Photocatalytic redox-neutral hydroxyalkylation of \(N\)-heteroaromatics with aldehydes†

Hiromu Fuse, a Hiroyasu Nakao, a Yutaka Saga, b Arisa Fukatsu, c Mio Kondo, d,b Shigeyuki Masaoka, d,b Harunobu Mitsunuma b and Motomu Kanai a,b

Hydroxyalkylation of \(N\)-heteroaromatics with aldehydes was achieved using a binary hybrid catalyst system comprising an acridinium photoredox catalyst and a thiophosphoric acid organocatalyst. The reaction proceeded through the following sequence: (1) photoredox-catalyzed single-electron oxidation of a thiophosphoric acid catalyst to generate a thyl radical, (2) cleavage of the formyl C–H bond of the aldehyde substrates by a thyl radical acting as a hydrogen atom transfer catalyst to generate acyl radicals, (3) Minisci-type addition of the resulting acyl radicals to \(N\)-heteroaromatics, and (4) a spin-center shift, photoredox-catalyzed single-electron reduction, and protonation to produce secondary alcohol products. This metal-free hybrid catalysis proceeded under mild conditions for a wide range of substrates, including isoquinolines, quinolines, and pyridines as \(N\)-heteroaromatics, as well as both aromatic and aliphatic aldehydes, and tolerated various functional groups. The reaction was applicable to late-stage derivatization of drugs and their leads.

An alternative pathway to hydroxyalkylated \(N\)-heteroaromatics is an oxidative Minisci reaction (Fig. 1A(b)).† Due to the inertness of the \(\alpha\)-oxy C–H bond of alcohols, however, this process requires a strong oxidant and large excess of alcohols resulting in low generality. On the other hand, Melchiorre recently reported the photochemical hydroxyalkylation of quinolines and isoquinolines by a novel spin-center shift (SCS) process (Fig. 1A(c)).† Although the reaction proceeded under mild conditions, the acyl radical sources, 4-acyl-1,4-dihydropyridines, were prepared from the corresponding ketoaldehydes under harsh conditions (i.e. heating neat at 120–130 °C). This limited substrate generality of hydroxyalkyl groups made the overall process less atom economical. Herein, we report a new catalytic method for synthesizing hydroxyalkylated \(N\)-heteroaromatics through a Minisci-type reaction between \(N\)-heteroaromatics and aldehydes, mediated by a hybrid catalyst system comprising an acridinium photoredox catalyst and a thiophosphoric acid (TPA) organo-hydrogen atom transfer (HAT) catalyst (Fig. 1B).† Notably, this reaction proceeded under redox-neutral conditions with high atom economy. This is in contrast to previously reported Minisci reactions between \(N\)-heteroaromatics and aldehydes, which required stoichiometric strong oxidants and produced acylated products.†

Results and discussion

Optimization of reaction conditions

Because the bond dissociation energy of a formyl C–H bond of aldehydes (88.7 kcal mol\(^{-1}\)) is much smaller than that of...
a C(sp²)–H bond of N-heteroaromatics (105 kcal mol⁻¹), we planned to incorporate a SCS process in the overall catalytic cycle to produce alcohol products (see below). There are preceding examples in which the SCS process was combined with the photoredox-catalyzed Minisci-type reaction of N-heteroaromatics. In these examples, formal alkylation of N-heteroaromatics were achieved using alcohols, ethers, or carbonyl compounds as an alkyl source. Specifically, MacMillan and Huang achieved the incorporation of HAT and SCS processes. Despite the versatile roles of hydroxy groups in organic synthesis, however, they were eliminated under their reaction conditions. Moreover, their mechanistic studies implied that hydroxyalkylated N-heteroaromatics were unstable under their reaction conditions.

Our working hypothesis for the catalytic cycle is shown in Fig. 2. A photoredox catalyst Mes-Acr⁺ in the excited state (*Mes-Acr⁺) oxidizes an organocatalyst (RSH) to produce a radical (RS⁺) acting as a HAT catalyst. This radical cleaves the formyl C–H bond of aldehyde 2. The resulting acyl radical 4 reacts with protonated N-heteroaromatics 5 through a Minisci reaction, giving radical cation 6. Deprotonation of 6 affords benzylic carbon-centered radical 7, which is converted to the α-oxo radical 8 via SCS. Finally, 8 is reduced by the reduced photoredox catalyst (Mes-Acr⁻), and the subsequent protonation affords target compound 3. On the basis of our previous findings, we envisioned that the combination of an acridinium photoredox catalyst (Mes-Acr⁺) and TPA organocatalyst would realize the designed hybrid catalysis.

We conducted optimization studies using isoquinoline (1a) and benzaldehyde (2a) (Table 1). Despite several possible side reactions such as reductive deoxygenation of 3a and reduction of 2a, we identified the optimized reaction conditions comprising 5 mol% Mes-Acr⁺ photoredox catalyst and 10 mol% TPA organocatalyst in the presence of 2 equiv. TFA, affording 3a in 94% yield (entry 1). Other organocatalysts for HAT, such as thiols, quinuclidine, and benzoic acid did not afford the product (entries 2–5). Control experiments revealed that Mes-Acr⁺, TPA, TFA, and visible light irradiation were indispensable for efficient reaction progress (entries 6–9). The addition of 1 equiv. TEMPO inhibited the reaction (entry 10), indicating the presence of radical intermediates.

**Substrate scope**

Under the optimized conditions, we investigated the substrate scope (Fig. 3). We first studied the aldehyde side (3a–l) using isoquinoline (1a) as an N-heteroaromatic substrate. Aromatic aldehydes containing various functional groups such as halogen (3b–d), ether (3e), trifluoromethyl (3f), and alkyl (3g) groups tolerated the reaction conditions. The electron density of the aromatic ring did not significantly affect the results. Moreover, steric hindrance at the ortho-position of the phenyl ring of aldehydes did not interfere with the reaction (3g). Aliphatic aldehydes, which are challenging substrates due to the presence of acidic α-C–H bonds and low electrophilicity, were a competent class of substrates in this reaction (3h–l). As a result, several hydroxy-alkylated isoquinolines containing...
ester (3i), phthalimide (3j), ketone (3k), and halogen (3l) groups were obtained in high yield. We then examined the scope of N-heteroaromatics. Various brominated isoquinolines exhibited good reactivity (3m–p). The reactions of isoquinolines containing amide (3q) and ester (3r) groups proceeded in good yield. This catalyst system was also applicable to the hydroxyalkylation of quinolines (3s–z). Quinolines containing ester (3u), halogen (3v–x), ether (3y), and phenyl (3z) groups were competent substrates. Moreover, pyridine derivatives were successfully converted to the corresponding products (3aa–ad). Ketone and ester functionalities were tolerated. Steric hindrance did not interrupt reaction progress and substituted pyridines were synthesized (3ab–ac).

Furthermore, this reaction was applicable to late-stage modifications of complex molecules because of the mild conditions (Fig. 4). Thus, camptothecin, which has anti-cancer activity, was transformed to the corresponding C7-hydroxyalkylated derivative (3ae). Introduction of functional groups to the C7-position of camptothecin could improve its pharmacological properties.1 A fasudil (ROCK2 inhibitor) derivative also reacted with propionaldehyde with excellent yield (3af). Functionalized hydroxyalkyl groups, which were

a General reaction conditions: 1a (0.10 mmol), 2a (0.20 mmol), Mes-Acr+ (0.005 mmol), TPA (0.010 mmol), and TFA (0.20 mmol) were reacted in dichloromethane (DCM; 2.0 mL) at room temperature under blue LED irradiation for 7 h. b Yield was determined by 1H NMR analysis of the crude mixture using 1,1,2,2-tetrachloroethane as an internal standard. c Isolated yield in parentheses. d Without Mes-Acr+. e Without TFA. f Without photoirradiation. g 1 equiv. TEMPO was added.

Fig. 3 Substrate scope. a General reaction conditions: 1a (0.10 mmol), 2a (0.20 mmol), Mes-Acr+ (0.005 mmol), TPA (0.010 mmol), and TFA (0.20 mmol) were reacted in dichloromethane (DCM; 2.0 mL) at room temperature under blue LED irradiation for 7 h. Yield is isolated yield unless otherwise noted. b 5 equiv. of the aldehyde was used with the reaction time 13 h. c Reaction time was 3 h. d Reaction time was 5 h.
difficult to use in the previous radical-mediated reactions, were also introduced to N-heterocycles under the present conditions (3ag–3ak). Thus, aldehydes derived from oxaprozin, loxoprofen, dehydrocholic acid, an amino acid derivative, and a sugar derivative afforded the corresponding N-heteroarylated products in good yields. It is noteworthy that substrates containing an oxazole ring which is susceptible to oxidative conditions (3ag) or a relatively weak benzylic C–H bond (3ah) tolerated our reaction conditions.

To gain preliminary insight into the mechanism, reactions were conducted using deuterated compounds (Fig. 5). When benzaldehyde-d (2a-d) was exposed to the reaction conditions, target compound 3a contained 85%-H at the α-position of the hydroxy group (Fig. 5a). Thus, the formyl C–H bond of the aldehyde was cleaved in the overall catalytic cycle. When TFA-d was utilized as an acid additive, however, 62%-H was still incorporated at the α-position (Fig. 5b). This result was contradictory to our hypothesis (Fig. 2), and could be due to contamination by H2O. Therefore, we assessed the H/D ratio incorporated in 3a in mixed solvents containing variable amounts of D2O. As a result, incorporation of D increased up to 95% according to the D2O concentration (Fig. 5b). This result indicates that the hydrogen atom at the α-position of the hydroxy group is introduced via protonation. These deuteration experiments support the feasibility of our mechanistic hypothesis shown in Fig. 2. The quantum yield was determined to be 0.046, which supports that the reaction proceeded through a closed catalytic cycle, not a radical chain pathway (see the ESI† for details).

Conclusions

In conclusion, we developed a binary hybrid catalyst system to achieve a one-step, redox-neutral hydroxyalkylation of N-heteroaromatic compounds with aldehydes without using a metal species. The reaction proceeded under mild conditions and high atom economy, enabling a broad substrate scope and application to late-stage modifications of drug-related molecules. Keys to the success were the sequential HAT, Minisci, and SCS processes. Further mechanistic studies are ongoing in our laboratory.
