltration depth which was been proved to be a risk factor in previous studies[5,21]. Therefore, a prospective controlled study with a higher level of evidence and external validation of the nomogram model would be needed to verify our conclusions.
Conclusion

Our study proved longer operation time, > 3/4 circumference of the esophageal lumen, lesion location, and postoperative fever were significantly associated with stricture after ESD. Nomogram, a ready-to-use predictive tool, was provided with the potential to select high-risk people with postoperative stricture. But this is a single-center retrospective study, further studies are necessary to verify whether our findings generalize to other patients.

Abbreviations

ESD: endoscopic submucosal dissection; EBD: endoscopic balloon dilatation; m2: lamina propria; HGIN: high-grade intraepithelial neoplasia; SCC: squamous cell carcinoma; WBC: White blood cell; SD: standard deviations; c2: Chi-square; HR: hazard ratios; 95%CI: 95% confidence intervals; ROC: receiver operating characteristic curves; AUC: area under the curve; TP: true positive rate; FP: false positive rate

Declarations

Ethics approval and consent to participate

This study was approved by the Institutional Ethics Committee of Beijing Friendship University, Capital Medical University at Beijing, China [2020-P2-290-01]. All procedures performed in this study using human data were in accordance with the 1964 Helsinki declaration and its later amendments or comparable ethical standards. Informed consent was waived by the Institutional Ethics Committee of Beijing Friendship University, Capital Medical University because of the retrospective nature of this study and all of the data from medical record.

Consent for publication

Not applicable.

Availability of data and material

The datasets used and analyzed during the current study available from the corresponding author on reasonable request.

Competing interest

The authors declare that they have no competing interests.

Funding

This work was fully supported by the Digestive Medical Coordinated Development Center of Beijing Hospitals Authority (grant no. XXZ01 and XXZ02). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.
Authors' contributions

XL, JX, PL and SZha conceived and designed the study. Data collection and analysis were performed by XL, JX, QZ and SZhu. The first draft of the manuscript was written by XL. And SZha proofread and revise the manuscript. All authors commented on the draft of the manuscript. All authors read and approved the final manuscript.
