Instability of Contact Surface in Cylindrical Explosive Waves

Yu V Tunik*

Abstract
In this paper are developed modifications of the Godunov scheme, based on Kolgan's scheme of the second order of accuracy in the spatial variables for smooth solutions. It is constructed schemes of the first and the variable order of approximation, which exceed the Godunov scheme in accuracy. Referencing to the system of differential equations for propagation of flat sound waves in a gas at rest, the Kolgan scheme and the first-order schemes obtained are investigated onto the ability to ensure the non decrease of entropy, that is, to product of physically justified numerical solutions.

The test problems of nonlinear gas dynamics on the decay of a discontinuity in a pipe and the transformation of a non uniformity in a plane-parallel flow are solved. Cylindrical explosion task is considered as the main one. The stability of a contact discontinuity behind a blast wave is investigated numerically in the Cartesian and polar coordinate systems. Analysis of obtained and published solutions does not confirm the instability of the contact discontinuity which initially has the circular shape. Change of the shape of initially perturbed break is largely caused by the instability of Taylor, not Richtmyer-Meshkov. Calculations are partially fulfilled using supercomputer “Lomonosov” of Moscow state university.

Keywords: Euler equations; Perfect gas; Blast; Non decreasing of entropy; Accuracy; Contact discontinuity; Richtmyer-Meshkov; Taylor instability

Introduction
The explosion task was first posed and solved by Sedov [1] and independently by von Neumann [2] for a point initiation and shock waves of high intensity. In subsequent works various aspects of blasting processes are studied. The problem of propagation of blast waves are solved subject to backpressure and the finite size of the region of initiation. The history of the explosion theory is in detail expound [3-4]. Development of finite-difference numerical methods [5-21] have allowed to simulate discontinuous solutions of the equations of inviscid gas dynamics. Currently, the problem of the explosion is considered as a test for modern numerical schemes of a high order of accuracy. An overview of these methods can be found, for example [22-24]. Performed calculations taking into account the backpressure and the finite region of the blast initiation indicate the development of instability of the contact discontinuity [24]. It has been suggested that this is a development of the Richtmyer-Meshkov instability [25].

In the present work for the solution of the problem of cylindrical blast taking into account the backpressure and the finite region of the explosion initiation there are used modifications of the scheme of S.K. Godunov, which increase the computation accuracy with respect to spatial variables. We numerically investigate the question of stability of the contact discontinuity.

Generalization of V. P. Kolgan Modification
The original Godunov’s scheme [5] was presented and analyzed on the example system of equations describing the propagation of plane sound waves in resting gaseous medium:

\[ \frac{\partial u}{\partial t} + c_0 \frac{\partial p}{\partial x} = 0 \]
\[ \frac{\partial p}{\partial t} + c_0 \frac{\partial u}{\partial x} = 0 \]

(1).

Here \( u = \sqrt{\rho_0 c_0} \cdot P \) \( \rho_0 \) : \( \rho_0 \) and \( c_0 \) - the density and speed of sound in the unperturbed environment; \( P \) and \( \bar{P} \) - the perturbation of velocity and pressure.

The Godunov scheme for the system of eqn. (1) on the uniform computational grid with step \( h \) on the spatial coordinates is equivalent ratios ([5])

\[ u^n = u_{n-1} - \text{CFL}(U_{n+1/2} - U_{n-1/2}) \]
\[ p^n = p_{n-1} - \text{CFL}(P_{n+1/2} - P_{n-1/2}) \]

(2).

Here and below upper indexes refer to variables at the upper time layer, the subscripts relate to lower layer; \( \text{CFL} = \tau c_0 / h \cdot \text{Courant number} \), \( \tau \) - time step, \( U_{n+1/2} \) and \( P_{n+1/2} \) values of \( u \) and \( p \) at the boundary between cells \( n \) and \( n+1 \):

\[ 2U_{n+1/2} = \left(P_{n+1} + P_n\right) - (u_{n+1} - u_n) \]
\[ 2P_{n+1/2} = \left(u_{n+1} + u_n\right) - \left(P_{n+1} + P_n\right) \]

(3).

The stability condition: \( \text{CFL} \leq 1 \), determines the maximum time step at which perturbations generated at the boundary of the cell come up to the centre and back after the interaction with the oncoming perturbation.

In the case of non-linear equations of hydrodynamics, the magnitudes like \( U_{n+1/2} \) and \( P_{n+1/2} \) represent flows of mass, momentum and energy, calculated using flow parameters at the boundary between neighboring cells. The required values of pressure, density and velocity are determined by solving the self-similar problem of break decay, and the Courant number is calculated by the maximum speed of propagation of perturbations [6].

The scheme of Godunov – Kolgan (SGK)
A first modification of the Godunov scheme is proposed by Kolgan

Entropy of the numerical solution in Godunov-Kolgan scheme

The non-decreasing entropy provides physically justified numerical solutions. In contrast to the Godunov scheme the corresponding problem exists in the case of schemes of a high accuracy and is discussed, for example, [16,26-28]. Here an ability of the Godunov-Kolgan scheme to satisfy the entropy condition is considered on the example of the system (1). The difference analogue of SGK for this system can be represented in the form

\[
\frac{\partial u}{\partial t} + c_0 \frac{\partial u}{\partial x} = -0.5 \frac{\partial^2 u}{\partial x^2} + (0.5 - \alpha)c_0 \frac{\partial^2 u}{\partial x^2} + O\left(\epsilon^2\right) + O\left(h^2\right).
\]

(9)

The residual term in the equation for the speed

\[
W_u = 0.5 \left( \frac{\partial^2 u}{\partial x^2} + (1 - 2\alpha)c_0 \frac{\partial^2 u}{\partial x^2} h \right).
\]

(10)

From (10) it is clear that while \(\alpha \in [0,0.5]\) the SGK has a first order of approximation, both in time and spatial variables. When \(\alpha = 0.5\) this scheme has second order in spatial variables. If take in account equality

\[
\frac{\partial^2 u}{\partial x^2} = \frac{c_0^2}{\partial x^2} \text{ and } \frac{\partial^2 p}{\partial x^2} = \frac{\partial^2 \rho}{\partial x^2},
\]

whose are consequence of the system (1), relations (9) can be rewritten

\[
\frac{\partial u}{\partial t} = \alpha \partial \mu_{\text{lim}}\left(\tau - \alpha, -\alpha\right) - \alpha \frac{\partial^2 u}{\partial x^2} + \left(\tau^2\right) + \left(\tau^2\right).
\]

(11)

The solution of eqn. (11) can be considered as an approximate solution of the propagation equations of flat sound waves in the resting viscous gas with viscosity coefficient

\[
\mu = 0.5\left[1 - 2\alpha - \text{CFL}\right] c_0 h.
\]

(12)

The smaller the viscosity coefficient, the numerical solution is more close to the exact solution of system (1) for inviscid gas. If \(\alpha = 0\) the scheme has the second order of approximation with respect to both time and space for the linear system (1). Since the SGK have to guarantee the non-decreasing of entropy, the viscosity coefficient cannot be negative. Then from (12) it follows that the Courant number should satisfy the condition \(\text{CFL} \leq 1 - 2\alpha\). If \(\alpha = 0.5\) the Courant number must be zero. Therefore, the Kolgan scheme does not guarantee the non-decreasing of entropy in numerical modeling of non-stationary processes, that may lead to physically unreasonable results.

Scheme with a variable approximation (SVA)

It is possible to consider SGK with a variable parameter \(\alpha = 0.5 \exp(-\beta k|\chi/\phi|^{2})\).

Here \(\chi = \text{mod}\left(\frac{d\phi}{d\eta}\right), \phi \) - any flow parameter on the lower time layer in the \(\eta\) cell, \(\beta\) - the additional unit order parameter, which defines the reaction rate of the scheme to high spatial gradients \(\chi\). If spatial gradient \(|\chi|\) is big: \(k|\chi/\phi| > 1\), the scheme has first order
is small the scheme has the second order in the spatial variables $\alpha=0.5$. So the obtained scheme is the scheme of a variable approximation (SVA).

**Test Tasks**

Test tasks is being solved on the base of two-dimensional unsteady Euler equations for perfect nonviscous gas with constant ratio of specific heats $\gamma=1.4$.

**The task of break decay in a pipe**

It is being solved in rectangle $-5 \leq x \leq 5$ and $0 \leq y \leq 1$ in the Cartesian coordinate system. At the initial moment pressure $p$ and density $\rho$ to the left of the line $x=0$ are equal unit: $p_1=1$ and $\rho_1=1$, on right $p=p_2=0.1$, $\rho=\rho_2=0.125$. The gas is at rest everywhere [29,30].

Computational grid has $100 \times 10$ cells. The calculation continues for the time during which a perturbation does not reach left and right boundaries of the computational domain, therefore parameters on the right and left border keep the initial values. On horizontal boundaries the normal derivatives of all parameters are set to zero.

The task can be solved in one-dimensional approximation; however, a two-dimensional formulation is used for checking the correctness of calculations in cells at the top and bottom borders.

As a result of a decay of high pressure region in low pressure region is propagated shock wave $D$, which is followed by density discontinuity $C$, onto left is propagated rarefaction wave $RW$ (Figure 1a and 1b). At the maximum possible values of the Courant number for the stable accounts the Kolgan scheme $(\alpha=0.5)$, SGK $(\alpha=0.4)$ and SVA with $\beta=1$ give similar results in throughout computational domain. Loses in accuracy of the Godunov scheme is particularly noticeable in the regions of the contact discontinuity and of the rarefaction wave (Figure 1c and 1d).

On the other hand the solution obtained by the Godunov scheme is monotonic throughout the computational domain, in particular, in the vicinity of the point of initial discontinuity $x=0$ (Figure 2a). The Kolgan scheme leads to a non-monotonic parameter distributions in this area. The monotony of the scheme Kolgan rises with decreasing Courant number (Figure 2b), that corresponds to the findings in the first section.

**Development of non-uniformity**

Development of non-uniformity in a plane-parallel gas flow is considered in rectangle, which in the Cartesian coordinate system $(x,y)$ is limited by direct lines $y=0$, $y=1$, $x=0$ and $x=40$. At the initial moment the pressure is equal to unit in whole region: $p=p_0=1$, the projection of the velocity on the $y$-axis is zero, longitudinal component of the velocity $u=1$. The flow has uniform density; $p=p_2=1$ everywhere except the limited region $a<x<b$, where $p_1 \neq p_2$. Parameters on inlet do not change over time. On other boundaries the normal derivatives are set to zero.

It is obviously, that the exact solution can be obtained by parallel shift of the initial distribution along abscissa axis. In this task interest is represented by diffusion properties of computation schemes.

Two options are considered: $p_1=0.2$ and $p_1=2$. In both cases, the maximal smearing of the non-uniformity occurs when using a Godunov scheme (Figure 3a). SGK (with $\alpha=0.4$) simulates the exact solution much more accurately than the scheme of Godunov. The Kolgan scheme gives the solution the most close to exact, which is providing almost constant density profile and preserving the extreme values almost at the initial level (Figure 3b). Similar properties has SVA at $\beta=1$ (Figure 3c).

On the other hand the solution obtained by the Godunov scheme is monotonic throughout the computational domain, in particular, in the vicinity of the point of initial discontinuity $x=0$ (Figure 2a). The Kolgan scheme leads to a non-monotonic parameter distributions in this area. The monotony of the scheme Kolgan rises with decreasing Courant number (Figure 2b), that corresponds to the findings in the first section.

**Development of non-uniformity**

Development of non-uniformity in a plane-parallel gas flow is considered in rectangle, which in the Cartesian coordinate system $(x,y)$ is limited by direct lines $y=0$, $y=1$, $x=0$ and $x=40$. At the initial moment the pressure is equal to unit in whole region: $p=p_0=1$, the projection of the velocity on the $y$-axis is zero, longitudinal component of the velocity $u=1$. The flow has uniform density; $p=p_2=1$ everywhere except the limited region $a<x<b$, where $p_1 \neq p_2$. Parameters on inlet do not change over time. On other boundaries the normal derivatives are set to zero.

It is obviously, that the exact solution can be obtained by parallel shift of the initial distribution along abscissa axis. In this task interest is represented by diffusion properties of computation schemes.

Two options are considered: $p_1=0.2$ and $p_1=2$. In both cases, the maximal smearing of the non-uniformity occurs when using a Godunov scheme (Figure 3a). SGK (with $\alpha=0.4$) simulates the exact solution much more accurately than the scheme of Godunov. The Kolgan scheme gives the solution the most close to exact, which is providing almost constant density profile and preserving the extreme values almost at the initial level (Figure 3b). Similar properties has SVA at $\beta=1$ (Figure 3c).

On the other hand the solution obtained by the Godunov scheme is monotonic throughout the computational domain, in particular, in the vicinity of the point of initial discontinuity $x=0$ (Figure 2a). The Kolgan scheme leads to a non-monotonic parameter distributions in this area. The monotony of the scheme Kolgan rises with decreasing Courant number (Figure 2b), that corresponds to the findings in the first section.

**Development of non-uniformity**

Development of non-uniformity in a plane-parallel gas flow is considered in rectangle, which in the Cartesian coordinate system $(x,y)$ is limited by direct lines $y=0$, $y=1$, $x=0$ and $x=40$. At the initial moment the pressure is equal to unit in whole region: $p=p_0=1$, the projection of the velocity on the $y$-axis is zero, longitudinal component of the velocity $u=1$. The flow has uniform density; $p=p_2=1$ everywhere except the limited region $a<x<b$, where $p_1 \neq p_2$. Parameters on inlet do not change over time. On other boundaries the normal derivatives are set to zero.

It is obviously, that the exact solution can be obtained by parallel shift of the initial distribution along abscissa axis. In this task interest is represented by diffusion properties of computation schemes.

Two options are considered: $p_1=0.2$ and $p_1=2$. In both cases, the maximal smearing of the non-uniformity occurs when using a Godunov scheme (Figure 3a). SGK (with $\alpha=0.4$) simulates the exact solution much more accurately than the scheme of Godunov. The Kolgan scheme gives the solution the most close to exact, which is providing almost constant density profile and preserving the extreme values almost at the initial level (Figure 3b). Similar properties has SVA at $\beta=1$ (Figure 3c).
the radius $R_c \geq R_1$ and sets the position of the density break in a rest gas region of high pressure. Another circumference in the general case has circles with centre at the origin. First of them with radius $R_1$ limits the area is in detail described in ref. [31] just as in a lot of early papers on the flow in a blast wave at breaking up of a high pressure cylindrical distortion of the contact surface in ref. [24] is explained by the instability of the initial contact discontinuity given by the circle. The last two the third order of accuracy. All indicate the development of the explosion agrees with description in ref. [31].

By Godunov scheme isochores are concentric circles (Figure 4a). Such development of the explosion agrees with description in ref. [31].

The results of calculations according to the scheme Kolgan substantially depend on the Courant number $CFL$. When $CFL=0.5$ (Figure 4b) isochores produce the chaotic and implausible picture. Monotonous flow is formed when $CFL=0.1$ (Figure 4c). The same result are obtained in the case of SGK ($\alpha=0.4$) and SVA at $CFL=0.25$.

In this task the Kolgan scheme improves the flow picture not essentially. On the grid $800 \times 800$ the scheme of Godunov leads to very close results (Figure 5a-5d).

The gas expansion in the central zone ensures a rapid alignment of the density near the contact discontinuity, the initial break becomes invisible (Figure 5a). High density gradient on the (Figure 5b) essentially. On the grid $800 \times 800$ the scheme of Godunov leads to very close results (Figure 5a-5d).

In the second series of calculations, the radius of the contact discontinuity is twice the radius region of high pressure: $R_c=0.5$, $R_1=0.25$ and $\rho_0=0.2$. As a result of the decay of the high pressure region at the distance $R_1$ from center is formed a second contact discontinuity (Figure 6a and 6b). In contrast to the previous case rarefaction waves have not time to eliminate the primary break of density before the formation of the converging shock wave. In flow behind the leading shock front 1 is being formed a ring area of high density 3 (Figure 6a and 6b). In contrast to the previous case rarefaction waves have not time to eliminate the primary break of density before the formation of the converging shock wave. In flow behind the leading shock front 1 is being formed a ring area of high density 3 (Figure 6a and 6b). Over time, the calculations according to the Kolgan scheme ($CFL=0.1$) the surface of the initial contact 2 becomes distorted (Figure 6a and 6b).

Cylindrical Explosion Task

Solution of the problem in Cartesian coordinate system

From the beginning the task is being solved in formulation, similar to ref. [21]: in the Cartesian system of co-ordinates $(x, y)$ are given two circles with centre at the origin. First of them with radius $R_1$ limits the computational domain is a square in the first quadrant of the plane $(x, y)$ with side $a=2$, which, as a rule, is divided into 400 equal parts. Calculations are made on the base of two-dimensional unsteady Euler equations. On the axes are set conditions normal flow lack. Parameter values at the other two boundaries are taken from the computational domain.

The first series of calculations is carried out at $R_c=0.25$, $R_1=0.25$ and $\rho_0=0.2$. As a result of disintegration of high-pressure zone, in the domain with low pressure propagates a circular shock front, followed by a contact discontinuity. Towards the center goes a rarefaction wave, which after reflection continues to reduce the gas density behind the contact discontinuity. In the central part gas becomes over rarefied. That leads to the formation of a convergent shock wave. The reflection of this wave generates a secondary shock wave coming from the center. (Figure 4a-4c) corresponds to the moment when the leading front of the blast wave is at a distance of 1.8 from the center, and the secondary shock wave is already formed.

In this work it is considered that the pressure $p=p_1=1$ in region $r \leq R_c$, and $p=p_0=0.1$ if $r > R_c$. The gas density is $\rho_0=\rho_1=1$ for $r \leq R_1$ and $p=p_0=0.2$ when $r > R_1$. The computational domain is a square in the first quadrant of the plane $(x, y)$ with side $a=2$, which, as a rule, is divided into 400 equal parts. Calculations are made on the base of two-dimensional unsteady Euler equations. On the axes are set conditions normal flow lack. Parameter values at the other two boundaries are taken from the computational domain.

The first four schemes have the second order and the last two the third order of accuracy. All indicate the development of the instability of the initial contact discontinuity given by the circle. The distortion of the contact surface in ref. [24] is explained by the instability of Richtmyer-Meshkov [25]. On the other hand, the development of the flow in a blast wave at breaking up of a high pressure cylindrical area is in detail described in ref. [31] just as in a lot of early papers on theory of an explosion without any mention about instability of contact discontinuity.

In this work it is considered that the pressure $p=p_1=1$ in region $r \leq R_c$, and $p=p_0=0.1$ if $r > R_c$. The gas density is $\rho_0=\rho_1=1$ for $r \leq R_1$ and $p=p_0=0.2$ when $r > R_1$. The computational domain is a square in the first quadrant of the plane $(x, y)$ with side $a=2$, which, as a rule, is divided into 400 equal parts. Calculations are made on the base of two-dimensional unsteady Euler equations. On the axes are set conditions normal flow lack. Parameter values at the other two boundaries are taken from the computational domain.

The first series of calculations is carried out at $R_c=0.25$, $R_1=0.25$
6a), like in ref. [24]. Similar results give calculations with use SGK (α=0.4) and SVA (β=1).

However, it should be noted that when using a rectangular computational grid in a Cartesian coordinate system, any circle, in particular, that which defines the initial form of the contact discontinuity, is approximated non-uniformly along the contour. So each step of numerical integration automatically perturbs the contact surface. In fact, we have another formulation of the cylindrical explosion task, solution of which does not answer the question about the stability of the contact break. In the calculations according to the Godunov scheme contact discontinuity remains circular form (Figure 6b). Distortions of the contact surface are localized near the boundaries of the computation domain. In this case that may be the consequence of a bad choice of coordinate system and computational grid.

The solution of the problem in polar coordinate system

To test the hypothesis [24] about the instability of the contact discontinuity and to eliminate errors caused by the bad choice of the computational grid, the cylindrical blast problem is being solved in polar coordinate system: \(x=r\cos(\theta), y=r\sin(\theta)\). In the variables \((r, \theta)\) the region of computation is the circular sector with central angle \(\pi/2\) and a radius equals 2. In the basic variant the computational domain radius is divided into 400 parts and the angle by 180 cells. On the axes \(\theta=0\) and \(\theta=\pi/2\) are set periodic boundary conditions. Such a construction of mesh eliminates the disturbance of the circular surface of initial discontinuity and ensures the symmetry of the flow with cylindrical waves.

The considered numerical schemes give almost identical results without any signs of the contact discontinuity instability, which initially is set as the circle with radius \(R_c=0.5\), while the radius of the high pressure region \(R_1=0.25, \rho_0=0.2\) (Figure 7a).

In this regard, the interest is the case of the circular break with an initial sinusoidal perturbation (Figure 7b). In the calculations, the amplitude of the initial perturbation AMP=0.02. Impulsive interaction of the blast wave with the contact discontinuity does not alter the ratio of the amplitude and of perturbation wavelength of the contact line KS (Figure 8a). In the flow are formed conditions for rise of the perturbation amplitude: the pressure difference on the contact in the area of the concavity is smaller than near of the convexity (Figure 8b). As a result of interaction of incident shock front and the break the convexities and concavities of the contact line are reversed (Figure 8c) that is typical for the Richtmyer-Meshkov instability. However, in the rarefaction wave which follows the shock front, the mechanism of the Richtmyer-Meshkov instability does not actuate, because the pressure difference along the discontinuity line is quickly equated (Figure 8d).

As a result of interaction of incident shock front and the break the convexities and concavities of the contact line are reversed (Figure 8c) that is typical for the Richtmyer-Meshkov instability. However, in the rarefaction wave which follows the shock front, the mechanism of the Richtmyer-Meshkov instability does not actuate, because the pressure difference along the discontinuity line is quickly equated (Figure 8d).

However, all the schemes, including the Godunov scheme, indicate the growth of the amplitude of the perturbation. The weakening of the blast wave leads to a deceleration of the flow behind the leading front. Gas with high density from the inner side of the contact discontinuity...
to the Kolgan scheme second order in the spatial variables. Promising accuracy than the Godunov scheme, and they produce results close caused by the instability of Taylor, not Richtmyer-Meshkov.

Conclusions

Thus, the cylindrical blast wave increases the initial perturbation of the primary contact surface, but to a certain limit. The reason for this gain is the Taylor instability.
