ABSTRACT

The secular approximation for the evolution of hierarchical triple configurations has proven to be very useful in many astrophysical contexts, from planetary to triple-star systems. In this approximation the orbits may change shape and orientation, on time-scales longer than the orbital time-scales, but the semimajor axes are constant. For example, for highly inclined triple systems, the Kozai–Lidov mechanism can produce large-amplitude oscillations of the eccentricities and inclinations. Here we revisit the secular dynamics of hierarchical triple systems. We derive the secular evolution equations to octupole order in Hamiltonian perturbation theory. Our derivation corrects an error in some previous treatments of the problem that implicitly assumed a conservation of the \( z \)-component of the angular momentum of the inner orbit (i.e. parallel to the total angular momentum of the system). Already to quadrupole order, our results show new behaviours including the possibility for a system to oscillate from prograde to retrograde orbits. At the octupole order, for an eccentric outer orbit, the inner orbit can reach extremely high eccentricities and undergo chaotic flips in its orientation. We discuss applications to a variety of astrophysical systems, from stellar triples to merging compact binaries and planetary systems. Our results agree with those of previous studies done to quadrupole order only in the limit in which one of the inner two bodies is a massless test particle and the outer orbit is circular; our results agree with previous studies at octupole order for the eccentricity evolution, but not for the inclination evolution.

Key words: minor planets, asteroids: general – planets and satellites: dynamical evolution and stability – binaries: close.

1 INTRODUCTION

Triple-star systems are believed to be very common (e.g. Tokovinin 1997; Eggleton, Kisseleva-Eggleton & Dearborn 2007). From dynamical stability arguments these must be hierarchical triples, in which the (inner) binary is orbited by a third body on a much wider orbit. Probably more than 50 per cent of bright stars are at least double (Tokovinin 1997; Eggleton et al. 2007). Given the selection effects against finding faint and distant companions we can be reasonably confident that the proportion is actually substantially greater. Tokovinin (1997) showed that 40 per cent of binary stars with period \( <10 \) d in which the primary is a dwarf (0.5–1.5 \( M_\odot \)) have at least one additional companion. He found that the fraction of triples and higher multiples among binaries with period (10–100 d) is \( \sim10 \) per cent. Moreover, Pribulla & Rucinski (2006) have surveyed a sample of contact binaries, and noted that among 151 contact binaries brighter than 10 mag, 42 \( \pm \) 5 per cent are at least triple.

Many close stellar binaries with two compact objects are likely produced through triple evolution. Secular effects (i.e. coherent interactions on time-scales long compared to the orbital period), and specifically Kozai–Lidov cycling (Kozai 1962; Lidov 1962, see below), have been proposed as an important element in the evolution of triple stars (e.g. Harrington 1969; Mazeh & Shaham 1979; Söderhjelm 1982; Kiseleva, Eggleton & Mikkola 1998; Fabrycky & Tremaine 2007; Perets & Fabrycky 2009; Thompson 2011; Shappee & Thompson 2013). In addition, Kozai–Lidov cycling has been suggested to play an important role in both the growth of black holes at the centres of dense star clusters and the formation of short-period binary black holes (Blaes, Lee & Socrates 2002; Miller & Hamilton 2002; Wen 2003). Recently, Ivanova et al. (2010) showed that the most important formation mechanism for black hole X-ray binaries (XRBs) in globular clusters may be triple-induced mass transfer in a black hole–white dwarf binary.
Secular perturbations in triple systems also play an important role in planetary system dynamics. Kozai (1962) studied the effects of Jupiter’s gravitational perturbation on an inclined asteroid in our own Solar system. In the assumed hierarchical configuration, treating the asteroid as a test particle, Kozai (1962) found that its inclination and eccentricity fluctuate on time-scales much larger than its orbital period. Jupiter, assumed to be in a circular orbit, carries most of the angular momentum of the system. Because of Jupiter’s circular orbit and the negligible mass of the asteroid, the system’s potential is axisymmetric and thus the component of the inner orbit’s angular momentum along the total angular momentum is conserved during the evolution. Kozai (1979) also showed the importance of secular interactions for the dynamics of comets (see also Quinn, Tremaine & Duncan 1990; Bailey, Chambers & Hahn 1992; Thomas & Morbidelli 1996). The evolution of the orbits of binary minor planets is dominated by the secular gravitational perturbation from the Sun (Perets & Naoz 2009); properly accounting for the resulting secular effects – including Kozai cycling – accurately reproduces the binary minor planet orbital distribution seen today (Naoz, Perets & Ragozzine 2010; Grundy et al. 2011). In addition, Kinoshita & Nakai (1991, 2007), Vaskov’yak (1999), Carruba et al. (2002), Nesvorný et al. (2003) and Čuk & Burns (2004) suggested that secular interactions may explain the significant inclinations of gas giant satellites and Jovian irregular satellites.

Similar analyses have been applied to the orbits of extrasolar planets (e.g. Innanen et al. 1997; Wu & Murray 2003; Fabrycky & Tremaine 2007; Wu, Murray & Ramsahai 2007; Veras & Ford 2010; Correia et al. 2011; Naoz et al. 2011). Naoz et al. (2011) considered the secular evolution of a triple system consisting of an inner binary containing a star and a Jupiter-like planet at several astronomical unit (au), orbited by a distant Jupiter-like planet or brown dwarf companion. Perturbations from the outer body can drive Kozai-like cycles in the inner binary, which, when planet–star tidal effects are incorporated, can lead to the capture of the inner planet on to a close, highly inclined or even retrograde orbit, similar to the orbits of the observed retrograde ‘hot Jupiters’. Many other studies of exoplanet dynamics have considered similar systems, but with a very distant stellar binary companion acting as perturber. In such systems, the outer star completely dominates the orbital angular momentum, and the problem reduces to test particle evolution (see Katz, Dong & Malhotra 2011; Lithwick & Naoz 2011; Naoz, Farr & Rasio 2012a). If the lowest level of approximation is applicable (e.g. the outer perturber is on a circular orbit), the z-component of the inner orbit’s angular momentum is conserved (e.g. Lidov & Ziglin 1974).

In early studies of high-inclination secular perturbations (Kozai 1962; Lidov 1962), the outer orbit was circular and again dominated the orbital angular momentum of the system. In this situation, the component of the inner orbit’s angular momentum along the z-axis is conserved. In many later studies the assumption that the z-component of the inner orbit’s angular momentum is constant was built into the equations (e.g. Eggleton, Kiseleva & Hut 1998; Mikkola & Tanikawa 1998; Zdziarski, Wen & Gierliński 2007). In fact these studies are only valid in the limit of a test particle forced by a perturber on a circular orbit. To leading order in the ratio of semimajor axes (SMA), the double averaged potential of the outer orbit is axisymmetric (even for an eccentric outer perturber), thus if taken to the test particle limit, this results in a conservation of the z-component of the inner orbit’s angular momentum. We refer to this limit as the ‘standard’ treatment of Kozai oscillations, i.e. quadrupole-level approximation in the test particle limit (test particle quadrupole, hereafter TPQ).

In this paper we show that a common mistake in the Hamiltonian treatment of these secular systems can lead to the erroneous conclusion that the z-component of the inner orbit’s angular momentum is constant outside the TPQ limit; in fact, the z-component of the inner orbit’s angular momentum is only conserved by the evolution in the test particle limit and to quadrupole order. To demonstrate the error we focus on the quadrupole (non-test-particle) approximation in the main body of the paper, but we include the full octupole-order equations of motion in the Appendix.

In what follows we show the applications of these two effects (i.e. correcting the error and including the full octupole-order equations of motion) by considering different astrophysical systems. Note that the applications illustrated in the text are inspired by real systems; however, we caution that we consider here only Newtonian point mass dynamics, while in reality other effects such as tides and general relativity can greatly affect the evolution. For example, general relativity may alter the evolution of the system, which can give rise to a resonant behaviour of the inner orbits eccentricity (e.g. Ford, Kozinsky & Rasio 2000b; Naoz et al. 2012b). Furthermore, tidal forces can suppress the eccentricity growth of the inner orbit, and thus significantly modify the evolutionary track of the system (e.g. Mazeh & Shaham 1979; Söderhjelm 1984; Kiseleva et al. 1998). In particular tides, in some cases, can considerably suppress the chaotic behaviour that arises in the presence of the octupole level of approximation (e.g. Naoz et al. 2011, 2012a). Therefore, while the examples presented in this paper are inspired by real astronomical systems, the true evolutionary behaviour will be modified from what we show once the eccentricity becomes too high.

This paper is organized as follows. We first present the general framework (Section 2); we then derive the complete formalism for the quadrupole-level approximation and the equations of motion (Section 3), we also develop the octupole-level approximation equations of motion in Section 4. We discuss a few of the most important implications of the correct formalism in Section 5. We also compare our results with those of previous studies (Section 5) and offer some conclusions in Section 6.

2 HAMILTONIAN PERTURBATION THEORY FOR HIERARCHICAL TRIPLE SYSTEMS

Many gravitational triple systems are in a hierarchical configuration – two objects orbit each other in a relatively tight inner binary while the third object is on a much wider orbit. If the third object is sufficiently distant, an analytic, perturbative approach can be used to calculate the evolution of the system. In the usual secular approximation (e.g. Marchal 1990), the two orbits torque each other and exchange angular momentum, but not energy. Therefore the orbits can change shape and orientation (on time-scales much longer than their orbital periods), but not SMA.

We first define our basic notations. The system consists of a close binary (bodies of masses \( m_1 \) and \( m_2 \)) and a third body (mass \( m_3 \)). It is convenient to describe the orbits using Jacobi coordinates (Murray & Dermott 2000, p. 441–443). Let \( r_1 \) be the relative position vector from \( m_1 \) to \( m_2 \) and \( r_2 \) the position vector of \( m_3 \) relative to the centre of mass of the inner binary (see Fig. 1). Using this coordinate system the dominant motion of the triple can be divided into two separate Keplerian orbits: the relative orbit of bodies 1 and 2, and the orbit of body 3 around the centre of mass of bodies 1 and 2. The Hamiltonian for the system can be decomposed accordingly into two Keplerian Hamiltonians plus a coupling term that describes the (weak) interaction between the two orbits. Let the SMA of the inner and outer orbits be \( a_1 \) and \( a_2 \), respectively. Then the coupling term
Secular dynamics in hierarchical three-body systems

Figure 1. Coordinate system used to describe the hierarchical triple system (not to scale). Here 'c.m.' denotes the centre of mass of the inner binary, containing objects of masses $m_1$ and $m_2$. The separation vector $r_1$ points from $m_1$ to $m_2$; $r_2$ points from 'c.m.' to $m_3$. The angle between the vectors $r_1$ and $r_2$ is $\Phi$.

In the complete Hamiltonian can be written as a power series in the ratio of the SMA $\alpha = a_1/a_2$ (e.g. Harrington 1968). In a hierarchical system, by definition, this parameter $\alpha$ is small.

The complete Hamiltonian expanded in orders of $\alpha$ is (e.g. Harrington 1968)

$$\mathcal{H} = \frac{k^2 m_1 m_2}{2a_1} + \frac{k^2 m_2 (m_1 + m_2)}{2a_2} + \frac{k^2}{a_2} \sum_{j=2}^{\infty} \alpha^j M_j \left( \frac{r_1}{a_1} \right)^j \left( \frac{r_2}{a_2} \right)^{j+1} P_j(\cos \Phi),$$

where $k^2$ is the gravitational constant, $P_j$ are Legendre polynomials, $\Phi$ is the angle between $r_1$ and $r_2$ (see Fig. 1) and

$$M_j = m_1 m_2 m_3 \frac{m_1^{-j-1} - (m_2)^{-j-1}}{(m_1 + m_2)^j}.$$

Note that we have followed the convention of Harrington (1969) and chosen our Hamiltonian to be the negative of the total energy, so that $\mathcal{H} > 0$ for bound systems.

We adopt the canonical variables known as Delaunay's elements, which provide a particularly convenient dynamical description of our three-body system (e.g. Valtonen & Karttunen 2006). The coordinates are chosen to be the mean anomalies, $l_1$ and $l_2$, the longitudes of ascending nodes, $h_1$ and $h_2$, and the arguments of periastron, $g_1$ and $g_2$, where subscripts 1 and 2 denote the inner and outer orbits.

Figure 2. Geometry of the angular momentum vectors. We show the total angular momentum vector $G_{\text{tot}}$, the angular momentum vector of the inner orbit ($G_1$) with inclination $i_1$ with respect to $G_{\text{tot}}$ and the angular momentum vector of the outer orbit ($G_2$) with inclination $i_2$ with respect to $G_{\text{tot}}$. The angle between $G_1$ and $G_2$ defines the mutual inclination $i_{\text{tot}} = i_1 + i_2$. The invariable plane is perpendicular to $G_{\text{tot}}$.

respectively. Their conjugate momenta are

$$L_1 = \frac{m_1 m_2}{m_1 + m_2} \sqrt{k^2 (m_1 + m_2) a_1},$$

$$L_2 = \frac{m_1 (m_1 + m_2)}{m_1 + m_2 + m_3} \sqrt{k^2 (m_1 + m_2 + m_3) a_2},$$

$$G_1 = L_1 \sqrt{1 - e_1^2}, \quad G_2 = L_2 \sqrt{1 - e_2^2}$$

and

$$H_1 = G_1 \cos i_1, \quad H_2 = G_2 \cos i_2,$$

where $e_1$ ($e_2$) is the inner (outer) orbit eccentricity. Note that $G_1$ and $G_2$ are also the magnitudes of the angular momentum vectors ($G_1$ and $G_2$), and $H_1$ and $H_2$ are the $z$-components of these vectors. Fig. 2 shows the resulting configuration of these vectors. The following geometric relations between the momenta follow from the law of cosines:

$$\cos i_{\text{tot}} = \frac{G_{\text{tot}}^2 - G_1^2 - G_2^2}{2G_1 G_2},$$

$$H_1 = \frac{G_{\text{tot}}^2 + G_1^2 - G_2^2}{2G_{\text{tot}}},$$

$$H_2 = \frac{G_{\text{tot}}^2 + G_2^2 - G_1^2}{2G_{\text{tot}}}.$$

where $G_{\text{tot}} = G_1 + G_2$ is the (conserved) total angular momentum, and the angle between $G_1$ and $G_2$ defines the mutual inclination $i_{\text{tot}} = i_1 + i_2$. From equations (7) and (8) we find that the inclinations $i_1$ and $i_2$ are determined by the orbital angular momenta:

$$\cos i_1 = \frac{G_{\text{tot}}^2 + G_1^2 - G_2^2}{2G_{\text{tot}} G_1},$$

$$\cos i_2 = \frac{G_{\text{tot}}^2 + G_2^2 - G_1^2}{2G_{\text{tot}} G_2}.$$
\[
\cos \delta z = \frac{G_{12}^2 + G_{13}^2 - G_{23}^2}{2G_{12}G_{23}}.
\]  

(10)

In addition to these geometrical relations we also have that

\[
H_1 + H_2 = G_{\text{tot}} = \text{const}.
\]  

(11)

The canonical relations give the equations of motion:

\[
\frac{dL_j}{dt} = \frac{\partial H}{\partial \dot{L}_j}, \quad \frac{dL_j}{dt} = -\frac{\partial H}{\partial \dot{L}_j},
\]  

(12)

\[
\frac{dG_j}{dt} = \frac{\partial H}{\partial \dot{G}_j}, \quad \frac{dG_j}{dt} = -\frac{\partial H}{\partial \dot{G}_j},
\]  

(13)

\[
\frac{dH_j}{dt} = \frac{\partial H}{\partial \dot{H}_j}, \quad \frac{dH_j}{dt} = -\frac{\partial H}{\partial \dot{H}_j},
\]  

(14)

where \( j = 1, 2 \). Note that these canonical relations have the opposite sign relative to the usual relations (e.g. Goldstein 1950) because of the sign convention we have chosen for our Hamiltonian. Finally we write the Hamiltonian through second order in \( \alpha \) as (e.g. Kozai 1962)

\[
\mathcal{H} = \frac{\beta_1}{2L_1^2} + \frac{\beta_2}{2L_2^2} + 4\beta_3 \left( \frac{L_1^4}{L_2^2} \right) \left( \frac{r_1}{a_1} \right)^2 \left( \frac{a_2}{r_2} \right)^3 (3 \cos 2\Phi + 1),
\]  

(15)

where the mass parameters are

\[
\beta_1 = k^2 m_1 m_2 L_2^2/a_1,
\]  

(16)

\[
\beta_2 = k^2 (m_1 + m_2) m_3 L_3^2/a_2,
\]  

(17)

and

\[
\beta_3 = \frac{k^4}{16} \frac{(m_1 + m_2)^2 m_3^2}{(m_1 + m_2 + m_3)^3}.
\]  

(18)

### 3 Secular Evolution to the Quadrupole Order

In this section, we derive the secular quadrupole-level Hamiltonian. In Appendix A we develop the complete quadrupole-level secular approximation and in particular in Appendix A3 we present the quadrupole-level equations of motion. The main difference between the derivation shown here (see also Appendix A) and those of previous studies lies in the ‘elimination of nodes’ (e.g. Kozai 1962; Jefferys & Moser 1966). This is related to the transition to a coordinate system with the total angular momentum along the \( z \)-axis, which is known as the invariable plane (e.g. Murray & Dermott 2000). In this coordinate system (see Fig. 2), the longitudes of the ascending nodes differ by \( \pi \), i.e.

\[
h_1 - h_2 = \pi.
\]  

(19)

Conservation of the total angular momentum implies that this relation holds at all times. Many previous works have exploited it to explicitly simplify the Hamiltonian by setting \( h_1 - h_2 = \pi \) before deriving the equations of motion. After the substitution, the Hamiltonian is independent of the longitudes of ascending nodes \( (h_1, h_2) \), and this can lead to the incorrect conclusion that \( \dot{H}_1 = \dot{H}_2 = 0 \) when the canonical equations of motion are derived. Some previous studies incorrectly concluded that the \( z \)-components of the orbital angular momenta are always constant (see also Appendix C). The substitution \( h_1 - h_2 = \pi \) is incorrect at the Hamiltonian level because it unduly restricts variations in the trajectory of the system to those where \( \delta h_1 = \delta h_2 \). After deriving the equations of motion, however, we can exploit the relation \( h_1 - h_2 = \Delta h = \pi \), which comes from the conservation of angular momentum. This considerably simplifies the evolution equations. We show (Appendices A3 and B) that one can still use the Hamiltonian with the nodes eliminated found in previous studies (e.g. Kozai 1962; Harrington 1969) as long as the evolution equations for the inclinations are derived from the total angular momentum conservation, instead of using the canonical relations. Of course, the correct evolution equations can also be calculated from the correct Hamiltonian (without the nodes eliminated), which we derive in this section.

We note that there are some other derivations of the secular evolution equations that avoid the elimination of the nodes (Farago & Laskar 2010; Laskar & Boué 2010; Mardling 2010; Katz & Dong 2011), and thus do not suffer from this error.\(^1\)

The secular Hamiltonian is given by the average over the rapidly varying \( l_1 \) and \( l_2 \) in equation (15) (see Appendix A for more details):

\[
\mathcal{H}_2 = \frac{C_2}{8} \left\{ 1 + 3 \cos (2i_2) \left[ \left( 1 + 3 \cos (2i_1) \right) \left[ 1 + 3 \cos (2i_1) \right] + 3 \cos (2\Delta h) \left( 10 \cos (2i_2) \cos (2i_1) \right) \right] \right. \\
\left. \times \left( 3 + \cos (2i_1) \right) + 4 (2 + 3 \cos^2 (2i_1) \sin^2 (i_2) \right) \sin^2 (i_2) + 12 (2 + 3 \cos^2 (2i_1) \cos (2\Delta h) \sin (2i_1) \sin (2i_2) + 120 \cos^2 (i_1) \sin (2i_2) \sin (2\Delta h) \right\} - 120 \cos^2 (i_1) \sin (2i_2) \sin (2\Delta h),
\]  

(20)

where

\[
C_2 = \frac{k^4}{16} \frac{(m_1 + m_2)^2}{(m_1 + m_2 + m_3)^3} \frac{m_3^2}{L_2^4} G_2^7.
\]  

(21)

Making the usual (incorrect) substitution \( \Delta h \to \pi \) (i.e. eliminating the nodes), we get the quadrupole-level Hamiltonian that has appeared in many previous works (see e.g. Ford et al. 2000b):

\[
\mathcal{H}_2 (\Delta h \to \pi) = C_2 \left\{ \left( 2 + 3 \cos^2 (i) \right) (3 \cos^2 i - 1) + 15 \cos^2 i \cos (2i_1) \right\},
\]  

(22)

where we have set \( i_1 + i_2 = i_{\text{tot}} \). Because this Hamiltonian is missing the longitudes of ascending nodes \( (h_1, h_2) \), many previous studies concluded that the \( z \)-components (i.e. vertical components) of the angular momenta of the inner and outer orbits (i.e. \( H_1 \) and \( H_2 \)) are constants.

We derive the quadrupole-level equations of motions in Appendix A3. In particular, we give the equations of motion of the \( z \)-component of the angular momentum of the inner and outer orbits derived from the Hamiltonian in equation (20). As we show in the subsequent sections the evolution of \( H_{1,2} \) produces a qualitatively different evolutionary route for many astrophysical systems considered in previous works.

\(^1\) It is possible to eliminate the nodes as long as one does not conclude that the conjugate momenta are constant, one example is Lidov & Ziglin (1976) and another is Malige, Robutel & Laskar (2002) that after eliminating the nodes introduced a different transformation which overcame the problem.
In Appendix A4 we show that the quadrupole approximation leads to well-defined minimum and maximum eccentricity and inclination. The eccentricity of the inner orbit and the inner (and mutual) inclination oscillate. In the test particle limit, our formalism gives the critical initial mutual inclination angles for large oscillations of \(39.2 \leq \Theta_{\max} \leq 140.8\) with nearly zero initial inner eccentricity, in agreement with Kozai (1962).

It is easy to show that \(H_1\) and \(H_2\) are constant only in the TPQ limit without using the explicit equations of motion in Appendix A. Because the Hamiltonian in equation (20) is independent of \(g_2\), \(G_2 = \text{const}\) at the quadrupole level. Combining this with the geometric relation in equation (7), \(H_1 = (G_{\text{tot}}^2 + G_1^2 - G_2^2)/(2G_{\text{tot}})\), and the constancy of the total angular momentum, \(G_{\text{tot}}\), we have that

\[
H_1 = \frac{G_1G_2}{G_{\text{tot}}},
\]

(23)

In the TPQ limit, \(G_{\text{tot}} \gg G_1\), so \(H_1 = -H_2 \approx 0\), and the \(z\)-component of each orbit’s angular momentum is conserved. Outside this limit, when \(G_1/G_2\) is not negligible, \(H_1\) and \(H_2\) cannot be constant. Note that the TPQ limit, where \(G_1 \ll G_{\text{tot}}\), is equivalent to the limit where \(i_2 \approx 0\) appearing in many previous works.

### 4 OCTUPOLE-LEVEL EVOLUTION

In Appendix B, we derive the secular evolution equations to octupole order. Many previous octupole-order derivations provided correct secular evolution equations for at least some of the elements, in spite of using the elimination of nodes substitution at the Hamiltonian level (e.g. Harrington 1968, 1969; Süssichovsky 1983; Krymolowski & Mazeh 1999; Ford et al. 2000b; Blaes et al. 2002; Lee & Peale 2003; Thompson 2011). This is because the evolution equations for \(e_2\), \(g_2\), \(g_1\) and \(e_1\) can be found correctly from a Hamiltonian that has had \(h_1\) and \(h_2\) eliminated by the relation \(h_1 - h_2 = \pi\); the partial derivatives with respect to the other coordinates and momenta are not affected by the substitution. The correct evolution of \(H_1\) and \(H_2\) can then be derived, not from the canonical relations, but from total angular momentum conservation. We discuss in more detail the comparison between this work and previous analyses in Section 5.

The octupole level terms in the Hamiltonian can become important when the eccentricity of the outer orbit is non-zero, and if \(\alpha\) is large enough. We quantify this by considering the ratio between the octupole to quadrupole-level coefficients, which is

\[
\frac{C_3}{C_2} = \frac{15}{4} \left( \frac{m_1 - m_2}{m_1 + m_2} \right) \frac{a_1}{a_2} \frac{1}{1 - e_2^2},
\]

(24)

where \(C_3\) is the octupole-level coefficient (equation B1) and \(C_2\) is the quadrupole-level coefficient (equation 21). We define

\[
\epsilon_{3M} = \frac{m_1 - m_2}{m_1 + m_2} \left( \frac{a_1}{a_2} \right) \frac{e_2}{1 - e_2^2},
\]

(25)

which gives the relative significance of the octupole level term in the Hamiltonian. This parameter has three important parts: first the eccentricity of the outer orbit \(e_2\); secondly, the mass difference of the inner binary \((m_1\) and \(m_2\)) and the SMA ratio.\(^2\) In the test particle limit (i.e. \(m_1 \gg m_2\)) \(\epsilon_{3M}\) is reduced to the octupole coefficient introduced in Lithwick & Naoz (2011) and Katz et al. (2011),

\[
\epsilon = \frac{a_1}{a_2} \frac{e_2}{1 - e_2^2}.
\]

(26)

We call the octupole-level behaviour of a system for which \(\epsilon_{3M} \ll 1\) is not satisfied the ‘eccentric Kozai–Lidov’ (EKL) mechanism.

The octupole terms vanish when \(e_2 = 0\). Therefore if one artificially held \(e_2 = 0\), in the test particle limit the inner body’s orbit would be given by the equations derived by Kozai (1962), i.e. by the test particle quadrupole equations. However, at octupole order the value of \(e_2\) evolves in time if the inner body is massive. Furthermore, even if the inner body is massless, if the outer body has \(e_2 > 0\) then the inner body’s behaviour will also be different than in Kozai’s treatment. For example, Lithwick & Naoz (2011) and Katz et al. (2011) find that the inner orbit can flip orientation (see below) even in the test particle, octupole limit. The octupole-level effects can change qualitatively the evolution of a system. Compared to the quadrupole-level behaviour, the eccentricity of the inner orbit in the EKL mechanism can reach a much higher value. In some cases these excursions to very high eccentricities are accompanied by a ‘flip’ of the orbit with respect to the total angular momentum, i.e. starting with \(i_1 < 90^\circ\) the inner orbit can eventually reach \(i_1 > 90^\circ\) (see Figs 6–9 for examples). Chaotic behaviour is also possible at the octupole level (Lithwick & Naoz 2011), but not at the quadrupole level.

Given the large, qualitative changes in behaviour moving from quadrupole to octupole order in the Hamiltonian, is it possible that similar changes in the secular evolution may occur at even higher orders? The answer to this question probably lies in the elimination of \(G_2\) as an integral of motion at octupole order, leaving only four integrals of motion: the energy of the system, and the three components of the total angular momentum. There are no more integrals of motion to be eliminated, and thus one might expect no more dramatic changes in the evolution when moving to even higher orders. It is possible to see this quantitatively for specific initial conditions through comparisons with direct \(n\)-body integrations. We compared our octupole equations with direct \(n\)-body integrations, using the MERCURY software package (Chambers & Migliorini 1997). We used both Bulirsch–Stoer and symplectic integrators (Wisdom & Holman 1991) and found consistent results between the two. We present the results of a typical integration compared to the integration of the octupole-level secular equations in Fig. 3. The initial conditions (see caption) for this system are those of Naoz et al. (2011), Fig. 1. We find good agreement between the direct integration and the secular evolution at octupole order. Both show a beat-like pattern of eccentricity oscillations, suggesting an interference between the quadrupole and octupole terms, and both methods show similar flips of the inner orbit.

### 5 IMPLICATIONS AND COMPARISON WITH PREVIOUS STUDIES

The Kozai (1962) and Lidov (1962) equations of motions are correct to quadrupole order and for a test particle, but differ from the correct evolution equations for non-test-particle inner orbits and/or at octupole order. In this section we show how these differences give rise to qualitatively different evolutionary behaviours than those assumed in some previous works.

\(^2\) Note here that the subscripts ‘1’ and ‘2’ refer to the inner bodies in \(m_1\) and \(m_2\), but the subscript ‘2’ refers to the outer body in \(e_2\).
The thin horizontal line in the top panel marks the 90° boundary, separating prograde and retrograde orbits. The initial mutual inclination of 65° corresponds to an inner and outer inclination with respect to the total angular momentum (parallel to \( z \)) of 64°7 and 0°3, respectively. Here, the arguments of pericentre of the inner orbit is set to \( g_1 = 45° \) and the outer orbit set to zero initially. The SMA of the two orbits (not shown) are nearly constant during the direct integration, varying by less than 0.02 per cent. The agreement in both period and amplitude of oscillation between the direct integration and the octupole-level approximation is quite good.

5.1 Massive inner object at the quadrupole level

The danger with working in the wrong limit is apparent if we consider an inner object that is more massive than the outer object. While the TPQ formalism incorrectly assumes that the orbit of the outer body is fixed in the invariable plane, and therefore the inner body’s vertical angular momentum is constant, the quadrupole-level equations presented in Appendix A3 do not.

We compare the two formalisms in Fig. 4. We consider the triple system PSR B1620−26 located near the core of the globular cluster M4. The inner binary contains a millisecond pulsar of mass \( 1.4 \, M_\odot \) and a companion of mass \( 0.3 \, M_\odot \) (McKenna & Lyne 1988). Following Ford et al. (2000a), we adopt parameters for the outer perturber of \( m_1 = 0.01 \, M_\odot \) and \( e_2 = 0 \). Note that Ford et al. (2000a) found \( e_2 = 0.45 \), but it is interesting to show that even for an axisymmetric outer potential the evolution of the system is qualitatively different than the TPQ approximation (see the caption for a full description of the initial conditions). Note that the actual measured inner binary eccentricity is \( e_1 \approx 0.045 \), however, in order to illustrate the difference we adopt a higher value (\( e_1 = 0.5 \)). For these initial conditions \( e_{i_{\text{tot}}} = 0.036 \), so a careful analysis would require incorporating the octupole-order terms in the motion; nevertheless, we consider the evolution of the system to quadrupole order for comparison with the TPQ formalism. We have verified, however, that the neglected octupole-order effects do not qualitatively change the behaviour of the system. This is because the outer companion mass is low, and hence the inner orbit does not exhibit large amplitude oscillations.\(^3\)

For the comparison, we do not compare the (constant) \( H_1 \) from the TPQ formalism to the (varying) \( H_1 \) of the correct formalism. Instead, we compare the (varying) \( H_1 \) from the correct formalism (solid red line) with \( G_1 \cos i_{\text{tot}} \) (dashed blue line), which is the vertical angular momentum that would be inferred in our formalism if the outer orbit were instantaneously in the invariable plane, as assumed in the TPQ formalism.

In Fig. 4, the mutual inclination oscillates between 106°7 and 57°5, and thus crosses 90°. These oscillations are mostly due to the oscillations of the outer orbit’s inclination, while \( i_1 \) does not change by more than \( \sim 1° \) in each cycle. Clearly, the outer orbit does not lie in the fixed invariable plane. Fig. 4, bottom panel, shows \( \sqrt{1-e_1^2 \cos i_{\text{tot}}} \), which, in the TPQ limit, is the vertical angular momentum of the inner body.

We can evaluate analytically the error introduced by the application of the TPQ formalism to this situation. We compare the vertical angular momentum (\( H_1 \)) as calculated here to

\(^3\) Unlike the test particle octupole-level approximation (Katz et al. 2011; Lithwick & Naoz 2011), back reaction of the outer orbit may suppress the eccentric Kozai effect. We address this in further detail in Teyssandier et al. (in preparation).
This assumption can be invalid if there are significant magnetic interactions during the quadrupole test particle approximation (Fabrycky & Tremaine 2007; Correia et al. 2011). Nonetheless, a difficulty with this ‘stellar Kozai’ mechanism is that even with the most optimistic assumptions it can only produce $\lesssim 10$ per cent of hot Jupiters (Wu et al. 2007).

Wu & Murray (2003), Wu et al. (2007), Fabrycky & Tremaine (2007) and Correia et al. (2011) studied the evolution of a Jupiter-mass planet in stellar binaries in the TPQ formalism. For example, the case of HD 80606b (Wu & Murray 2003; Fabrycky & Tremaine 2007, fig. 1; Correia et al. 2011, fig. 1) was considered with an outer stellar companion at 1000 au. However, if the companion is assumed to be eccentric $e_M$ is not negligible, and the system is more appropriately described with the test particle octupole-level approximation (e.g. Katz et al. 2011; Lithwick & Naoz 2011). Furthermore, the statistical distribution for closer stellar binaries in Wu et al. (2007) and Fabrycky & Tremaine (2007) is only valid in the approximation where the outer orbit’s eccentricity is zero. In fact, for the systems considered in those studies $e_M$ is not negligible and the octupole-level approximation results in dramatically different behaviour as was shown in Naoz et al. (2012a). The same dramatic difference in behaviour also exists in the analysis of triple stars (e.g. Fabrycky & Tremaine 2007; Perets & Fabrycky 2009), see Section 5.4.

A dramatic difference between the octupole and quadrupole level of approximation is that the former often generates extremely high eccentricities. In real systems, such high eccentricities can be suppressed by tides or general relativity (e.g. Söderhjelm 1984; Eggleton et al. 1998; Kiseleva et al. 1998; Borkovits, Forgács-Dajka & Regály 2004). Flips can also be prevented because they typically occur shortly after extreme eccentricities (see Teyssandier et al., in preparation). In our previous studies that include tides, planetary perturbers typically allow flips to happen, while stellar perturbers mostly suppress them (Naoz et al. 2011, 2012a). But in both cases, tides quantitatively affect the evolution.

Naoz et al. (2011) considered planet–planet–stellar interactions with tidal interactions as a possible source of retrograde hot Jupiters. In this situation $e_M$ is not small, requiring computation of the octupole-level secular dynamics. In Figs 6 and 7 we show the evolution of a representative configuration (see the caption for a full description of the initial conditions). For this configuration, $e_M = 0.083$. Flips of the inner orbit are associated with evolution to very high eccentricity (see Figs 6 and 7).

5.3 Octupole-level Solar system dynamics

Kozai (1962) studied the dynamical evolution of an asteroid due to Jupiter’s secular perturbations. He assumed that Jupiter’s eccentricity is strictly zero. However, Jupiter’s eccentricity is $\sim 0.05$, and thus studying the evolution of a test particle in the asteroid belt ($a_1 \sim 2–3$ au) places the evolution in a regime where the EKL effect could be significant, with $e_M = e = 0.03$ (Katz et al. 2011; Lithwick & Naoz 2011).

We considered the evolution of asteroid at 2 au (assumed to be a test particle) due to Jupiter at 5 au with eccentricity of $e_2 = 0.05$ (see the caption for a full description of the initial conditions). The asteroid is a test particle and therefore $i_2 \approx i_1$. In Fig. 8 we compare the evolution of an asteroid using the TPQ limit (e.g. Kozai 1962; Thomas & Morbidelli 1996; Kinoshita & Nakai 2007) and

![Figure 5. The ratio between the correct, changing $z$-component of the angular momentum, $H_1$, and the TPQ assumption often used in the literature, $H_{1\text{TPQ}} = G_1 \cos i_{\text{tot}}$. This ratio was calculated analytically for various total angular momentum ratios, $G_1/G_2$, and inclinations. The curves, from bottom to top, have $i = 40^\circ$, $50^\circ$, $60^\circ$, $70^\circ$, $80^\circ$ and $89^\circ$.](https://academic.oup.com/mnras/article-abstract/431/3/2155/1069745)
the octupole-level evolution discussed here. For this value of $\epsilon$, the EKL effect significantly alters the evolution of the asteroid, even driving it to such high inclination that the orbit becomes retrograde. Though we deal only with point masses in this work, note that the eccentricity is so high that the inner orbit’s pericentre lies well within the Sun.

The value of $\epsilon$ here is mainly due to the relative high $\alpha$ in the problem (an issue raised in the original work on this problem; Kozai 1962). The system is very packed which raises questions with regards to the validity of the hierarchical approximation. Even in the EKL formalism, such high eccentricities occur that the asteroid collides with the Sun and the apocentre of the asteroid approaches about 1 au from Jupiter’s orbit. To determine the importance of these effects, we ran an $N$-body simulation using the MERCURY software package (Chambers & Migliorini 1997). We used both Bulirsch–Stoer and symplectic integrators (Wisdom & Holman 1991). The results are depicted in Fig. 8, which show that the TPQ limit is indeed inadequate for the system. In addition the octupole-level approximation has some deviations from the direct $N$-body integration, particularly in the high-eccentricity regime. Note that the evolution of the asteroid in the direct integration resulted in a collision with the Sun. In reality, it is likely that a planetary encounter would remove the asteroid from the Solar system before this point.

As shown in Fig. 8, taking into account Jupiter’s eccentricity ($\sim 0.05$), produces a dramatically different evolutionary behaviour, including retrograde orbits for the asteroid. Thomas & Morbidelli (1996) applied the TPQ formalism to the asteroid–Jupiter setting (see for example their fig. 2 for $a_1 = 3$ au). Kinoshita & Nakai
(2007) developed an analytical solution for the TPQ limit (see also Kinoshita & Nakai 1991, 1999).

The TPQ formalism has also been applied to the study of the outer Solar system. Kinoshita & Nakai (2007) applied their analytical solution to Neptune’s outer satellite Laomedia. This system has $\epsilon \rightarrow 0$ and thus the TPQ limit there is justified. In addition, Perets & Naoz (2009) have studied the evolution of binary minor planets using the TPQ approximation. In this problem $\epsilon \rightarrow 0$ and thus the TPQ approximation is valid.

Lidov & Ziglin (1976, sections 3 and 4) also solved analytically the quadrupole-level approximation but, unlike Kinoshita & Nakai (2007), they did not restrict themselves to the TPQ limit, and used the total angular momentum conservation law in order to calculate the inclinations. Thus, their formalism is equivalent to ours at quadrupole order. Later, Maze & Shaham (1979) also derived evolution equations outside the TPQ limit (their equations A1–A8), allowing for small eccentricities and inclinations of the outer body.

5.4 Octupole-level perturbations in triple stars

The evolution of triple stars has been studied by many authors using the standard (TPQ) formalism (e.g. Maze & Shaham 1979; Eggleton et al. 1998; Kiseleva et al. 1998; Mikkola & Tanikawa 1998; Eggleton & Kiseleva-Eggleton 2001; Fabrycky & Tremaine 2007; Perets & Fabrycky 2009). In some cases the corrected formalism derived here can give rise to qualitatively different results. We show that some of the previous studies should be repeated in order to account for the correct dynamical evolution, and give one example where the EKL mechanism dramatically changes the evolution.

Fabrycky & Tremaine (2007) studied the distribution of triple-star properties using Monte Carlo simulations. We choose a particular system from their triple-star suite of simulations to illustrate how the dynamics including the octupole order can be qualitatively different from what would be seen at quadrupole order (see the caption for a full description of the initial conditions). For this system $\epsilon_M = 0.042$ (and $\epsilon = 0.0703$). The evolution of the system is shown in Fig. 9. At octupole order, the inclination of the inner orbit oscillates between about 40° and 140°, often becoming retrograde (relative to the total angular momentum), while the quadrupole-order behaviour is very different and the inner orbit remains always prograde. The octupole-order treatment also gives rise to much higher eccentricities (Krymolowski & Maze 1999; Ford et al. 2000b). In Fig. 10 we compare the octupole-level evolution (of the same system) with direct three-body integration.

The evolution shown in Fig. 9 is for point-mass stars; in reality, these high-eccentricity excursions would actually drive the inner binary to its Roche limit, leading to mass transfer. For these high eccentricities tides will play an important role and thus in reality flips in similar systems may be suppressed. Similarly the high eccentricities often excited through the eccentric Kozai mechanism can also lead to compact object binary merger.

The possibility of forming blue stragglers through secular interactions in triple-star systems has been suggested by Perets & Fabrycky (2009) and Geller, Hurley & Mathieu (2011). As shown in Krymolowski & Maze (1999), Ford et al. (2000b) and in the example above the minimum pericentre distance of the inner binary can differ significantly between the TPQ and EKL formalisms. This suggests that using the correct EKL formalism could significantly increase the computed likelihood of such a formation mechanism for blue stragglers.

For many years CH Cygni was considered to be an interesting triple candidate because it exhibits two clear distinguishable periods of about 40 and 90 a, and $H_0 = 98 m$, with $a_2 = 7 M$ and $H_0 = 0.6 M$. These different periods often excited through the eccentric Kozai mechanism can differ significantly between the TPQ and EKL formalisms. This example above the minimum pericentre distance of the inner binary can also lead to compact object binary merger.

Figure 9. An example of dramatically different evolution between the quadruple and octuple approximations for a triple-star system. The system has $m_1 = 1 M_{\odot}$, $m_2 = 0.25 M_{\odot}$ and $m_3 = 0.6 M_{\odot}$, with $a_1 = 60$ au and $a_3 = 800$ au. We initialize the system with $\epsilon_1 = 0.01$, $\epsilon_2 = 0.6$, $g_1 = g_2 = 0^2$ and $f_{\text{tot}} = 98^\circ$, taken from Fabrycky & Tremaine (2007). For these initial conditions $i_1 = 90.02$ and $i_2 = 7.98$. We show both the (correct) quadruple-level evolution (light-blue lines) and the octuple-level evolution (red lines). $H_1$ and $H_2$, the z-components of the angular momenta of the orbits, are normalized to the total angular momentum. Note that the octuple-level evolution produces periodic transitions from prograde to retrograde inner orbits (relative to the total angular momentum), while at the quadrupole level the inner orbit remains prograde. See Fig. 10 for comparison with direct numerical integration of the three-body system.

Figure 10. The evolution for the first 6 Myr of Fig. 9 where we show a comparison between direct three-body integration (using a B–S integrator), and the octuple-level of approximation. The red lines are from the integration of the octuple-level perturbation equations, while the black lines are from the direct numerical integration of the three-body system.
and $g(2.5,2,1.7)M$ by almost a factor of $a\epsilon_m$ corresponds to inner- and outer-orbit inclinations of 91° and 0.14° (see the caption for a full description of the initial conditions, where $i_N$ is fixed). Note that the masses and orbital parameters used in Kiseleva et al. (1998) and Eggleton & Kiseleva-Eggleton (2001) are out of date. However, a triple system model based on the TPQ Kozai mechanism (Mikkola & Tanikawa 1998) did not reproduce the observed masses of the system (Hinkle et al. 1993; Hinkle, Fekel & Joyce 2009). Applying the corrected formalism in this paper to the system parameters derived in Mikkola & Tanikawa (1998) gives a very different evolution than in the TPQ formalism. Therefore, it seems likely that an analysis based on the formalism discussed in this paper would give a significantly different fit. In Fig. 11 we illustrate the differences between the TPQ, correct quadrupole and octupole evolution of the system. The best-fitting parameters of the system are taken from Mikkola & Tanikawa (1998) where $e_{\text{fit}} = 0.14$ (see the caption for a full description of the initial conditions, where we allowed for a freedom in our choice of $e_\text{fit}, g_1, g_2$ and $\lambda_\text{fit}$ since the best fit was found using the TPQ limit, at which $e_\text{fit}$ is fixed). Note that the choice of the inner eccentricity does not strongly influence the evolution while the choice of the outer orbit’s eccentricity does. Most importantly, the rather large $e_{\text{fit}}$ for this system implies that the system is not stable, i.e. the averaging over the orbits is not justified.

Figure 11. An example of dramatically different evolution between the quadruple and octupole approximations for a triple-star system representing the best-fitting parameters from the Mikkola & Tanikawa (1998) analysis of CH Cygni. The system has $m_1 = 3.51M_\odot$, $m_2 = 0.5M_\odot$ and $m_3 = 0.909M_\odot$, with $a_1 = 0.05$ au and $a_2 = 0.21$ au. We initialize the system with $e_1 = 0.32$, $e_2 = 0.6$, $g_1 = 145^\circ$, $g_2 = 0^\circ$, and $i_\text{fit} = 72^\circ$. For these initial conditions $i_1 = 57.02$ and $i_2 = 14.98$. We show both the (non-TPQ) quadrupole-level evolution (light-blue lines) and the octupole-level evolution (red lines). $H_1$ and $H_2$, the $z$-components of the angular momenta of the orbits, are normalized to the total angular momentum. Note that the octupole-level evolution produces periodic transitions from prograde to retrograde inner orbits (relative to the total angular momentum), while at the quadrupole level the inner orbit remains prograde. To avoid clutter in the figure we have omitted the TPQ result. In the TPQ formalism, the evolution of the inclination and eccentricity is similar to the general quadrupole-level approximation, but $H_{1,2}$ are constant.

Note that the masses and orbital parameters used in Kiseleva et al. (1998) and Eggleton & Kiseleva-Eggleton (2001) are out of date. New observations (e.g. Baron et al. 2012) find the secondary mass to be smaller than the primary and the mutual inclination to be closer to 90°. In Fig. 12 we show the octupole-level evolution of the system considering the new parameters. In the absence of any additional physical mechanism, such as general relativity, tides, mass transfer

Figure 12. The time evolution of an Algol-like system (Eggleton et al. 1998), with $(m_1, m_2, m_3) = (2.5, 2, 1.7)M_\odot$. The inner orbit has $a_1 = 0.095$ au and the outer orbit has $a_2 = 2.777$ au. The initial eccentricities are $e_1 = 0.01$ and $e_2 = 0.23$ and the initial relative inclination $i_{\text{fit}} = 100°$. The $z$-components of the inner and outer orbital angular momentum, $H_1$ and $H_2$, are normalized to the total angular momentum. The initial mutual inclination of $100°$ corresponds to inner- and outer-orbit inclinations of 91.6° and 8.4°, respectively. We consider the (correct) quadrupole-level evolution (blue lines), octupole-level evolution (dashed lines) and also the standard (incorrect) TPQ evolution. In the latter we have assumed, as in previous papers, that $i_{\text{fit}} = i_1$, which results in the discrepancy between the inclination values. See also Fig. 13 for the evolution of the Algol-like system using the updated masses and orbital parameter, following Baron et al. (2012).

From direct integration we found that the system undergoes strong encounters and the inner binary collides in this example. It is also interesting to investigate a system for which the eccentric Kozai mechanism is suppressed due to comparable masses for the inner orbit, and low eccentricity of the outer orbit (i.e. $e_{\text{fit}} \ll 1$). Kiseleva et al. (1998) and Eggleton & Kiseleva-Eggleton (2001) studied the Algol triple system (Lestrade et al. 1993) using the TPQ equations. The TPQ equations were also used in the paper that introduced the influential KCTF mechanism (Mazeh & Shaham 1979; Eggleton et al. 1998). Note that tides dominate the evolution of the Algol system today (e.g. Söderhjelm 2006). Fig. 12 compares the evolution computed in the (incorrect) TPQ formalism, the correct quadrupole formalism and the octupole-level EKL formalism applied to an Algol-like system. The correct quadrupole formalism decreases the minimum value of $1 - e_1$ by almost a factor of 2 relative to the TPQ formalism. The reduced pericentre distance would strongly increase the effects of tidal friction (not included here), which may lead to rapid circularization of the inner orbit. The octupole-level computation decreases the minimum pericentre distance by a further 40 per cent.

Note that the masses and orbital parameters used in Kiseleva et al. (1998) and Eggleton & Kiseleva-Eggleton (2001) are out of date. New observations (e.g. Baron et al. 2012) find the secondary mass to be smaller than the primary and the mutual inclination to be closer to 90°. In Fig. 13 we show the octupole-level evolution of the system considering the new parameters. In the absence of any additional physical mechanism, such as general relativity, tides, mass transfer...
the inner and outer orbits' angular momentum, and thus $i$. The inner orbit has $a_1 = 0.062$ au and the outer orbit has $a_2 = 2.68$ au. The initial eccentricities are $e_1 = 0.001$ and $e_2 = 0.23$ and the initial relative inclination $\iota_{\text{rel}} = 90^\circ$. The initial mutual inclination of 90° corresponds to inner- and outer-orbit inclinations of 86°/4 and 3°/respectively. We consider only the octupole-level evolution. Compare this to the evolution in Fig. 12.

etc., the EKL mechanism could play a very important role in the dynamical evolution of the system.

We note that the inner binary in the Algol system is dominated by tidal effects (Söderhjelm 1975; Kiseleva et al. 1998; Eggleton & Kiseleva-Eggleton 2001) and Figs 12 and 13 do not represent the system today but an Algol-like analogy. We use the Algol parameters here only to show hypothetical outcomes of the correct dynamical evolution. It would be interesting to study stellar evolution including tides in the context of the EKL mechanism, for a system such as Algol.

5.5 The danger of the quadrupole level of approximation

The octupole-level Hamiltonian and equations of motion were previously derived by Harrington (1968, 1969), Sidiichovsky (1983), Marchal (1990), Krymolowski & Mazeh (1999), Ford et al. (2000b), Blaes et al. (2002) and Lee & Peale (2003). Most of the equations of motion can be derived correctly when applying the elimination of the nodes – only the $H_1$ and $H_2$ equations are affected. These authors calculated the time evolution of the inclinations (i.e. $H_1$ and $H_2$) from the total (conserved) angular momentum, and thus avoided the problem that arises when eliminating the nodes from the Hamiltonian. In Appendix B we show the complete set of equations of motion for the octupole-level approximation, derived from a correct Hamiltonian, including the nodal terms.

As displayed here the octupole-level approximation gives rise to a qualitatively different evolutionary behaviour for cases where $\epsilon_m$ (see equation 25) is not negligible. We note that many previous studies applied the quadrupole-level approximation, which may lead to significantly different results (e.g. Mazeh & Shaham 1979; Quinn et al. 1990; Bailey et al. 1992; Innanen et al. 1997; Eggleton et al. 1998; Mikkola & Tanikawa 1998; Eggleton & Kiseleva-Eggleton 2001; Valtonen & Karttunen 2006; Fabrycky & Tremaine 2007; Wu et al. 2007; Zdziarski et al. 2007; Takeda et al. 2008; Perets & Fabrycky 2009). Neglecting the octupole-level approximation can cause changes in the dynamics varying from a few per cent to completely different qualitative behaviour.

Some other derivations of octupole-order equations of motion dealt with the secular dynamics in a general way, without using Hamiltonian perturbation theory or elimination of the nodes (Farago & Laskar 2010; Laskar & Boué 2010; Mardling 2010; Katz & Dong 2011). In these works there were no references to the discrepancy between these derivations and the previous studies. Also, note that the results of Holman, Touma & Tremaine (1997) are based on a direct $N$-body integration, and thus are not subject to the errors mentioned above.

6 CONCLUSIONS

We have shown that the ‘standard’ TPQ Kozai formalism (Kozai 1962; Lidov 1962) has been applied in inappropriate situations. A common error in the implementation of the relevant Hamiltonian mechanics (premature elimination of the nodes) leads to the (incorrect) conclusion that the conservation of the $z$-component of each orbit’s angular momentum from the TPQ dynamics generalizes beyond the TPQ approximation. Correcting the formalism we find that the $z$-components of both the inner and outer orbits’ angular momenta in general change with time at both the quadrupole and octupole level. The conservation of the inner orbit’s $z$-component of the angular momentum (the famous $\sqrt{1 - e_1^2} \cos i = \text{constant}$) only holds in the quadrupole-level test particle approximation. We have explained in details the source of the error in previous derivations (Appendix C).

We have re-derived the secular evolution equations for triple systems using Hamiltonian perturbation theory to the octupole level of approximation (Section 2 and Appendix A, Section 4 and Appendix B). We have also shown that one can use the simplified Hamiltonian found in the literature (e.g. Ford et al. 2000b) as long as the equations of motion for the inclinations are calculated from the total angular momentum.

The correction shown here has important implications to the evolution of triple systems. We discussed a few interesting implications in Section 5. We showed that already at the quadrupole-level approximation the explicit assumption that the vertical angular momentum is constant can lead to erroneous results, see for example Fig. 4. In this figure we showed that far from the test particle limit in the quadrupole level one can already find a significant difference in the evolutionary behaviour. The correct results agree with the test particle limit only when $G_1/G_2 < 10^{-4}$ (see Fig. 5). We show in Appendix A4 that at the quadrupole level of approximation, the inner eccentricity and the mutual inclination have a well-defined maximum and minimum irrespective of the mass of the inner bodies. In the test particle limit these values converge to the well-known critical inclinations (39.2° ≤ $i_0$ ≤ 140.8°) for large oscillatory amplitudes.

The most notable outcome of the results presented here happens in the octupole level of approximation (which we call the EKL formalism), when the inner orbit flips from prograde to retrograde with respect to the total angular momentum. Just before the flip the inner orbit has an excursion of extremely high eccentricity. In the presence of tidal forces (not included in this study) the outcome of a system can be different than the one assumed while using the TPQ formalism. Krymolowski & Mazeh (1999), Ford et al. (2000b), Blaes et al. (2002), Lee & Peale (2003) and Laskar & Boué (2010)
present the correct octupole equations of motion. Had these authors integrated their equations for systems such as those presented in this paper, they could already have discovered the possibility of flipping the inner orbit.

ACKNOWLEDGEMENTS

We thank Boaz Katz, Rosemary Mandling and Eugene Chiang for useful discussions. We thank Staffan Söderhjelm, our referee, for very useful comments that improved the manuscript in great deal. We also thank Keren Sharon and Paul Kiel for comments on the manuscript. APPENDIX A: THE QUADRUPOLE LEVEL OF APPROXIMATION

We develop the complete quadrupole-level secular approximation in this section. As mentioned, the main difference between the derivation shown here and those of previous studies lies in the 'elimination
of nodes’ (e.g. Kozai 1962; Jefferys & Moser 1966), which relates to the transition the invariable plane (e.g. Murray & Dermott 2000) coordinate system, where the total angular momentum lies along the z-axis.

### A1 Transformation to the invariable plane

We choose to work in a coordinate system where the total initial angular momentum of the system lies along the z-axis (see Fig. 2), the x-y plane in this coordinate system is known as the invariable plane (e.g. Murray & Dermott 2000), and therefore we call this coordinate system the invariable coordinate system. We begin by expressing the vectors \( r_1 \) and \( r_2 \) each in a coordinate system where the periastron of the orbit is aligned with the x-axis and the orbit lies in the x-y plane, called the ‘orbital coordinate system’, and then rotating each vector to the invariable coordinate system. The rotation that takes the position vector in the orbital coordinate system to the position in the invariable coordinate system is given by (see Murray & Dermott 2000, chapter 2.8 and fig. 2.14 for more details)

\[
\mathbf{R}_c(\theta) = \begin{pmatrix} \cos \theta & -\sin \theta & 0 \\ \sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{pmatrix}
\]

\[
\mathbf{R}_v(\theta) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta \\ 0 & \sin \theta & \cos \theta \end{pmatrix}.
\]

Thus, the angle between \( r_1 \) and \( r_2 \) is given by

\[
\cos \Phi = \mathbf{r}_{1,\text{orb}}^T \mathbf{R}_c^{-1}(g_2) \mathbf{R}_v^{-1}(i_2) \mathbf{R}_c(h_2) \mathbf{R}_v(i_1) \mathbf{R}_c(g_1) \mathbf{r}_{1,\text{orb}},
\]

where \( \mathbf{r}_{1,\text{orb}} \) is a unit vector that points along \( r_{1,\text{orb}} \). In the orbital coordinate system, we have

\[
\mathbf{r}_{1,\text{orb}} = \begin{pmatrix} \cos(f_1) \\ \sin(f_1) \\ 0 \end{pmatrix}.
\]

where \( f_1(f_2) \) is the true anomaly for the inner (outer) orbit. Note that \( \mathbf{R}_c^{-1}(h_2) \mathbf{R}_c(h_1) = \mathbf{R}_c(\Delta h) \), so the Hamiltonian will depend on the difference in the longitudes of the ascending nodes; in a similar manner, the Hamiltonian depends on \( f_1 \) and \( f_2 \) only through expressions of the form \( f_1 + g_1 \) and \( f_2 + g_2 \). Replacing \( \cos \Phi \) in the Hamiltonian, equation (15), we can now integrate over the mean anomaly angles using the Kepler relations between the mean and true anomalies:

\[
df_i = \frac{1}{\sqrt{1-e_i^2}} \left( \frac{P}{a_i} \right)^2 df_i.
\]

where for the outer orbit one should simply replace the subscript ‘1’ with ‘2’.

### A2 Transformation to eliminate mean motions

Because we are interested in the long-term dynamics of the triple system, we now describe the transformation that eliminates the short-period terms in the Hamiltonian that depend on \( l_1 \) and \( l_2 \). The technique we will use is known as the Von Zeipel transformation (for more details, see Brouwer 1959).

Write the triple system Hamiltonian in equation (15) as

\[
\mathcal{H} = \mathcal{H}_K^1 + \mathcal{H}_K^2 + \mathcal{H}_Z,
\]

where \( \mathcal{H}_K^1 \) and \( \mathcal{H}_K^2 \) are the Kepler Hamiltonians that describe the inner and outer elliptical orbits in the triple system and \( \mathcal{H}_Z \) describes the quadrupole interaction between the orbits. Note that \( \mathcal{H}_Z \) is \( O(\alpha^2) \), and is the only term in \( \mathcal{H} \) that depends on \( l_1 \) or \( l_2 \). We seek a canonical transformation that can eliminate the \( l_1 \) and \( l_2 \) terms from \( \mathcal{H}_Z \). Such a transformation must be close to the identity, since \( \mathcal{H}_Z \ll \mathcal{H} \); let the generating function be

\[
S(L'_j, G'_j, H'_j, l'_j, g'_j, h'_j) = \sum_{j=1}^{2} \left[ L'_j l'_j + G'_j g'_j + H'_j h'_j \right] + \alpha^2 S_2(L'_j, G'_j, H'_j, l'_j, g'_j, h'_j),
\]

where we indicate the new momenta with a superscript asterisk, and \( S_2 \) is the non-identity piece of the transformation that we will use to eliminate \( \mathcal{H}_Z \). The relationship between the new and old canonical variables is

\[
p_i = \frac{\partial S}{\partial q'_i} = p'_i + \alpha^2 \frac{\partial S_2}{\partial q'_i},
\]

and

\[
q'_i = \frac{\partial S}{\partial p'_i} = q_i + \alpha^2 \frac{\partial S_2}{\partial p'_i},
\]

where the momenta \( p_i \in \{L_i, G_i, H_i\} \), and the coordinates \( q_i \in \{l_i, g_i, h_i\} \). Because our generating function is time independent, the new and old Hamiltonians agree when evaluated at the corresponding points in phase space:

\[
\mathcal{H}(q'_i, p'_i) = \mathcal{H}^*(q'_i, p'_i),
\]

when the phase-space coordinates satisfy equations (A9) and (A10). Inserting these relations into the untransformed Hamiltonian, and expanding to lowest order in \( \alpha^2 \), we have

\[
\mathcal{H}(q'_i, p'_i) + \alpha \frac{\partial \mathcal{H}}{\partial q'_i} \frac{\partial S_2}{\partial q'_i} - \alpha^2 \frac{\partial \mathcal{H}}{\partial q'_i} \frac{\partial S}{\partial q'_i} \frac{\partial S_2}{\partial p'_i} = \mathcal{H}^*(q'_i, p'_i).
\]

Equating terms order-by-order in \( \alpha \) gives

\[
\mathcal{H}_K^1(q'_i, p'_i) = \mathcal{H}_K^1(q, p),
\]

and

\[
\mathcal{H}_K^2(q'_i, p'_i) = \mathcal{H}_K^2(q'_i, p'_i),
\]

and

\[
\mathcal{H}_Z(q'_i, p'_i) + \alpha^2 \sum_{i=1}^{2} \frac{\partial \mathcal{H}}{\partial p'_i} \frac{\partial S}{\partial q'_i} \frac{\partial S_2}{\partial q'_i} + \alpha^2 \sum_{i=1}^{2} \frac{\partial \mathcal{H}}{\partial q'_i} \frac{\partial S}{\partial p'_i} \frac{\partial S_2}{\partial p'_i} = \mathcal{H}_Z^*(q'_i, p'_i).
\]

Since the last two terms on the left-hand side of this latter equation are already \( O(\alpha^2) \), only the \( \mathcal{H}_K^1 \) and \( \mathcal{H}_Z^2 \) parts of \( \mathcal{H} \) contribute. These Kepler Hamiltonians only depend on \( L_1 \) and \( L_2 \), so there are only two non-zero partials of \( \mathcal{H} \) at order \( \alpha^2 \):

\[
\mathcal{H}_Z(q'_i, p'_i) + \alpha^2 \frac{\partial \mathcal{H}_K^1}{\partial L_1} \frac{\partial S}{\partial l_1} + \alpha^2 \frac{\partial \mathcal{H}_K^2}{\partial L_2} \frac{\partial S}{\partial l_2} = \mathcal{H}_Z^*(q'_i, p'_i).
\]

We must use the terms that depend on \( S_2 \) to cancel any terms in \( H_1 \) that depend on \( l_1 \) and \( l_2 \). Note that \( \mathcal{H}_Z \) is periodic in
both \( H_1 \) and \( H_2 \) evolve with time because the Hamiltonian is not independent of \( h_1 \) and \( h_2 \). From equation (7), we see that

\[
H_1 = \frac{G_1}{G_{\text{tot}}} \dot{G}_1 - \frac{G_2}{G_{\text{tot}}} \dot{G}_2,
\]

and from equation (11) we see that \( H_1 = -\dot{H}_1 \). The quadrupole-level Hamiltonian does not depend on \( g_2 \); thus the magnitude of the outer orbit’s angular momentum, \( G_2 \), is constant,³ and therefore

\[
H_1 = \frac{G_1 G_i}{G_{\text{tot}}},
\]

From relations (12)–(14) we have \( \dot{H}_1 = \partial H/\partial h_1 \), and \( \dot{G}_1 = \partial H/\partial g_1 \). The former gives

\[
\dot{H}_1 = -30C_2 \varepsilon_1^2 \sin i_2 \sin i_{\text{tot}} \sin(2g_1),
\]

and the latter evaluates to

\[
\dot{G}_1 = -30C_2 \varepsilon_1^2 \sin^2 i_{\text{tot}} \sin(2g_1).
\]

Employing the law of sines, \( G_{\text{tot}}/\sin i_{\text{tot}} = G_1/\sin i_2 = G_2/\sin i_1 \), equation (A26) can also be written as

\[
H_1 = -\frac{G_1}{G_{\text{tot}}} 30C_2 \varepsilon_1^2 \sin^2 i_{\text{tot}} \sin(2g_1),
\]

which satisfies the relation in equation (A25). The evolution of the arguments of periapse are given by

\[
\dot{g}_1 = 6C_2 \left\{ \frac{1}{G_1} \left[ 4 \cos^2 i_{\text{tot}} + (5 \cos(2g_1) - 1) \right] \times (1 - \varepsilon_1^2 - \cos^2 i_2) + \frac{\cos i_{\text{tot}}}{G_2} \left[ 2 + \varepsilon_1^2(3 - 5 \cos(2g_1)) \right] \right\},
\]

and

\[
\dot{g}_2 = 3C_2 \left[ \frac{2 \cos i_{\text{tot}}}{G_1} \left[ 2 + \varepsilon_1^2(3 - 5 \cos(2g_1)) \right] + \frac{1}{G_2} \left[ 4 + 6 \varepsilon_1^2 + (5 \cos^2 i_{\text{tot}} - 3)(2 + \varepsilon_1^2[3 - 5 \cos(2g_1)]) \right] \right].
\]

Previous quadrupole-level calculations that made the substitution error in the Hamiltonian lack the 1/\( G_2 \) terms in these equations. The evolution of the longitudes of ascending nodes is given by

\[
\dot{h}_1 = -\frac{3C_2}{G_1 \sin i_1} \left\{ 2 + 3 \varepsilon_1^2 - 5 \varepsilon_1^2 \cos(2g_1) \right\} \sin(2i_{\text{tot}})
\]

and

\[
\dot{h}_2 = -\frac{3C_2}{G_2 \sin i_2} \left\{ 2 + 3 \varepsilon_1^2 - 5 \varepsilon_1^2 \cos(2g_1) \right\} \sin(2i_{\text{tot}}).
\]

Using the law of sines, \( G_1 \sin i_1 = G_2 \sin i_2 \), from which we get \( h_1 = h_2 \), as required by the relation \( h_1 - h_2 = \pi \). In many systems it is useful to calculate the time evolution of the eccentricity, obtained through the following relation:

\[
\frac{d \varepsilon_j}{dt} = \frac{\partial \varepsilon_j}{\partial G_j} \frac{\partial H}{\partial G_j}.
\]

³ This conserved quantity is lost at higher orders of the approximation; see Section 4 and Appendix B.
In the quadrupole approximation \( \dot{e}_2 = G_2 = 0 \) (which is not the case at higher order in \( e \); see Appendix B). The eccentricity evolution for the inner orbit is given by

\[
\dot{e}_1 = C_2 \frac{1 - e_1^2}{G_1} 30 e_1 \sin^2 i_{\text{tot}} \sin(2g_1).
\]

(A34)

Another useful parameter is the inclination, which can be found through the \( z \)-component of the angular momentum:

\[
\frac{d\cos i_j}{dt} = \frac{H_1 - G_1}{G_1} \cos i_j,
\]

(A35)

and similarly for \( i_2 \) (but note again that \( G_2 = 0 \) to quadrupole order).

A4 Maximum eccentricity and ‘Kozai’ angles in the quadrupole approximation

First note that setting \( \dot{e}_1 = 0 \) also means that \( \dot{G}_1 = 0 \). The values of the argument of periapsis that satisfy these relations are \( g_1 = 0 + \pi n/2 \), where \( n = 0, 1, 2, \ldots \). Also, setting \( G_1(e_{\text{1,max,min}}) = 0 \) means that \( H_1(e_{\text{1,max,min}}) = 0 \) and \( i_1 = 0 \), i.e. an extremum of the eccentricity is also an extremum of both the inner and outer inclinations.

The conservation of the total angular momentum, i.e. \( G_1 + G_2 = G_{\text{tot}} \) sets the relation between the total inclination and inner orbit eccentricity. We re-write equation (6) as

\[
L_2^2(1 - e_2^2) + 2L_1L_2 \sqrt{1 - e_1^2} \sqrt{1 - e_2^2} \cos i_{\text{tot}} = G_{\text{kin}}^2 - G_2^2
\]

(A36)

where in the quadrupole-level approximation \( e_2 \) and \( G_2 \) are constant. The right-hand side of the above equation is set by the initial conditions. In addition, \( L_1 \) and \( L_2 \) (see equations 3 and 4) are also set by the initial conditions. Using the conservation of energy we can write, for the minimum eccentricity case (i.e. setting \( g_1 = 0 \)),

\[
\frac{E}{2C_2} = 3 \cos^2 i_{\text{tot}}(1 - e_1^2) - 1 - 6e_1^2
\]

(A37)

where we also used the relation \( \Delta h = \pi \). We find a similar equation if we set \( g_1 = \pi/2 \):

\[
\frac{E}{2C_2} = 3 \cos^2 i_{\text{tot}}(1 + 4e_1^2) - 1 - 9e_1^2
\]

(A38)

Equations (A36)–(A38) give a simple relation between the total inclination and the inner eccentricity. The remainder of the parameters in the equations are defined by the initial conditions. Thus, using equations (A37) and (A36) we can find the minimum eccentricity reached during the oscillation and using equations (A38) and (A36) we can find also the maximum and the minimum inclinations. The following example illustrates the relation defined by these equations between the inclination and the eccentricity.

For simplicity we set initially \( e_0 = 0 \), \( g_1 = 0 \) and \( e_0 = 0 \) (the superscript 0 stand for initial values). In this appendix we consider only the quadrupole-level approximation, and thus \( e_2 \) does not change. Using these initial conditions (and for some initial mutual inclination \( i_0 \)) we can write equation (A36) as

\[
\sqrt{1 - e_1^2} \cos i_{\text{tot}} = \cos i_0 + \frac{L_1}{L_2} e_1^2.
\]

(A39)

We show these curves for different \( i_0 \) in Fig. A1 (short dashed curves) for a hypothetical system with the parameters of an Algol-like system (but with \( e_2 = 0 \), see Section 5.4). Note that there is a slight asymmetry between the prograde and retrograde orbits due to the \( L_1/L_2 \) factor (which is not the case for the test particle case; see

Figure A1. The total inclination and eccentricity relation for an Algol-like system. We show constant energy curves (solid curves, equation A40) and constant total angular momentum curves (dashed curves, equation A39). The initial conditions considered here are \( e_0 = 0 \), \( g_0 = 0 \) and \( L_1/L_2 = 0.07 \), appropriate for the Algol system (see Section 5.4). We consider four different initial inclinations and their symmetric 90° counterparts, from bottom to top 10°, 30°, 60° and 90°. We also show an example (highlighted curve) for the system which is a result of integration of the quadrupole-level approximation equations.

Katz et al. 2011; Lithwick & Naoz 2011). Similar analysis for the Algol system was done in Söderhjelm (2006, fig. 1). We also write equations (A37) and (A38) using the initial conditions. Equation (A37) can be simplified to

\[
(1 - e_1^2) \cos^2 i_{\text{tot}} = \cos^2 i_0 - 2e_1^2,
\]

(A40)

depicted in Fig. A1 (solid curves, for different \( i_0 \)). As can be seen from the figure, this equation gives the minimum eccentricity, which is the crossing point with equation (A39). For these choice of initial conditions the minimum eccentricity is \( e_1^0 = 0 \). Equation (A38) becomes

\[
(1 + 4e_1^2) \cos^2 i_{\text{tot}} = \cos^2 i_0 + 3e_1^2
\]

(A41)

which is depicted in Fig. A1 (long dashed curves, for \( i_0 = 80° \) and 100°). We now use this equation and equation (A39) to find the maximum eccentricity. After some algebra we find

\[
\left( \frac{L_1}{L_2} \right)^2 e_1^2 + \left( 3 + \frac{L_1}{L_2} \cos i_0 + \left( \frac{L_1}{2L_2} \right)^2 \right) e_1^2
\]

\[
+ \frac{L_1}{L_2} \cos i_0 - 3 + 5 \cos^2 i_0 = 0.
\]

(A42)

As we approach the TPQ limit, \( L_2 \gg L_1 \), and this equation becomes

\[
e_1^2 = 1 - \frac{5}{3} \cos^2 i_0,
\]

(A43)

which gives the maximum eccentricity as a function of mutual initial inclination with zero initial inner eccentricity. In Fig. A1 we show that this approximation still holds fairly well even for an Algol-like system, where \( L_1/L_2 \sim 0.07 \). Equation (A43) has been found previously (e.g. Innanen et al. 1997; Kinoshita & Nakai 1999;
Valtonen & Karttunen 2006) in the TPQ approximation, but in these works it is assumed valid outside that limit. A solution exists only if the right-hand side of this equation is positive, thus we find the critical angles for large Kozai oscillation in the TPQ limit:

\[39.2 \leq \theta_0 \leq 140.8^\circ.\]  
(A44)

For larger \(L_1/L_2\) and/or for initial \(e_1 > 0\) this limit and \(e_{\text{max}}\) are different and the full solution of equations (A36)–(A38) is required. In fact for each initial set of \(e_1 > 0\) and \(i_{01}\), there is a specific \(L_1/L_2\) that will produce an angular momentum curve that crosses 90°. Thus, for initial \(g_1 > 90^\circ\) the mutual inclination can oscillate from value below 90° to above. This happens because the inclination of the outer orbit \(i_2\) changes considerably, while the inner orbit retains its prograde or retrograde orientation.

**APPENDIX B: THE FULL OCTUPOLE-ORDER EQUATIONS OF MOTION**

We define

\[C_3 = -\frac{15}{16} \frac{k^3}{(m_1 + m_2)^9} m_1^0 (m_1 - m_2)^2 G_1^6 \left( \frac{m_1}{m_2} \right)^3 L_1^6 G_2^6.\]  
(B1)

Note that this definition differs in sign from Ford et al. (2000b), and is consistent with Blaes et al. (2002) and Ford, Kozinsky & Rasio (2004). For \(m_1 = m_2\) this factor is zero. We also define

\[A = 4 + 3\epsilon_1^2 = \frac{5}{2} B \sin i_{01},\]  
(B2)

where

\[B = 2 + 5\epsilon_1^2 - 7\epsilon_2^2 \cos(2g_1),\]  
(B3)

and

\[\cos \phi = -\cos g_1 \cos g_2 - \cos i_{01} \sin g_1 \sin g_2.\]  
(B4)

As mentioned in Section 4 the evolution equations for \(e_2, g_2, i_1\) and \(\epsilon_1\) can be found correctly from a Hamiltonian that has had \(h_1\) and \(h_2\) eliminated by the relation \(h_1 = -h_2 = \pi\); the partial derivatives with respect to the other coordinates and momenta are not affected by the substitution. The time evolution of \(H_1\) and \(H_2\) (and thus \(i_1\) and \(i_2\)) can be derived from the total angular momentum conservation. Thus it is useful to write the much simpler the doubly averaged Hamiltonian after eliminating the nodes:

\[\mathcal{H}(\Delta h \to \pi) = C_3 \left\{ (2 + 3\epsilon_1^2) (3 \cos^2 i_{01} - 1) \right.\]
\[+ 15\epsilon_1^2 \sin^2 i_{01} \cos(2g_1) \} \]
\[+ C_3 e_1 e_2 \left\{ A \cos \phi \right.\]
\[+ 10 \cos i_{01} \sin^2 i_{01} (1 - \epsilon_1^2) \sin g_1 \sin g_2 \} \right\}.\]  
(B5)

The time evolution of the argument of periapse for the inner and outer orbits are given by

\[\dot{g}_1 = 6C_2 \left\{ \frac{1}{G_1} \right\} \frac{1}{4 \cos^2 i_{01} + (5 \cos(2g_1) - 1)} \]
\[\times (1 - \epsilon_1^2 - \cos^2 i_{01}) + \frac{\cos i_{01}}{G_2} \left\{ 2 + \epsilon_1^2 (3 - 5 \cos(2g_1)) \} \right\} \]
\[+ C_3 e_1 \left\{ \left( \frac{1}{G_2} + \frac{\cos i_{01}}{G_1} \right) \right.\]
\[\times \{ \sin g_1 \sin g_2 (10(3 \cos^2 i_{01} - 1)(1 - \epsilon_1^2) + A) \right\}\]  
(B6)

and

\[g_2 = 3C_2 \left\{ \frac{2 \cos i_{01}}{G_1} \right\} (2 + 3\epsilon_1^2 (3 - 5 \cos(2g_1))) \]
\[+ \frac{1}{G_2} \left\{ 4 + 6\epsilon_1^2 + (5 \cos^2 i_{01} - 3)(2 + \epsilon_1^2 (3 - 5 \cos(2g_1)) \}\right\} \]
\[+ C_3 e_1 \left\{ \sin g_1 \sin g_2 \left( 4 \epsilon_1^2 + 1 \right) \frac{\cos i_{01} \sin^2 i_{01} (1 - \epsilon_1^2) }{e_2 G_2} \right\} \]
\[+ \cos \phi \left\{ 5B \cos i_{01} e_2 \left( \frac{1}{G_1} + \frac{\cos i_{01}}{G_2} \right) + \frac{4 \epsilon_1^2 + 1}{e_2 G_2} A \right\}.\]  
(B7)

The time evolution of the longitude of ascending nodes is given by

\[h_1 = \frac{-3C_2}{G_1 \sin i_1} \left( 2 + 3\epsilon_1^2 - 5\epsilon_1^2 \cos(2g_1) \right) \sin(2i_{01}) \]
\[+ C_3 e_1 e_2 \left( 5B \cos i_{01} \cos \phi \right) \]
\[- A \sin g_1 \sin g_2 + 10(1 - 3 \cos^2 i_{01}) \]
\[\times (1 - \epsilon_1^2) \sin g_1 \sin g_2 \frac{\sin i_{01}}{G_1 \sin i_1},\]  
(B8)

where in the last part we have used again the law of sines for which \(\sin i_1 = G_2 \sin i_{01}/G_{01}\). The evolution of the longitude of ascending nodes for the outer orbit can be easily obtained using

\[h_2 = h_1.\]  
(B9)

The evolution of the eccentricities is

\[e_1 = C_2 \frac{1 - \epsilon_1^2}{G_1} \left\{ 30 \epsilon_1^2 \sin^2 i_{01} \sin(2g_1) \right\} \]
\[+ C_3 e_2 \frac{1 - \epsilon_2^2}{G_1} \left\{ 35 \cos \phi \sin^2 i_{01} \sin(2g_1) \right\} \]
\[- 10 \cos i_{01} \sin^2 i_{01} \sin g_1 \sin g_2 (1 - \epsilon_1^2) \]
\[- A(\sin g_1 \cos g_2 - \cos i_{01} \cos g_1 \sin g_1) \sin g_1 \sin g_2 \right\} \]  
(B10)

and

\[e_2 = -C_3 e_1 \frac{1 - \epsilon_1^2}{G_2} \left\{ 10 \cos i_{01} \sin^2 (i_{01}) (1 - \epsilon_1^2) \sin g_1 \cos g_2 \right\} \]
\[+ A(\cos g_1 \sin g_2 - \cos(i_{01}) \sin g_1 \cos g_1) \right\}.\]  
(B11)

We also write the angular momenta derivatives as a function of time; for the inner orbit

\[G_1 = -C_3 30 \epsilon_1^2 \sin(2g_1) \sin^2(i_{01}) + C_3 e_1 e_2 \left\{ \right\]  
\[\left. -35 \epsilon_1^2 \sin^2(i_{01}) \sin(2g_1) \cos \phi + A(\sin g_1 \cos g_2 - \cos i_{01} \cos g_1 \sin g_1) \right\}. \]  
(B12)
and for the outer orbit (where the quadrupole term is zero)

\[ G_2 = C_3 e_1 e_2 \left[ A \cos g_1 \sin g_2 - \cos(i_{tot}) \sin g_1 \cos g_2 \right] + 10 \cos(i_{tot}) \sin^2(i_{tot}) [1 - e_1^2] \sin g_1 \cos g_2. \]  

(B13)

Also,

\[ H_1 = \frac{G_1}{G_{tot}} \hat{G}_1 - \frac{G_2}{G_{tot}} \hat{G}_2, \]  

(B14)

where using the law of sines we write

\[ H_1 = \frac{\sin i_1}{\sin i_{tot}} \hat{G}_1 - \frac{\sin i_2}{\sin i_{tot}} \hat{G}_2. \]  

(B15)

The inclinations evolve according to

\[ (\cos i_1) = \frac{H_1}{G_1} - \frac{\hat{G}_1}{G_1} \cos i_1 \]  

(B16)

and

\[ (\cos i_2) = \frac{H_2}{G_2} - \frac{\hat{G}_2}{G_2} \cos i_2. \]  

(B17)

Our equations are equivalent to those of Ford et al. (2000b), but we give the evolution equations for \( H_1 \) and \( H_2 \) (and \( i_1 \) and \( i_2 \)).

APPENDIX C: ELIMINATION OF THE NODES AND THE PROBLEM IN PREVIOUS QUADRUPOLE-LEVEL TREATMENTS

Since the total angular momentum is conserved, the ascending nodes relative to the invariant plane follow a simple relation, \( h_1(t) = h_2(t) = \pi \). If one inserts this relation into the Hamiltonian, which only depends on \( h_1 \) and \( h_2 \), the resulting ‘simplified’ Hamiltonian is independent of \( h_1 \) and \( h_2 \). One might be tempted to conclude that the conjugate momenta \( H_1 \) and \( H_2 \) are constants of the motion. However, that conclusion is false. This incorrect argument has been made by a number of authors.\(^9\)

In general, using dynamical information about the system – in this case that angular momentum is conserved, implying that \( G_1 + G_2 = G_{tot} \) at all times and therefore \( h_1 = h_2 = \pi \) – to simplify the Hamiltonian is not correct. The derivation of Hamilton’s equations relies on the possibility of making arbitrary variations of the system’s trajectory, and such simplifications restrict the allowed variations to those which respect the dynamical constraints. Once Hamilton’s equations are employed to derive equations of motion for the system, however, dynamical information can be employed to simplify these equations.

In our particular case, equations of motion for components of the system that do not involve partial derivatives with respect to \( h_1 \) or \( h_2 \) will not be affected by the node-elimination substitution. For this reason, it is correct to derive equations of motion for all components except for \( H_1 \) and \( H_2 \) from the node-eliminated Hamiltonian; expressions for \( H_1 \) and \( H_2 \) can then be derived from conservation of angular momentum. This approach has been employed in at least one computer code for octupole evolution, though the discussion in the corresponding paper incorrectly eliminates the nodes in the Hamiltonian (Ford et al. 2000b).

In some later studies, (Sidlichovsky 1983; Innanen et al. 1997; Eggleton et al. 1998; Kiseleva et al. 1998; Mikkola & Tanikawa 1998; Kinoshita & Nakai 1999; Eggleton & Kiseleva-Eggleton 2001; Wu & Murray 2003; Valtonen & Karttunen 2006; Fabrycky & Tremaine 2007; Wu et al. 2007; Zdziarski et al. 2007; Perets & Fabrycky 2009), the assumption that \( H_1 = const \) (i.e. the TPQ approximation) was built into the calculations of quadrupole-level secular evolution for various astrophysical systems, even when the condition \( G_2 \gg G_1 \) was not satisfied. Moreover many previous studies simply set \( i_2 = 0 \). This is equivalent to the TPQ approximation; for non-test-particles, given the mutual inclination \( i \), the inner and outer inclinations \( i_1 \) and \( i_2 \) are set by the conservation of total angular momentum (see equations 9 and 10).

\(^9\) For example, Kozai (1962, p. 592) incorrectly argues that ‘as the Hamiltonian \( F \) depends on \( h \) and \( h \)’ as a combination \( h - h \), the variables \( h \) and \( h \) can be eliminated from \( F \) by the relation (5). Therefore, \( H \) and \( H \) are constant’.
