Performance of waste glass powder (WGP) supplementary cementitious material (SCM) – Workability and compressive strength

1. Introduction

It is a challenge in civil engineering to transform the industrial wastes into construction material components. The increasing amount of unmanaged wastes has resulted in a critical environmental impact. The recycling of industrial wastes and the use of them as construction materials can provide a promising solution from both economy and ecology point of view, by the decrease of pollution and by the more economic design and architecture. Environmentally friendly and low-cost construction materials receive increasing attention recently, due to their attractiveness as building materials benefiting to the environment and promoting sustainability in the building construction industry.

Concrete is the most commonly used construction material in the planet and it is the second most consumed product after water [1].

As of 2012, the annual global cement production is over 3.6 billion tons, and is expected to be increased soon to over 4 billion tons per year, nevertheless, the cement industry is confronting with the continuous increase in cost for energy supplies, the obligations to reduce CO₂ emission and the need of appropriate supply of raw materials both in quality and quantity [2,3]. It is estimated that about 0.9–1.0 tons of CO₂ are produced for a ton of clinker depending on the type of fuels used [4].

Nowadays, the clinker content of cements is intensively replaced by supplementary cementitious materials. Fly ash, blast furnace slag, natural pozzolans and limestone are used in increasing amounts that can substitute some clinker in the cement. Fig. 1 illustrates how the proportions of OPC declined over time in relation to the cements with other major constituents [2]. As a result, an average specific CO₂ emission per ton of cement today is 20% lower compared to the 1990s.

Ecological and environmental benefits of the supplementary cementitious materials are 1) non-recycled waste is used rather than increase the amount of landfills, 2) the consumption of non-renewable natural resources is reduced, 3) the energy needed for cement production is reduced, 4) the emission of greenhouse gases is reduced [5].

2. Waste glass for supplementary cementitious material

Soda-lime glass is the most widely used glass for both packaging and in the building construction, however, based on chemical composition, glass can be categorized into several other categories as well. Containers, float and sheet glass are mostly soda-lime glass and, as a consequence, industrial waste glass is composed over 80% by weight of soda-lime glass [6].

For soda-lime glass the typical composition is approximately: 70% SiO₂, 13–17% Na₂O and 10% CaO.

The characteristics of soda-lime glass make it suitable for consideration as an aggregate to concrete or as a supplementary cementitious material (SCM), but the high alkali content of soda-lime glass is one typical concern for the use in concrete. The possible formation of the harmful alkali-silica reaction (ASR) in contact with Portland cement may limit the
applications. Alkalis can cause alkali-aggregate reaction and expansion if the aggregate of the concrete is reactive.

Experimental results have demonstrated that both particle size and glass colour have an influence on the expansion during alkali-silica reaction [7]. Generally, the finer glass particles exhibit considerably lower expansion; pozzolanic activity increases as fineness increases. Fine particles of waste glass powder (WGP) also tend to perform a relatively rapid pozzolanic reaction with Portland cement on the contrary to the much slower alkali-silica reaction. The combined use of other supplementary cementing materials such as fly ash, ground blast furnace slag and metakaolin can also decrease the expansion from ASR.

The pozzolanic properties of waste glass powder (WGP) are first notable at particle sizes below approximately 300 μm. Below 100 μm, glass can have a pozzolanic reactivity which is greater than that of fly ash. When ground to about the same fineness as Portland cement, waste glass powder (WGP) has advantageous pozzolanic behaviour: the amorphous silica (SiO₂) reacts with portlandite (Ca(OH)₂) generated during cement hydration to form gel of calcium silicate hydrate (CSH). No alkali-silica reaction was detected with particle size below 100 μm [6].

It was found experimentally that 30% waste glass powder (WGP) could be incorporated as cement replacement in concrete without any long term disadvantageous effect [8]. Several studies have shown further beneficial effects, including increased workability and reduced permeability, of using WGP as a supplementary cementitious material (SCM), but the compressive strength is often lower when WGP is used as cement replacement, especially at early ages. Cement replacement with waste glass powder was shown to reduce early-age compressive strength, concrete mixtures with glass powder reached strength values close to the strength values for control mixtures at 28 days, and only one glass powder mixture reached a greater strength than the corresponding control at 91 days according to [9].

It was also shown that cement mortar with 20% waste glass powder replacement gained significant strength between 28 and 90 days showing pozzolanic reaction taking place in this period [10]. The continued strength development clearly indicates the beneficial pozzolanic reaction of the glass powder [11].

A reduction in the 28 days compressive strength of about 15% was observed when 20% of cement was replaced by waste glass powder [10,12].

3. Experimental studies

Laboratory tests were carried out on cement paste specimens, in which waste glass powder (WGP) addition was used as supplementary cementitious material (SCM) during a cooperation research between the Budapest University of Technology and Economics (BME), Department of Construction Materials and Engineering Geology and the Riga Technical University (RTU), Institute of Materials and Structures (IMS), Department of Building Materials and Products.

3.1 Materials

For the specimens, CEM I 42.5 N Portland cement was used provided by a Hungarian cement manufacturer, with a specific surface area of 344 m²/kg. The WGP addition materials were prepared in RTU IMS laboratory directly for the present experiments, using waste glass cullet collected in Latvia. Five different WGPs were studied. Fluorescent lamp tube glass waste cullet (LB) and incandescent light bulb borosilicate glass waste cullet (DRL) were received from a lamp recycling centre in Liepaja, Latvia. Container glass was obtained as bottles in green (G), amber (A) and flint (F) colours which were collected at a glass bottle return point in Riga, Latvia, and were manually crushed into cullet under laboratory conditions. The cullet was washed, dried and ground for 30 minutes in a laboratory planetary ball mill (Retsch PM400) with rotation speed 300 min⁻¹. The specific surface area of the WGP was obtained by a Zwick/Roell ToniPERM automatic Blaine apparatus; further details of the WGP preparation are available in [13].

Earlier experiences have indicated that the five WGPs used in the present studies can serve as supplementary cementitious materials. It was demonstrated on concrete specimens [14] that WGP addition improves workability and results a softer consistency (demonstrated by standard slump tests), can contribute to the compressive strength of the hardened concrete and due to the relatively high specific surface area (maximum particle size was found to be smaller than 200 μm in each case [13]) they have a relatively small influence on ASR expansion.
The consistency was tested by a standard flow table (Fig. 2) according to EN 1015-3:1999 [16]. The flow table tests were repeated twice for each mixture. After the 15 drops of the flow table (one drop in 2 seconds) the final diameter of the sample was measured in two directions by a steel ruler. Flow table test results are indicated in Fig. 3. It can be seen that the WGP addition increases the flow of the fresh pastes. The higher is the amount of the WGP, the higher is the improvement in workability.

3.3 Compressive strength

For the compressive strength tests, 30 mm size cubic specimens were prepared in steel moulds. During the first 14 days of curing period specimens were kept in water in the climatic chamber, after 14th days half of specimens was stored in the climatic chamber (at temperature 20±2 °C and relative humidity >65%) and half of the specimens was kept continuously under water. Compressive strength of cement paste specimens was determined at the age 2, 7, 14, 28, 91, 147 and 302 days (Fig. 4) according to EN 196-1:2005 [15]. The evolution of the compressive strength of the specimens stored under water is indicated in Fig. 5, where the hardened neat cement paste is indicated with red colour.

4. Discussion of strength results

The development of the compressive strength is indicated in separate diagrams for the five GWPs in comparison to the neat cement paste (see Fig. 6.a, 7.a, 8.a, 9.a, 10.a). Strength development of the hardened neat cement paste at the age of $t$ days, is indicated with red colour in each diagram. It can be generally concluded that the cement replacement by GWP was successful form a compressive strength point of view and no significant reduction of the compressive strength can be realised, especially for the mature specimens.

The effectiveness of the cement replacement can be characterised more precisely if the relative development of the compressive strength is studied. Fig. 6.b, 7.b, 8.b, 9.b, 10.b indicate the relative compressive strength values corresponding to the different GWPs. The level of 1.0 indicates the compressive strength of the hardened neat cement paste at the age of $t$ days, as a reference level in each diagram (indicated with red colour). It can be seen that the compressive strength of the pastes containing WGP addition reaches that of the reference hardened cement paste at the age of 28 to 91 days, according to the present laboratory tests. The significance of the WGP amount is also visible: usually, the 20% replacement resulted higher compressive strength values than the 30% replacement. It seems that only a part of the WGP can be activated by ordinary Portland cement during the period of the present experiments (~ one year). A rapid development of the compressive strength is visible between the ages of 28 to 91 days, being faster than that of the hardened neat cement paste that is attributed to a supposed very active hydration of the GWPs during that period of time. At later ages the relative rate of hydration is balanced between the cement and the GWPs, resulted in a decelerated rate and a constant difference in compressive strength values.

It can be also demonstrated that the particle size of the GWPs has a stronger influence on the effectiveness of the cement replacement than e.g. the chemical composition. Fig. 11 indicates...
the relative compressive strength values corresponding to the age of 302 days over the specific surface area of the WGP's used in the present experiments, according to [13]. The effectiveness of the cement replacement increases as the specific surface area increases. The flint WGP seems to be an outlier during the present tests. The results further confirm the importance of the preparation of WGP's with high specific surface area for the optimal supplementary cementitious material performance.

5. Conclusions

The present paper has summarised the experimental results of a laboratory test series carried out on cement paste specimens, in which waste glass powder (WGP) addition was used as a supplementary cementitious material (SCM) during a cooperation research between the Budapest University of Technology and Economics (BME), Department of Construction Materials and Engineering Geology and the Riga Technical University (RTU), Institute of Materials and Structures (IMS). CEM I 42.5 N Portland cement was used with WGP substitution at levels of 20% or 30% per mass of cement.

It was demonstrated that the WGP addition:

- improves the workability of fresh pastes,
- can be effectively used as cement replacement for compressive strength.

It was demonstrated that the particle size of the WGP's (specific surface area) has a stronger influence on the effectiveness of the cement replacement than the chemical composition.

Megőrült hulladék üveg (WGP) cement kiegészítő anyag (SCM) tulajdonságai – Bedolgozhatóság és nyomószilárdság vizsgálata

A megőrült hulladék üveg cement kiegészítő anyagként történő felhasználása gazdasági és ökológiai hatásossága is jár: csökkenthető a hulladékdépödniákban elhelyezett anyag mennyisége, csökkenthető a nem megújuló nyersanyag felhasználás mértéke, csökkenthető a cementgyártás energiaigénye (kevesebb cement gyártása szükséges), csökkenthető ez által az üvegháztartást okozó gázok kibocsátásának mennyisége. Egy laboratóriumi vizsgálat sorozat keretein belül megőrült hulladék üveget alkalmaztunk cement kiegészítő anyagként. A kiegészítő anyag mennyiségét 20% és 30% volt a cement tömegére vonatkoztatva. Kimutattuk, hogy a megőrült hulladék üveg cement kiegészítő anyag javítja a cementpapír bedolgozhatóságát és köreműködik a meg- szilárdult pép nyomószilárdságában. Megfigyeltük, hogy a megőrült hulladék üveg fajlagos felületének nagyobb szerepe van a kiegészítő anyagként történő hatékonyság működésben, mint a kémiai összetételének.
