The effects of 2 µg and 4 µg doses of dexmedetomidine in combination with intrathecal hyperbaric bupivacaine on spinal anesthesia and its postoperative analgesic characteristics

A Yektas, E Belli

OBJECTIVE: To compare the postoperative analgesic characteristics and side effects of two different doses of intrathecal dexmedetomidine in combination with hyperbaric bupivacaine, and to evaluate the effects of these combinations on spinal anesthesia.

METHODS: After obtaining approval from the local ethics committee, 60 male patients who were undergoing inguinal surgery and were classified as American Society of Anesthesiologists physical status class I were included in the study. The present study was conducted in 2003 in a military hospital with a capacity of 100 beds. The patients were randomly assigned to three groups of 20 patients: group 1, 0.5 mL saline added to 3 mL (15 mg) hyperbaric bupivacaine; and groups 2 and 3, 2 µg dexmedetomidine and 4 µg dexmedetomidine added to 3 mL (15 mg) hyperbaric bupivacaine, respectively. Medications were administered by intrathecal injection in a total volume of 3.5 mL. The postoperative analgesic characteristics, effects on spinal anesthesia and side effects were recorded.

RESULTS: Demographic characteristics were similar among the groups. The mean (± SD) time to onset of pain was 220.75±112.7 min in group 1, 371.5±223.5 min in group 2 and 1042.50±366.78 min in group 3. Time to first pain sensation in group 3 was significantly longer than in groups 1 and 2 (P<0.001).

CONCLUSION: Two different doses of dexmedetomidine, an α2-adrenoceptor agonist with analgesic effects, resulted in an increased duration of analgesia and efficacy, decreased postoperative analgesic use and was associated with no notable adverse effects.

Key Words: Adjuvants; Anesthesia; Anesthetics; Bupivacaine; Dexmedetomidine; Local; Spinal

Despite developments in postoperative pain management, many patients continue to experience postoperative pain. It is difficult to provide effective postoperative pain management with manageable side effects. Although intrathecal opioids are effectively and widely used, their use is limited due to side effects (1,2). One way to reduce the intensity and frequency of side effects in analgesic treatment is the use of two or more drugs of different classes in a low-dose combination. For this purpose, multimodal or balanced analgesia has acquired a crucial role in postoperative pain management in recent years (3,4).

Recent studies have focused on nonopioid receptors with additional analgesic effects. Previous studies have revealed that intrathecal dexmedetomidine, an α2-adrenoceptor agonist, provides analgesia in several species, including humans, and that combinations with local anesthetics decrease the side effects of local anesthetics and postoperative analgesic use (5-8). Tamagaki et al (9) showed that intrathecal dexmedetomidine increased the analgesic effects of systemic daily morphine by means of upregulation of the adrenergic receptor subtypes (α1A, α1B and α1C) on the dorsal horn and the lumbar dorsal root ganglia. In the present study, we aimed to compare the postoperative analgesic characteristics and side effects of different doses of intrathecal dexmedetomidine added to hyperbaric bupivacaine, and to evaluate the effects of these combinations on spinal anesthesia.

METHODS

After the study was approved by the local ethics committee of Fırat University Medical Faculty (Turkey) (approval date and number: 25.09.2003; 7/3), 60 male patients scheduled for inguinal surgery under spinal anesthesia, classified as American Society of Anesthesiologists physical status class I and between 20 and 30 years of age, were included in the study. The present study was conducted in 2003 in a military hospital with a capacity of 100 beds. After the patients were informed about the study and the study procedures, informed consent was obtained.

The criteria for exclusion from the study were: patients with drug addiction; patients who had required additional sedation and analgesia...
during previous surgical procedures; patients who had undergone previous surgical procedures and recalled experiencing pain; patients in whom cerebrospinal fluid (CSF) could not be obtained after three attempts during spinal anesthesia; and patients whose levels of education were below graduation from primary school.

Patients were not premedicated. Before being taken to the operating room, the spinal anesthesia procedure was explained to the patients and, during the postoperative period, they were requested to state the time of onset of pain. They were informed about the digital pain scale and were trained on the use of patient-controlled analgesia (PCA) before spinal anesthesia (11). A loading dose was given only to patients who needed analgesics.

In the operating room, all patients were monitored using electrocardiography, pulse oximetry and noninvasive arterial blood pressure. A 20-gauge intravenous cannula was inserted. After spinal anesthesia was administered, 0.9% saline infusion was initiated at a rate of 10 mL/h. The patients were placed in a seated position and, following the sterilization of the lumbar regions using polyvinyl povidone iodine, 2 mL of 2% prilocaine was administered to the cutaneous and the subcutaneous tissues. A 25-gauge Quincke spinal needle was inserted into L4–L5 disc space. When the CSF flow was observed, the prepared medical solution was administered.

The patients were randomly divided into three groups according to the medical mixture administered to the CSF: group 1: 15 mg of 0.5% hyperbaric bupivacaine plus 0.5 mL saline; group 2: 15 mg of 0.5% hyperbaric bupivacaine plus 2 µg dexmedetomidine; and group 3: 15 mg of 0.5% hyperbaric bupivacaine plus 4 µg dexmedetomidine.

Following intrathecal administration of the medication, the patients were placed in the supine position. The sensory block level was assessed by the pin-prick test, and the motor block level was evaluated by Bromage scoring (0, lifting leg; 1, bending knee; 2, moving foot; 3, no movement) at 5 min and 20 min. The mean arterial pressure, heart rate (HR) and peripheral oxygen saturation were recorded at baseline (before spinal anesthesia), at the first minute of spinal anesthesia and at 5 min intervals until the regression of sensory block and the recovery of motor block. The end of the sensory block duration was recorded as the moment when the sensory block duration dropped by two levels after it reached the highest level as of the moment spinal anesthesia was performed. The end of the motor block duration was recorded as the moment when the Bromage score returned to 0 after the spinal anesthesia was performed. Surgery commenced 20 min after intrathecal administration of the medication.

In the intraoperative and postoperative period, side effects, including bradycardia, hypotension, nausea, vomiting and sedation, were recorded. The side effects were treated symptomatically. A decrease in mean arterial pressure <80% of initial values was considered to represent hypotension and was treated with intravenous 5 mg epinephrine and fluid infusion. An HR <50 beats/min was considered to be bradycardia, and was managed by intravenous atropine (0.5 mg). In case of nausea and vomiting (without hypotension), 8 mg of ondansetron was administered intravenously. In cases of shivering, the patients were warmed using a warming unit. Those who complained of itching received 45.5 mg of intravenous pheniramine. The intraoperative sedation level of the patients was assessed using the Ramsay sedation scale (RSS) (10). The patient was considered to be sedated if the RSS score was ≥2.

Hot-pack application was used in patients with urinary retention; if urinary retention became persistent, the urine was collected using a Foley catheter and removed. The patients were not mobilized for 24 h following the intrathecal medications. Following mobilization, postspinal headache (PSH) was managed by intravenous fluid infusion and oral acetaminophen 250 mg + propyphenazone 150 mg + caffeine 50 mg. The patients who continued to experience headache in spite of the three-day treatment received an epidural blood patch. None of the patients developed persistent PSH. The modified Aldrete scoring system (11), a discharge scoring tool, was used to assess the sedation levels of the patients. According to the Aldrete scoring system, patients who achieved a total score ≥9 were considered to be fit for discharge. After the patients completely recovered from the sensory and motor blockade, patients with a modified Aldrete's score of ≥9 were referred to the department of general surgery and their ensuing follow-ups were performed in this department. The patients were discharged after a follow-up period of one week. The pain onset time in the postoperative period was recorded. A numerical pain rating scale was used for the assessment of pain. Each patient was asked to rate his pain from 0 (no pain) to 10 (unbearable pain). Following the recording of pain, a patient-controlled analgesia pump was connected. Following the administration of intrathecal medications, intravenous medication infusion continued for up to 24 h. At the end of 24 h, the total amount of tramadol used was recorded in milligrams. After discharge, the patients received a neurological examination on an annual basis. Limb and thoracic-spinal magnetic resonance imaging (MRI) images of the patients were performed 10 years after the administration of intrathecal dexmedetomidine. The lower-extremities radiculopathy protocol and electromyography (EMG) studies were performed at year 10.

Statistical analysis

The sample size was calculated according to the time to initiation of pain, and it was estimated that a group sample size of 20 patients for each group would be sufficient to detect a difference of 140 min between group 1 and group 2, with a significance level of 0.05 and β=0.2. The study was planned as a randomized and double-blind study. All data were assessed using SPSS version 11.5 (IBM Corporation, USA) for Windows (Microsoft Corporation, USA). Mean (± SD) values were used for the complementary statistics of the data. Data distribution was assessed using the Kolmogorov-Smirnov test. The χ² test was used for the assessment of the demographic data and occurring side effects. The time to initiation of pain and the numerical pain rating scale score at that moment, the amount of tramadol used until 24 h after administration of intrathecal medication, and the motor and sensory block levels at 5 min and 20 min were compared among the groups using the Kruskal-Wallis test. The Mann-Whitney U test with Bonferroni corrections was used in the subgroup analysis. P<0.05 was considered to be statistically significant.

RESULTS

The mean age, height and weight of the patients in the study groups were similar (Table 1). The sensory and motor block levels and durations of the groups are presented in Table 2. There was a significant difference among groups with respect to sensory block levels at 5 min (P=0.001). Group 3 achieved a significantly higher sensory block level than group 1 and group 2 (P<0.001). There was a significant difference among the groups with regard to the sensory block levels at 20 min (P=0.001). The sensory block level of group 1 was significantly lower than that of groups 2 and 3 (P<0.001 and P<0.001, respectively). There was a significant difference for motor block levels at 5 min (P<0.001). Group 3 had a significantly higher motor block level than that of group 1 and group 2 (P<0.001 and P<0.001, respectively). No significant difference was observed in the motor block levels achieved at 20 min (P=0.195). The sensory block durations of the groups displayed significant differences (P<0.001). Group 1 had a significantly shorter sensory block duration than groups 2 and 3 (P=0.001 and P=0.001, respectively). The duration of motor block showed significant differences

### Table 1

**Characteristics of the patients in the study groups**

| Characteristic | Group 1 (n=20) | Group 2 (n=20) | Group 3 (n=20) | P |
|---------------|---------------|---------------|---------------|---|
| Age, years    | 21.9±2.2      | 21.8±1.4      | 21.7±1.7      | 0.839 |
| Height, cm    | 174.2±7.2     | 173.0±6.3     | 172.7±5.2     | 0.817 |

Data presented as mean ± SD unless otherwise indicated. Group 1: 15 mg of 0.5% hyperbaric bupivacaine plus 0.5 mL saline; Group 2: 15 mg of 0.5% hyperbaric bupivacaine plus 2 µg dexmedetomidine; Group 3: 15 mg of 0.5% hyperbaric bupivacaine plus 4 µg dexmedetomidine.
TABLE 2
The mean sensory and motor block levels and durations of the study groups

|                     | Group 1 (n=20) | Group 2 (n=20) | Group 3 (n=20) | P     |
|---------------------|---------------|---------------|---------------|-------|
| Sensory block (pin-prick), thoracic segment |               |               |               |       |
| 5 min               | 7.05±2.78     | 5.15±3.39     | 3.50±2.43     | 0.001 |
| 20 min              | 5.50±1.84     | 5.55±1.43     | 3.00±2.31     | <0.001|
| Motor block (Bromage score) |               |               |               |       |
| 5 min               | 1.80±0.61     | 1.75±0.78     | 3.00±0.00     | <0.001|
| 20 min              | 2.75±0.83     | 2.80±0.52     | 3.00±0.00     | 0.195 |
| Sensory block duration, min | 86±28.03     | 98.75±34.40   | 147±50±13.72  | <0.001|
| Motor block duration, min | 130.50±42.73 | 151.50±29.96  | 226.50±65.47  | <0.001|

Data presented as mean ± SD unless otherwise indicated. *When sensory block levels at 5 min were compared for group 3 (15 mg of 0.5% hyperbaric bupivacaine plus 4 µg dexmedetomidine) and groups 1 (15 mg of 0.5% hyperbaric bupivacaine plus 0.5 mL saline) and 2 (15 mg of 0.5% hyperbaric bupivacaine plus 2 µg dexmedetomidine), the sensory block level in group 2 was higher than in groups 1 and 2 (P<0.001). When sensory block levels were compared at 20 min, there was a statistically significant difference among the groups (P<0.001). †When sensory block levels of group 3 and groups 1 and 2 were compared at 20 min, the block level in group 3 was higher than that in groups 1 and 2 (P<0.001 and P<0.001, respectively); ‡Motor block levels in group 3 were significantly higher than in groups 1 and 2 at 5 min (P<0.001 and P>0.001, respectively); §Sensory block duration in group 3 was lower than that in groups 2 and 3 (P<0.001 and P>0.001, respectively); ¶Sensory block duration in group 2 was lower than that in group 3 (P<0.001); **Motor block duration in group 3 was higher than that in groups 1 and 2 (P<0.001 and P<0.001, respectively).

TABLE 3
Time to first pain onset and numerical pain rating scale scores of the study groups

|                     | Group 1 (n=20) | Group 2 (n=20) | Group 3 (n=20) | P     |
|---------------------|---------------|---------------|---------------|-------|
| Time to first pain onset, min | 220.7±112.7   | 371.5±223.5   | 1042.50±366.78| <0.001|
| Numerical rating scale scores | 9.35±6.77     | 1.55±0.68     | 1.30±0.57     | <0.001|

Data presented as mean ± SD unless otherwise indicated. *The time to pain onset in group 3 (15 mg of 0.5% hyperbaric bupivacaine plus 4 µg dexmedetomidine) was longer than that in groups 1 (15 mg of 0.5% hyperbaric bupivacaine plus 0.5 mL saline) and 2 (15 mg of 0.5% hyperbaric bupivacaine plus 2 µg dexmedetomidine) (P=0.001 and P<0.001, respectively); †Numerical rating scale scores in group 1 were higher than in groups 2 and 3 (P=0.001 and P<0.001, respectively).

TABLE 4
The amount of tramadol consumption from the time of pain onset up to 2 h and at 24 h

|                     | Group 1 (n=20) | Group 2 (n=20) | Group 3 (n=20) | P     |
|---------------------|---------------|---------------|---------------|-------|
| From the time of pain onset up to 2 h, mg | 69.00±5.03     | 45.00±0.00    | 20.00±0.00   | <0.001|
| During 24 h following spinal anesthesia, mg | 107.25±14.64   | 69.75±13.13   | 47.06±60.22  | <0.001|

Data presented as mean ± SD unless otherwise specified. *Group 1 (15 mg of 0.5% hyperbaric bupivacaine plus 0.5 mL saline) consumed more tramadol than groups 2 (15 mg of 0.5% hyperbaric bupivacaine plus 2 µg dexmedetomidine) and 3 (15 mg of 0.5% hyperbaric bupivacaine plus 4 µg dexmedetomidine) during the first 2 h after the time of pain onset (P=0.001 and P<0.001, respectively); †Consumed tramadol in 24 h was higher in group 1 than that in groups 2 and 3 (P=0.001 and P<0.001, respectively); ‡Consumed tramadol in 24 h was higher in group 2 than in group 3 (P=0.002).

among the groups (P<0.001). Group 1 and group 2 had shorter motor block durations than group 3 (P=0.001 and P<0.001, respectively).

The time of pain onset and numerical pain rating scale scores of the groups are presented in Table 3. The time to initiation of pain was significantly different among the groups (P<0.001). The time to initiation of pain was significantly shorter in group 1 and group 2 compared with group 3 (P<0.001 and P<0.001, respectively). There was a significant difference among the groups with respect to the numerical pain rating scale scores at pain onset (P<0.001). The pain rating score of group 1 was significantly higher than that of group 2 and group 3 (P<0.001 and P<0.001, respectively).

The amount of tramadol used in the first 2 h (after the onset of pain) and during 24 h following spinal anesthesia are presented in Table 4. The tramadol requirement in the first 2 h after initiation of pain and the total tramadol requirement during 24 h following spinal anesthesia were significantly different among the groups (P<0.001 for each). Tramadol requirement in the first 2 h and during 24 h in group 1 was significantly higher than that of group 2 and group 3 (P<0.001 and P<0.001, respectively).

There was no significant difference between group 2 and group 3 regarding tramadol requirement in the first 2 h (P=0.277); however, the total amount of tramadol requirement during 24 h was significantly higher in group 2 than in group 3 (P<0.001).

The intraoperative and postoperative side effects are summarized in Table 5. Itching, sweating, dizziness and respiratory depression were not observed in any of the patients.

There was a significant difference among the groups with respect to the frequency of hypotension (P<0.001). Hypotension was more frequent in group 1 than in the other groups (P<0.05 for each).

There were no statistically significant differences among groups in terms of bradycardia (P=0.626), nausea/vomiting (P=0.459), shivering (P=0.459), urinary retention (P=0.449) and PSH (P=0.349). After spinal anesthesia, one patient in group 1 and one in group 3 received epidural blood patches on day 5 due to PSH.

The annual neurological examinations of the patients in the groups were assessed and judged to be normal. The thoracic and lumbar MRI images in year 10 were assessed and judged to be normal. No findings that would support radiculopathy in the lower extremities of patients were encountered in the EMG study.

There were significant differences among the groups in occurrence of sedation (P<0.05). Sedation was only observed in group 3.

DISCUSSION

In the present study, we evaluated whether different doses of intrathecal dexmedetomidine had any effects on the properties of hyperbaric bupivacaine used for spinal anesthesia. Our aim was to provide quality anesthesia and prolonged postoperative analgesia, while reducing the requirement for postoperative analgesics. We observed that intrathecal dexmedetomidine at 2 µg and 4 µg doses provided prolonged postoperative analgesia and reduced the need for postoperative analgesics.
Dexmedetomidine is a highly specific, potent and selective \( \alpha_2 \)-adrenoceptor agonist (7,8). It provides anxiolysis, analgesia and cooperative sedation without suppressing respiration (12,13).

In radioligand-binding studies, \( \alpha_2 \)-adrenoceptors have been shown to have \( \alpha_{2A} \), \( \alpha_{2B} \), \( \alpha_{2C} \) and \( \alpha_{2D} \) subtypes (14). \( \alpha_{2A} \)-receptors play a crucial role in most principle pharmacological and therapeutic effects of dexmedetomidine. Functional \( \alpha_{2A} \)-receptor-deficient mice were shown to lack sedative, anesthetic and analgesic effects of dexmedetomidine, while mice with inactivated \( \alpha_{2B} \) and \( \alpha_{2C} \) receptors displayed normal responses (15).

A meta-analysis by Abdallah and Brull (16) showed that dexmedetomidine is a potential local anesthesic adjuvant that can exhibit a facilitatory effect when administered intrathecally as part of spinal anesthesia. However, there are presently insufficient safety data to support the use of perineural dexmedetomidine in the clinical setting (16).

Many animal studies have been performed on the effects of intrathecal dexmedetomidine. Konakci et al (17) studied the effects of epidural dexmedetomidine in 21 New Zealand rabbits. They divided the rabbits into three groups and administered 5 \( \mu \)g or 10 \( \mu \)g dexmedetomidine, and lidocaine only, respectively, to the groups. There was a significant difference in demyelination of the oligodendrocytes in the white matter between the lidocaine-only and 10 \( \mu \)g dexmedetomidine groups; however, there was no difference between the lidocaine-only and 5 \( \mu \)g dexmedetomidine groups in this regard. Brummett et al (18) performed a study involving 31 Sprague Dawley rats. The sciatic nerve of the rats was blocked with bupivacaine, or dexmedetomidine and bupivacaine; the contralateral sciatic nerve blocked with only bupivacaine. The researchers used 0.005% hyperbaric bupivacaine plus 4 \( \mu \)g dexmedetomidine, with a higher hypotension rate in group 1 (P=0.012). When the groups were compared in terms of sedation, statistically significant differences were observed among the groups (P<0.001). When the groups were compared in pairs, there were statistically significant differences between group 1 and group 3; group 1 had a higher rate of sedation (P=0.002). There were statistically significant differences between group 2 and group 3: group 3 had a higher rate of sedation (P=0.002).

In a study by Ishii et al (7), the effects of dexmedetomidine on postsynaptic transmission in substantia gelatinosa were investigated using the whole-cell patch technique in rat spinal cord sections. Dexmedetomidine hyperpolarized the membrane potentials of substantia gelatinosa neurons by G-protein-mediated activation of \( K^+ \) channels through \( \alpha_{2A} \) and \( \alpha_{2C} \)-adrenoceptors. This action of dexmedetomidine may contribute, at least in part, to its antinociceptive action in the spinal cord. It was reported that this mechanism of action partially contributed to the antinociceptive action of dexmedetomidine in the spinal cord. Although the time to initiation of pain was similar in the groups receiving physiological saline and 2 \( \mu \)g of dexmedetomidine, the numerical pain rating scale scores in the group receiving 2 \( \mu \)g dexmedetomidine was significantly lower than that of the group receiving physiological saline.

In a study by Marc et al (8) involving dogs, it was demonstrated that following intrathecal, epidural and intravenous dexmedetomidine administration, there was an increase in twitching of the skin against painful stimuli and stimulation of withdrawal by mechanical pressure on the rear paw. Maximum medication effect was observed at 3 min of intravenous administration and at 15 min of intrathecal and epidural applications. The duration of action was 90 min by intravenous and intrathecal routes, and 240 min by the epidural route following maximum effective dose. Maximum antinociceptive effects were observed around the dermatomes proximal to the catheter tip following intrathecal administration. Following epidural or intrathecal application, the time to maximum distribution of the block was assessed and withdrawal of the rear paw was suppressed, but no suppression was seen in the front paw. When compared with the respiratory rates before administration of the medication, an intravenous dose of 10 \( \mu \)g/kg, an epidural dose of 50 \( \mu \)g and an intracisternal dose of 15 \( \mu \)g dexmedetomidine led to a significant decrease in the respiratory rates at rest; however, no change was observed in end-tidal carbon dioxide at rest. Reversal of the decrease in respiratory rate was dependent on atipamezole (300 \( \mu \)g/kg) but independent of naloxone (30 \( \mu \)g/kg). HR significantly decreased in a dose-dependent manner after intravenous application. The notable decrease in HR following epidural administration was only observed at 50 \( \mu \)g, which was the highest dose administered. Following an intrathecal 10 \( \mu \)g and an intracisternal 15 \( \mu \)g dose, the HR decreased slightly, although not significantly. When the highest dose of medication was administered to the animals through intrathecal, epidural and intracisternal routes, only minor depression was observed. Additionally, a dose-dependent decrease was observed in the core temperature following intravenous, intracisternal and epidural dexmedetomidine (lower dose) application; however, no change was observed in the core temperature following intrathecal application. Similarly, the level of sensory

### TABLE 5

| Side effect                | Group          | 1 (n=20) | 2 (n=20) | 3 (n=20) | P     |
|----------------------------|----------------|----------|----------|----------|-------|
| Hypotension                |                | 14       | 6        | 7        | 0.022 |
| Bradycardia                |                | 11       | 8        | 9        | 0.626 |
| Vomiting/nausea            |                | 2        | 4        | 5        | 0.459 |
| Tremor                     |                | 2        | 4        | 5        | 0.459 |
| Urinary retention          |                | 3        | 6        | 6        | 0.449 |
| Posterior headache         |                | 0        | 2        | 1        | 0.349 |
| Sedation                   |                | 0        | 0        | 8        | <0.001 |

Data presented as n unless otherwise indicated. *Based on a comparison of groups in terms of hypotension, statistically significant differences were observed among groups (P=0.022). When the groups were compared in pairs, group 1 (15 mg of 0.5% hyperbaric bupivacaine plus 0.5 mL saline) and group 2 (15 mg of 0.5% hyperbaric bupivacaine plus 2 \( \mu \)g dexmedetomidine) were significantly different, with a higher hypotension rate in group 1 (P=0.012). There were statistically significant differences between group 1 and group 3 (15 mg of 0.5% hyperbaric bupivacaine plus 4 \( \mu \)g dexmedetomidine), with a higher hypotension rate in group 1 (P=0.029). When the groups were compared in terms of sedation, statistically significant differences were observed among the groups (P<0.001). When the groups were compared in pairs, there were statistically significant differences between group 1 and group 3; group 1 had a higher rate of sedation (P=0.002). There were statistically significant differences between group 2 and group 3: group 3 had a higher rate of sedation (P=0.002).
and motor block at 5 min significantly increased in a dose-dependent manner in our study. Following maximum effective dose, the duration of action was found to be 90 min by the intrathecal route in the above-mentioned study, and the duration of action was 371.5±223.5 min and 1042.50±366.78 min in groups 2 and 3 in the present study, respectively; however, instead of dexmedetomidine, we used a combination of dexmedetomidine and bupivacaine in our study. Following maximum effective dose, the duration of action was found to be 90 min by the intrathecal route in the above-mentioned study, and the duration of action was 371.5±223.5 min and 1042.50±366.78 min in groups 2 and 3 in the present study, respectively; however, instead of dexmedetomidine, we used a combination of dexmedetomidine and bupivacaine in our study.

In a study by Calasans-Maia et al (6) involving guinea pigs using α2-adrenoceptor agonists together with local anesthetics (6). The affinity of dexmedetomidine for α2-adrenoceptors was found to be stronger than that of clonidine (6). This study investigated whether intrathecal or intraperitoneal dexmedetomidine with 0.5% levobupivacaine caused motor nerve block. Seventy-two guinea pigs were randomly divided into 12 groups, and intrathecal levobupivacaine (50 µL dose) was administered to all animals. One-half of the animals received intrathecal dexmedetomidine, while the remaining received intraperitoneal dexmedetomidine. Intrathecal dexmedetomidine (0.1 µg to 0.2 µg and 0.4 µg) prolonged motor block produced by levobupivacaine and extended the duration of motor block from 48 min to 84.5 min to 101.5 min and 105 min, respectively. Similarly, intraperitoneal dexmedetomidine prolonged motor block duration from 48.5 min to 88 min to 114.5 min, respectively. When yohimbine was added before intrathecal or intraperitoneal dexmedetomidine application, motor block duration decreased from 101.5 min to 76.5 min and from 114.5 min to 90 min, respectively. The duration of motor block following spinal injection of levobupivacaine was prolonged by intrathecal and systemic dexmedetomidine. This effect is partially dependent on α2-adrenoceptor activation (6). Similarly, the duration of motor and sensory block prolonged with increasing doses of dexmedetomidine in our study (Table 2).

When a certain amount of clonidine is systemically administered, it causes hypotension; however, this effect is lower in the case of dexmedetomidine, which is more selective (25). We observed hypotension in seven patients in the 5 µg dexmedetomidine group (Table 5). In a study performed by Shukla et al (26), the patients were divided into three groups as follows: the dexmedetomidine group (15 mg hyperbaric bupivacaine plus 50 µg dexmedetomidine), the magnesium sulphate group (15 mg hyperbaric bupivacaine plus 50 mg magnesium sulphate) and the control group (15 mg hyperbaric bupivacaine plus 0.1 mL saline), and the medications were administered via the intrathecal route. In the dexmedetomidine group, the onset of anesthesia in the magnesium group was no significant difference among the groups with regard to the frequency of side effects and hemodynamic changes (26) (Table 6).

### Table 6: Comparing the results of our findings with trial outcomes

| Author (reference), year | Study groups | Bupivacaine or ropivacaine, mg | Sensory block duration (time to regression to S1), min | Motor block duration, min | Time to first pain onset, min | Side effects (n) |
|--------------------------|--------------|--------------------------------|------------------------------------------------------|---------------------------|-------------------------------|-----------------|
| Shukla et al (26), 2011   | 10 µg dexmedetomidine (n=30) | 15 | 352±45 | 331±35 | 241.67±21.67 | Nausea (2) |
|                          | 0.1 mL saline (n=30)          | 15 | 194±55 | 140±34 | 478.4±20.9 | Hypotension (1) |
|                          | 0.1 mL (50 mg) magnesium sulfate (n=30) | 15 | 265±65 | 251±51 |                               |                 |
| Gupta et al (27), 2011    | 0.1 mL saline + ropivacaine (n=30) | 5 µg dexmedetomidine + ropivacaine (n=30) | 15 | 239.33±16.8 | 62.7±8.3 | 241.67±21.67 | Nausea (1) |

4.  Murali Krishna T, Panda NB, Barra YK, Rajeev S. Combination of 4 µg dose of the hyperbaric bupivacaine needs to be adjusted.

5.  In the present study, dexmedetomidine accelerated the onset of sensory and motor block (at 5 min) compared with bupivacaine alone. Dexmedetomidine significantly increased the sensory block levels at 20 min, but motor block levels at 20 min were similar in all groups. Dexmedetomidine significantly prolonged the sensory and motor block durations and, as the dose of dexmedetomidine was increased, block duration was also increased.

6.  In another study by Gupta et al (28), it was demonstrated that intrathecal dexmedetomidine prolonged hemodynamic stability and the duration of motor and sensory block; when compared with fentanyl, it reduced the analgesic requirement in 24 h. We also observed that the requirement for analgesics in the postoperative 24 h was significantly lower in the 4 µg dexmedetomidine group than that of the other groups. The numerical pain rating scores at pain onset was significantly lower in the dexmedetomidine-added groups, and as dexmedetomidine dose increased, the numerical pain scores decreased.

7.  In a study by Kanazi et al (29), it was demonstrated that when added to 3 µg dexmedetomidine or 30 µg clonidine, intrathecal bupivacaine retained hemodynamic stability and extended motor and sensory block durations, requiring no sedation. The results of our study were similar (Table 6).

8.  In a study by Al-Mustafa et al (30), dexmedetomidine had a dose-dependent effect on the onset and regression of sensory and motor block when used as an adjuvant to bupivacaine in spinal anesthesia. The results of our study were similar (Table 6).

9.  In a study by Eid et al (31), 10 µg of dexmedetomidine administered intrathecally provided significant increase in the sensory and motor block of spinal anesthesia in addition to prolonged postoperative analgesia. The longer sensory and motor blockade produced by a 15 µg dose and the desirable sedation level may be beneficial in patients undergoing lengthy complex surgery as an alternative to epidural or prolonged general anesthetics, and may preclude the use of intravenous sedatives. It may be prudent to compare the anesthetic and postoperative effects of dexmedetomidine with long-acting intrathecal opioids. The results of our study were similar (Table 6).

10. In the present study, dexmedetomidine accelerated the onset of sensory and motor blocks (at 5 min) compared with bupivacaine alone. Dexmedetomidine significantly increased the sensory block levels at 20 min, but motor block levels at 20 min were similar in all groups. Dexmedetomidine significantly prolonged the sensory and motor block durations and, as the dose of dexmedetomidine was increased, block duration was also increased.

11. Dexmedetomidine prolonged the time to initiation of pain in a dose-dependent manner. The time to initiation of pain was significantly longer in the 4 µg dexmedetomidine group than that of the other groups. The numerical pain rating scores at pain onset was significantly lower in the dexmedetomidine-added groups, and as dexmedetomidine dose increased, the numerical pain scores decreased.

12. In a study by Eid et al (31), 10 µg of dexmedetomidine administered intrathecally provided significant increase in the sensory and motor block of spinal anesthesia in addition to prolonged postoperative analgesia. The longer sensory and motor blockade produced by a 15 µg dose and the desirable sedation level may be beneficial in patients undergoing lengthy complex surgery as an alternative to epidural or prolonged general anesthetics, and may preclude the use of intravenous sedatives. It may be prudent to compare the anesthetic and postoperative effects of dexmedetomidine with long-acting intrathecal opioids. The results of our study were similar (Table 6).

13. In the present study, dexmedetomidine accelerated the onset of sensory and motor blocks (at 5 min) compared with bupivacaine alone. Dexmedetomidine significantly increased the sensory block levels at 20 min, but motor block levels at 20 min were similar in all groups. Dexmedetomidine significantly prolonged the sensory and motor block durations and, as the dose of dexmedetomidine was increased, block duration was also increased.

14. Dexmedetomidine prolonged the time to initiation of pain in a dose-dependent manner. The time to initiation of pain was significantly longer in the 4 µg dexmedetomidine group than that of the other groups. The numerical pain rating scores at pain onset was significantly lower in the dexmedetomidine-added groups, and as dexmedetomidine dose increased, the numerical pain scores decreased.

15. In a study by Kanazi et al (29), it was demonstrated that when added to 3 µg dexmedetomidine or 30 µg clonidine, intrathecal bupivacaine retained hemodynamic stability and extended motor and sensory block durations, requiring no sedation. The results of our study were similar (Table 6).

16. In another study by Gupta et al (28), it was demonstrated that intrathecal dexmedetomidine prolonged hemodynamic stability and the duration of motor and sensory block; when compared with fentanyl, it reduced the analgesic requirement in 24 h. We also observed that the requirement for analgesics in the postoperative 24 h was significantly lower in the 4 µg dexmedetomidine group than that of the other groups. The numerical pain rating scores at pain onset was significantly lower in the dexmedetomidine-added groups, and as dexmedetomidine dose increased, the numerical pain scores decreased.

17. In a study by Kanazi et al (29), it was demonstrated that when added to 3 µg dexmedetomidine or 30 µg clonidine, intrathecal bupivacaine retained hemodynamic stability and extended motor and sensory block durations, requiring no sedation. The results of our study were similar (Table 6).

18. In the present study, dexmedetomidine accelerated the onset of sensory and motor blocks (at 5 min) compared with bupivacaine alone. Dexmedetomidine significantly increased the sensory block levels at 20 min, but motor block levels at 20 min were similar in all groups. Dexmedetomidine significantly prolonged the sensory and motor block durations and, as the dose of dexmedetomidine was increased, block duration was also increased.

19. In a study by Eid et al (31), 10 µg of dexmedetomidine administered intrathecally provided significant increase in the sensory and motor block of spinal anesthesia in addition to prolonged postoperative analgesia. The longer sensory and motor blockade produced by a 15 µg dose and the desirable sedation level may be beneficial in patients undergoing lengthy complex surgery as an alternative to epidural or prolonged general anesthetics, and may preclude the use of intravenous sedatives. It may be prudent to compare the anesthetic and postoperative effects of dexmedetomidine with long-acting intrathecal opioids. The results of our study were similar (Table 6).

20. In the present study, dexmedetomidine accelerated the onset of sensory and motor blocks (at 5 min) compared with bupivacaine alone. Dexmedetomidine significantly increased the sensory block levels at 20 min, but motor block levels at 20 min were similar in all groups. Dexmedetomidine significantly prolonged the sensory and motor block durations and, as the dose of dexmedetomidine was increased, block duration was also increased.

CONCLUSIONS

A 4 µg dose of dexmedetomidine, an intrathecal adjuvant, leads to hemodynamic stability and remarkable effects on spinal anesthesia, and can be safely used to decrease tramadol requirement in the postoperative period with intrathecal hyperbaric bupivacaine. Because it significantly prolongs the sensory and motor block duration, we conclude that it can be used for long operations that require spinal anesthesia. In the other hand, 40% of the patients in the 4 µg dexmedetomidine group developed sedation in the range of RSS = 2 to 4. Because the sensory block level rose above the level of T4, the dose of the hyperbaric bupivacaine needs to be adjusted.
