Abstract

Human-specific pseudogenization of the CMAH gene eliminated the mammalian sialic acid (Sia) Neu5Gc (generating an excess of its precursor Neu5Ac), thus changing ubiquitous cell surface “self-associated molecular patterns” that modulate innate immunity via engagement of CD33-related-Siglec receptors. The Alu-fusion-mediated loss-of-function of CMAH fixed ~2–3 Ma, possibly contributing to the origins of the genus Homo. The mutation likely altered human self-associated molecular patterns, triggering multiple events, including emergence of human-adapted pathogens with strong preference for Neu5Ac recognition and/or presenting Neu5Ac-containing molecular mimics of human glycans, which can suppress immune responses via CD33-related-Siglec engagement. Human-specific alterations reported in some gene-encoding Sia-sensing proteins suggested a “hotspot” in hominin evolution. The availability of more hominid genomes including those of two extinct hominins now allows full reanalysis and evolutionary timing. Functional changes occur in 8/13 members of the human genomic cluster encoding CD33-related-Siglecs, all predating the human common ancestor. Comparisons with great ape genomes indicate that these changes are unique to hominins. We found no evidence for strong selection after the Human–Neanderthal/Denisovan common ancestor, and these extinct hominin genomes include almost all major changes found in humans, indicating that these changes in hominin sialobiology predate the Neanderthal–human divergence ~0.6 Ma. Multiple changes in this genomic cluster may also explain human-specific expression of CD33rSiglecs in unexpected locations such as amnion, placental trophoblast, pancreatic islets, ovarian fibroblasts, microglia, Natural Killer (NK) cells, and epithelia. Taken together, our data suggest that innate immune interactions with pathogens markedly altered hominin Siglec biology between 0.6 and 2 Ma, potentially affecting human evolution.

Key words: sialic acid, hominin, evolution, CD33rSiglecs, common ancestor, Neanderthal/Denisovan, great apes, archaic hominin.

Introduction

Prior to the mid-1990s, the extreme similarity of human and chimpanzee protein sequences suggested that phenotypic differences were primarily due to differences in gene regulation (King and Wilson 1975). The first definitive exception was a fixed loss-of-function genomic mutation unique to the human lineage, in the gene-encoding CMP-Neu5Ac hydroxylase (CMAH) (Chou et al. 1998), an event mediated by an Alu–Alu fusion (Hayakawa et al. 2001). This mutation eliminated biosynthesis of the common mammalian sialic acid (Sia)
N-glycoly neuraminic acid (Neu5Gc) and caused accumulation of its precursor N-acetyly neuraminic acid (Neu5Ac), radically changing cell surface extracellular glycosylation throughout the body in the hominin lineage. The mutation was dated to >2 Ma by multiple methods (Chou et al. 2002; Hayakawa et al. 2006). Additional examples emerged a few years later, including the forkhead box protein P2 (FOXP2) (Enard et al. 2002, 2009), a myosin heavy chain family member (MYH16) (Currie 2004; Stedman et al. 2004), and examples of gene duplication followed by adaptive evolution (Johnson et al. 2001). Along with biomedical considerations (Varki 2000), such discoveries lead to sequencing of the chimpanzee genome (Chimpanzee Sequencing and Analysis Consortium 2005). There are now many more defined genetic differences between humans and our closest evolutionary cousins, involving not only gene expression (Enard et al. 2002; Fujiyama et al. 2002; Watanabe et al. 2004; Calarco et al. 2007; Kehrer-Sawatzki and Cooper 2007; Cruz-Gordillo et al. 2010; Otto et al. 2014; Atkinson et al. 2018) but also other distinct genomic changes ranging from massive (mega-base) structural variation to differences in gene copy numbers, de novo genes, pseudogenization (O’Brien et al. 2012; Ruiz-Orera et al. 2015), human-accelerated regions in noncoding regions, and microRNA genes (Eddy 2001; Mello and Conte 2004; Kim 2005; Ruiz-Orera et al. 2015).

This study focuses on human genes involved in the biology of sialic acids. All living cells are covered with complex arrays of glycoconjugates, with sialic acids occupying the majority of terminal positions on such glycan chains in animals of the Deuterostome lineage (including echinoderms and vertebrates) (Gagneux et al. 2015). These acidic, nine-carbon backbone amino-sugars play important roles in cell–cell and cell–matrix interactions, as well as in host–pathogen interactions (Varki et al. 2015). The hominin-specific loss-of-function mutation in CMAH mentioned above eliminated biosynthesis of Neu5Gc, which was a target for selective cell recognition by various nonhuman pathogens and toxins (Iwagishima et al. 1989; Martin et al. 2005; Campanero-Rhodes et al. 2007; Deng et al. 2014; Alisson-Silva et al. 2018). It is reasonable to speculate that exogenous pathogen recognition could have initially driven the CMAH loss-of-function, generating a polymorphism as the recessive loss-of-function mutant allele rose in frequency. However, this deletion was then fixed in an ancestral hominin population ~2–3 Ma (Chou et al. 2002), possibly by directional selection against Neu5Gc via female immunity during reproduction, a mechanism demonstrated in vivo using transgenic mice that carry the same mutation in their Cmah gene as humans (Ghaderi et al. 2011). Given the likely timing of these events, we speculated that anti-Neu5Gc immunity of hominin females immunized against Neu5Gc by increased contact with Neu5Gc-rich vertebrate animal prey might have contributed to the origins of the genus Homo ~2 Ma (Wood and Boyle 2016; Bergfeld et al. 2017). Early discovery of some additional human-specific changes affecting sialic acid biology (Brinkman-Van der Linden et al. 2000; Angata, Verki, et al. 2001; Gagneux et al. 2003; Sonnenburg et al. 2004; Hayakawa et al. 2005; Nguyen et al. 2006) and system-wide genomic and biochemical comparisons of sialic acid biology among primates and rodents (Altheide et al. 2006) suggested a possible “hotspot” in human sialic acid evolution (Varki 2009). With the availability of more human genomes (1000 Genomes Project Consortium et al. 2015), a recent study showed the patterns of genetic variation of 55 sialic acid biology-related genes in modern human populations did not significantly deviate from neutral expectations and were in fact not significantly different among genes belonging to different functional categories (Moon et al. 2018).

Sialic acid binding Ig-like lectin (Siglecs) are type I transmembrane proteins with an N-terminal immunoglobulin (lg)-like-V-set domain that mediates sialic acid recognition, and a variable number of lg-like-C-2 type domains (Angata, Hingorani, et al. 2001). Siglecs often have a cytoplasmic tail with one or more immunoreceptor tyrosine-based inhibitory motifs that can suppress immune cell activation. Alternatively, they can recruit adaptor proteins with immunoreceptor tyrosine-based activating motifs. Although Siglecs likely have multiple functions, one prominent role appears to be recognition of endogenous sialylated glycans as self-associated molecular patterns, suppressing reactions of innate immune cells against self (Varki 2011). Activating Siglecs have a positively charged arginine or lysine in their transmembrane domains that can recruit DAP12 and activate cellular immune responses against pathogens mimicking endogenous sialic acids (Schwarz et al. 2017). CD33-related Siglecs are rapidly evolving and among this family, nine inhibitory (hSiglec-3 and hSiglec-5 to hSiglec-12) and two activating members (hSiglec-14 and hSiglec-16) have been characterized in humans. Recently, an article published from our group showed variable presence or absence of functional changes in the CD33rSIGLEC cluster in 26 mammalian species including great apes (Khan et al. 2020).

With the availability of genomes from both living great apes (Prado-Martinez et al. 2013; Xue et al. 2015; Kronenberg et al. 2018) and extinct archaic hominins (Reich et al. 2010; Meyer et al. 2012; Pruefer et al. 2014), we now systematically reassess the previous discoveries from multiple groups and also report on several new findings. Overall, we find that multiple complex changes in genes involving sialic acid biology beyond the initial CMAH mutation did indeed occur but are mostly confined to the CD33rSIGLEC gene cluster on chromosome 19 (Angata, Hingorani, et al. 2001), encoding CD33rSiglecs, prominent on innate immune cells (Varki and Angata 2006).

Overall, we found that multiple changes in the CD33rSIGLEC gene cluster are common in all human populations, postdate the common ancestor with the chimpanzee/
bonobo lineage, but predate the common ancestor with Neanderthals and Denisovans. Such multiple complex changes in this gene cluster appear to be associated with altered expression of these genes, not just confined to innate immune cells, but also in other unexpected human cell types, some associated with diseases that appear to be uniquely human.

**Materials and Methods**

**Genome Assembly and Identification of Variants across Humans and Great Apes**

The great ape genome data (total number 147) for *CMAH* and *CD33rSIGLEC* were derived from three publications (Prado-Martínez et al. 2013; Xue et al. 2015; de Manuel et al. 2016; Kronenberg et al. 2018). These great ape genomes were mapped to human reference genome (GRCh37/hg19) retrieved from UCSC genome browser, using Burrows–Wheeler aligner and further processed with Picard tool to remove duplicates and variant were called using Genome-analysis toolkit. Moreover, the variants in variant call format of chimpanzee, bonobos, gorilla, and orangutan were visualized in integrative genome viewer with their respective reference genome (PanTro4, Gorgor3, and PonAbe2) and annotation file. All archaic hominins raw and processed files were obtained from the Max Planck Institute for Evolutionary Anthropology (Reich et al. 2010; Castellano et al. 2014; Prüfer et al. 2014; Slon et al. 2018) (http://cdna.eva.mpg.de/neandertal). Bed coordinates of *SIGLEC* and *CMAH* genes were provided for each human and ape lineage as supplemental (chimpanzee, bonobos, gorilla, and orangutan) (supplementary file 1, Supplementary Material online). Additionally, bed coordinates of additional polymorphism present in *CD33rSIGLEC* with allele frequency in great ape population were also provided as supplemental (supplementary file 2, Supplementary Material online).

**Inference of Strong Archaic Natural Selection**

The genes involved in sialic acid biology (67 genes) were overlapped with regions displaying signatures of ancient selective sweeps (Peyrégne et al. 2017). The method used to identify these signatures of archaic selection relies on a hidden Markov model to detect extended regions in the genome where the Neanderthal and Denisovan lineages fall outside the human variation (Meyer et al. 2012; Prüfer et al. 2014). This method can only detect events that occurred between the split of modern and archaic humans around 0.5 Ma (Prüfer et al. 2017) and the split of modern human populations from each other around 0.2 Ma (Schiffels and Durbin 2014). For events with a selective advantage of 0.5% or larger, with an origin of the beneficial mutation as old as 600,000 years ago, the false positive rate of the method is lower than 0.1% and its true positive rate is larger than 65% (Peyrégne et al. 2017). We also note that signals of positive selection are not detectable if the selection coefficient is smaller than 0.1%. The Ensembl database (release 82) (Aken et al. 2016) was used to annotate each gene with hg19 coordinates from transcription start to transcription end. Furthermore, *L1CAM, PECAM, CMAH, SIGLEC13, SIGLEC16,* and *SIGLEC17* were excluded because they fall either in filtered regions not considered for the ancient sweep screen or could not be mapped to hg19 coordinates. As regulatory regions may also have been the target of positive selection, we extended the start and end coordinates 1 Mb upstream and downstream, respectively. If a neighboring gene was within 1 Mb, we only extended the coordinates until 5 or 1 kb from the transcription start or end of this neighboring gene. In order to test whether the lack of signatures of ancient selection is statistically significant, the candidate regions of ancient selection were randomly placed in the genome and the random placements of all regions were iterated 1,000 times, counting how often no overlap with genes involved in sialic acid biology was detected. The depletion in selection is not significant (356 sets never overlap; P value = 0.356).

**Immunohistochemistry of Siglecs**

Paraffin sections were deparaffinized in xylene and rehydrated in decreasing concentrations of ethanol and Tris-buffered saline–Tween (TBST). Following this, endogenous binding sites and peroxidases were blocked with 1% bovine serum albumin/TBST and 0.3% H2O2/TBST. This was followed by blocking of endogenous biotin and then heat-induced antigen retrieval was performed in citrate buffer pH 6. Primary antibodies (mouse anti-Siglec-7 and Rabbit anti-Siglec-13) or mouse IgG were then overlaid at optimal dilutions, and slides were incubated overnight at 4°C in a humid chamber. Specific binding was detected using a biotinylated antimouse or anti-rabbit (for Siglec-13), followed by Horseradish Peroxidase (HRP) streptavidin and then biotinyl tyramide enhancement and then HRP streptavidin. Substrate color was developed, and nuclei were counterstained with hematoxylin and the slides were aqueous mounted for viewing and digital photomicroscopy using an Olympus BH2 microscope with an Olympus magnifire camera.

**Results**

Multiple Derived, Fixed, or Polymorphic Genomic SIGLEC Variants Are Present in All Modern Human Populations

Table 1 summarizes events and frequencies in human populations based on the 1000 Genomes Project data and compares these with archaic hominin and great ape genomes. All human genomic changes in *CD33*-related *SIGLEC* (affecting 8 out of 13 members of this class of genes) were present across modern human populations. Genome-wide

Hominin SIGLEC Biology and Innate Immunity
the mutations observed in human populations. Instead, we only observed independent changes in critical arginine residues in V-set domain of SIGLEC5/14, rendering them unable to recognize sialic acids (table 1). Although the essential arginine change (Arg -> His) in SIGLEC5 was found to be polymorphic in chimpanzee and gorilla, sequences in orangutan were not recognized due to low mappability. The SIGLEC14 essential arginine change (Arg -> His) was found to be polymorphic in chimpanzee, bonobo, and gorilla. However, sequences of SIGLEC14 in orangutan were not determined in most of the species due to low coverage, except for one that harbors an essential arginine change to tyrosine (Arg -> Tyr). The CMAH gene is functional in all great apes as expected, given that both types of sialic acids (Neu5Ac and Neu5Gc) are present in all these species (Muchmore et al. 1998). Overall, human genomes harbored a far greater number of structural/functional changes in CD33rSIGLEC genes (see fig. 1 and supplementary file 2, Supplementary Material online).

Most Human Lineage-Specific Mutations Are Also Found in Archaic Hominin Genomes

To further understand the timing of these human genomic changes of these human genomic variants, we looked for their presence in archaic human genomes, that is,
Neanderthal and Denisovan. The exon deletion leading to loss-of-function of the \textit{CMAH} gene is shared by these two archaic genomes, as expected based on the existing estimates of fixation of the mutation over 2 Ma (Hayakawa et al. 2001). Notably, almost all other human \textit{CD33rSIGLECs} variants (except for \textit{CD33} linked variants protective against late onset Alzheimer’s disease) were also present in these archaic hominin genomes in variable frequency (listed in table 1 and fig. 1) placing their origin before the human–Neanderthal common ancestor \((/C240.6 \text{ Ma})\) (Prufer et al. 2017; Hajdinjak et al. 2018). Due to unavailability of well annotated sequences, the \textit{SIGLEC14} fusion/deletion could not be determined in archaic hominins.

Lack of Evidence for Strong Selection up to 500,000 Years Ago

The presence of all genomic \textit{SIGLEC} changes in human populations indicates that they predate the common ancestor of modern humans \(\sim0.2–0.3 \text{ Ma}\) (Hublin et al. 2017). Consistent with this observation, the recent article by Moon et al. (2018) found that the patterns of genetic variation of most \textit{CD33rSIGLEC} genes did not significantly deviate from neutral expectations, and the few that did significantly deviate from neutrality experienced either soft sweeps or population-specific hard sweeps (Moon et al. 2018). Using a method that allows detection of selection in deeper time \((/C240.5 \text{ Ma})\) (Peyregne et al. 2017), we also found no evidence of strong selection after the ancestors of modern and archaic humans (Neanderthal–Denisovan) split from each other around 500,000 years ago. As selection may also target neighboring regulatory regions, we defined regulatory domains around each gene and looked for overlaps with candidate sweep regions. Using these extended gene coordinates, we again found no overlap with candidate regions for selective sweeps, suggesting that none of the genes involved in sialic acid biology exhibits strong signatures of selection more recently than 0.5 Myr in the common ancestral population of all modern humans. The description of extended lineage sorting (ELS) is provided in figure 2.

Human-Specific Expression of \textit{CD33rSiglec}s in Nonimmune Tissues

In addition to these multiple, polymorphic complex genomic changes in the human \textit{CD33rSIGLEC} gene cluster, there appear to be unusual (derived) human-specific expression patterns of \textit{CD33rSiglec} genes in nonhemopoietic cells) in locations such as placental trophoblast (\textit{SIGLEC6}) (Kang et al. 2011), ovarian fibroblasts (\textit{SIGLEC11/16}) (Wang et al. 2011), amnion epithelium (\textit{SIGLECS5/14}) (Ali et al. 2014), and microglia (\textit{SIGLEC11/16}) (Hayakawa et al. 2005). In each of the above instances, we have previously reported human-specific expression and lack of expression in chimpanzee tissue samples (in some instances also other available great ape tissues). With regard to the recent report of \textit{SIGLEC7} expression in human pancreatic islets (Yamaguchi et al. 2017), we now show that such expression is missing in chimpanzee pancreatic islets.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig2.png}
\caption{Description of the ELS scan. (A) Illustration of the selection signature. Patterns of shared mutations (dots) were used to reconstruct the genealogy that relate an archaic human Altai Neanderthal (Prufer et al. 2014); or Denisovan (Meyer et al. 2012); top rectangle to modern humans (bottom rectangles) at any given position along their genomes. There are two types of genealogies: the archaic falls either outside the modern human variation (external genealogy) or inside (internal genealogy). The internal genealogy is the most frequent in the genome. However, if a mutation spread among the ancestors of modern humans (blue dot) more recently than the population split with the ancestors of archaic humans, the archaic will be expected to fall outside the modern human variation in the genomic region around the mutation that has not been unlinked by recombination (blue rectangles). This region is expected to be large if the mutation was positively selected and spread quickly in the population, not leaving enough time for recombination to break its linkage with other mutations (black dots). (B) Time scales for the signatures of selection in humans. The tree represents the simplified population history of Neanderthals, Denisovans, and modern humans (Prufer et al. 2017). The colors indicate the time scales investigated by the ELS scan (red) and other methods (blue) used to detect events of positive selection on the modern human lineage.}
\end{figure}
We also found that Siglec-13, which is deleted in hominins, is highly expressed in chimpanzee intestinal epithelium and skin (fig. 3). Current and previously published data are summarized in table 2. Although we obviously cannot detect tissue-specific expression in Neanderthals or Denisovans, it is reasonable to consider the possibility that these unusual human-specific expression patterns arose during the course of the large-scale changes affecting the CD33rSIGLEC gene cluster during the proposed “hotspot” and would thus have already existed in both of those extinct relatives.

Discussion

Recent availability of sequences of many modern human genomes (1000 Genomes Project Consortium et al. 2015), archaic hominins (Green et al. 2010; Reich et al. 2010, 2011; Meyer et al. 2012, 2016; Castellano et al. 2014; Prüfer et al. 2014, 2017; Sawyer et al. 2015; Kuhlwilm et al. 2016; Slon et al. 2018), and great apes (Prado-Martinez et al. 2013; Xue et al. 2015; de Manuel et al. 2016) provides a tool for understanding the role of evolution in shaping genetic architecture and allowing us to identify the genetic basis of phenotypic traits of various species (Haffter et al. 1996; Bryk and Tautz 2014; Valenzano et al. 2015; Castellano and Munch 2020). Our earlier studies noted multiple genomic changes affecting sialic acid biology, and we suggested the possibility of a hotspot in humans affecting these pathways compared with our closest evolutionary relatives (Altheide et al. 2006). However, the limited availability of annotated and high coverage genomes at the time left the question unresolved, and our suggestion has been recently tested by others (Moon et al. 2018), who could not find evidence for strong selective sweeps in current human populations. We herewith show that apart from the fixed CMAH null mutation and increased expression of ST6GAL1 (Gagneux et al. 2003), most of the human-specific changes affecting sialic acid biology are found in the SIGLEC gene cluster on chromosome 19, and that although great ape genomes do not show many changes in this cluster, almost all the human changes are also found in archaic genomes of Neanderthals and Denisovans (Reich et al. 2010; Castellano et al. 2014; Prüfer et al. 2014; Slon et al. 2018; Bokelmann et al. 2019).

In keeping with this overall conclusion, there was no evidence for strong selective pressure in this cluster after ~0.6 Ma, when the human lineage diverged from Neanderthal–Denisovan common ancestor.

With regard to timing and order of changes, the most likely possibility is that the CMAH mutation first dramatically altered sialic acids throughout the body, possibly initiating a series of events that resulted in SIGLEC cluster changes. The complex and dynamic relationships between host and pathogens is often characterized by the Red Queen hypothesis, whereby slowly evolving hosts have to keep changing to keep pace with the pressure exerted by more rapidly evolving pathogens. Sialic acids form one primary interface, “the molecular frontier” in this evolutionary arms race. The loss-of-function of CMAH and the changes in ST6GAL1 expression undoubtedly led to multiple alterations of human–pathogen interactions. The direct consequence was the change in human cell surfaces, leading to overexpression of Neu5Ac, escaping Neu5Gc-specific pathogens, and favoring human pathogens that interact with Neu5Ac. There are many other known and possible biological consequences of human Neu5Gc loss (Varki 2009; Okerblom and Varki 2017), including protection from various Neu5Gc-recognizing pathogens such as malaria caused by Plasmodium reichenowi in African great apes (Martin et al. 2005), Escherichia coli K99 gastroenteritis (Kyogashima et al. 1989), transmissible gastroenteritis coronavirus (Schwegmann-Wessels and Herrler 2006), and simian virus 40 (Campanero-Rhodes et al. 2007). Conversely, CMAH loss likely made humans susceptible to Neu5Ac-prefering pathogens such as Vibrio cholerae (causative agent of the human-specific disease cholera) (Alisson-Silva et al. 2018) and typhoid fever caused by a secreted bacterial toxin that...

preferentially recognizes Neu5Ac (Deng et al. 2014). Another human-specific pathogen Streptococcus pneumoniae recognizes free Neu5Ac released from human cells by its secreted sialidase (Hentrich et al. 2016). Yet another secondary consequence appears to have been the evolution of pathogens that express Neu5Ac on their surfaces as a way to engage CD33-related Siglecs and downregulate innate immune responses in the human host. Again, the existence of many human-specific pathogens that display Neu5Ac supports this scenario (Angata 2018). For example, Group B Streptococcus type III, interacts with Siglec-9 through sialylated CPS and inhibits inflammatory response by neutrophils (Carlin et al. 2009). Likewise, nontypeable Haemophilus influenzae expressing sialic acid on its lipooligosaccharide binds to Siglec-5 and reduces cytokine production by myeloid cells (Angata et al. 2013), and the E. coli K1 strain that causes meningitis in neonates and infection in urinary tract, engages Siglec-11, and escapes killing (Hayakawa et al. 2017). Also, as expected, nonhuman primate Siglec-9 prefers binding to Neu5Gc, whereas human Siglec-9 prefers binding to Neu5Ac (Sonnenburg et al. 2004). Likewise, human Siglec-5 and CD33 prefer binding to Neu5Ac, compared with the baboon CD33, which strongly prefers Neu5Gc (Padder-Karavani et al. 2014). These findings imply that Siglecs underwent adaptation in new environments to “catch up” with the changes in human sialome caused by the hominin CMAH mutation. Some human Siglecs still prefer binding to Neu5Gc (Angata 2018), perhaps due to incomplete adaptation to the derived, human Neu5Ac-dominant sialome.

Although these genomic changes are ancient, evidence also suggests that existing human polymorphisms are associated with several diseases such as Chronic obstructive pulmonary disease, asthma, Alzheimer’s disease, and meningitis (Yamanaka et al. 2009; Gao et al. 2010; Ali et al. 2014; Schwarz et al. 2016). In addition, human Siglec-XII and chimpanzee Siglec-12 are expressed on macrophages and luminal epithelia (Mitra et al. 2011). However, human Siglec-XII harbors a universal mutation (R122C) that makes the protein unable to recognize sialic acid. Interestingly, chimpanzee Siglec-12 and human Siglec-XII with its arginine experimentally restored strongly prefer Neu5Gc (Mitra et al. 2011). These results suggest a scenario where Siglec-12 lost an endogenous ligand and is thus being eliminated from the population.

Prior studies have reported human-specific Siglec expression changes in placenta (Siglec-6) (Brinkman-Van der Linden et al. 2007), brain microglia (CD33/Siglec11/16) (Hayakawa et al. 2005; Schwarz et al. 2016), amniotic epithelium (Siglec-5/14) (Ali et al. 2014), ovarian fibroblasts (Siglec11/16) (Wang et al. 2011), and NK cells (Siglec-17) (Wang, Mitra, Secundino, et al. 2012). We here add to these expression differences by showing that Siglec-7 is upregulated in human but not chimpanzee pancreatic islets, and that the SIGLEC13 deletion resulted in a loss of Siglec-13 expression from human epithelia. Many of these expression changes could represent secondary consequences of multiple genomic changes that occurred in this gene cluster earlier in the hominin lineage. Overall, it is likely that the selective pressures driving all these changes were most prominent sometime after the split from the common ancestor of human and chimpanzee, but before the split from the Human–Neanderthal–Denisovan common ancestor. Taken together, our data suggest that innate immune encounters with pathogens markedly altered hominin Siglec biology between 0.6 and 2 Ma, potentially affecting human evolution. Notably, this is the time period when a variety of changes were occurring in genus Homo, including exploration of new habitats (White et al. 1993; Semaw et al. 1997; deMenocal 2011), striding bipedalism and running (Bramble and Lieberman 2004; Lieberman 2015), and scavenging and hunting, involving butchery of animal carcasses with stone tools (Semaw et al. 1997; O’Connell et al. 2002; McPherron et al. 2010; Sayers and Lovejoy 2014; Harmand et al. 2015; Baird et al. 2016), activities that may have increased risk of injury, novel infections, and use of fire (Smith et al. 2015). In this regard, it is also interesting that human-like elimination of Cmah in mice enhances running ability (Okerblom et al. 2018) as well as macrophage activation (Okerblom et al. 2017).
