ABSTRACT
We study quenching in seven green valley galaxies on kpc scales by resolving their molecular gas content using 12CO(1–0) observations obtained with NOrthern Extended Millimeter Array and Atacama Large Millimeter Array, and their star formation rate using spatially resolved optical spectroscopy from the Mapping Nearby Galaxies at Apache Point Observatory survey. We perform radial stacking of both data sets to increase the sensitivity to molecular gas and star formation, thereby avoiding biases against strongly quenched regions. We find that both spatially resolved gas fraction ($f_{\text{gas}}$) and star formation efficiency (SFE) are responsible for quenching green valley galaxies at all radii: both quantities are suppressed with respect to typical star-forming regions. $f_{\text{gas}}$ and SFE have roughly equal influence in quenching the outer disc. We are, however, unable to identify the dominant mechanism in the strongly quenched central regions. We find that $f_{\text{gas}}$ is reduced by $\sim 1$ dex in the central regions, but the star formation rate is too low to be measured, leading to upper limits for the SFE. Moving from the outer disc to central regions, the reduction in $f_{\text{gas}}$ is driven by an increasing $\Sigma_1$ profile rather than a decreasing $\Sigma_{\text{H}_2}$ profile. The reduced $f_{\text{gas}}$ may therefore be caused by a decrease in the gas supply rather than molecular gas ejection mechanisms, such as winds driven by active galactic nuclei. We warn more generally that studies investigating $f_{\text{gas}}$ may be deceiving in inferring the cause of quenching, particularly in the central (bulge-dominated) regions of galaxies.

Key words: – galaxies: star formation.

1 INTRODUCTION

Star-forming and passive galaxies differ in key properties, such as colour, morphology, and star formation rate (SFR; Strateva et al. 2001; Baldry et al. 2004; Springel, Di Matteo & Hernquist 2004; Renzini & Peng 2015). Galaxies in the green valley (GV) region of the colour–magnitude diagram have intermediate properties and the majority of these are thought to be transitioning from being blue and star forming to red and passive (Martin et al. 2007; Wyder et al. 2007), a process commonly referred to as quenching.

The advent of large optical integral field unit (IFU) surveys is enabling spatially resolved studies of the physics governing galaxy quenching. For example, outside-in quenching models (e.g. ram-pressure stripping; Kenney, van Gorkom & Vollmer 2004) can be tested against inside-out models (e.g. feedback from active galactic nuclei (AGNs), Fabian 2012) by resolving the spatial distribution of star formation. One such study of spatially resolved star formation demonstrated that massive GV galaxies host central low-ionization emission-line regions (cLIERs; Belfiore et al. 2017). These cLIER galaxies form stars in their outer discs, but their central emission is dominated by old stellar populations, indicating a lack of recent star formation. Belfiore et al. (2018) found that, although the quenching is most extreme in the central regions, star formation is suppressed at all radii: quenching does not simply occur inside-out.

Data from IFUs and submillimetre interferometers, with matched kpc-scale spatial resolution, can be combined to investigate the conversion of gas into stars, a process that is governed on local, spatially resolved scales (Schimmerer et al. 2019). The ALMA-MaNGA QUEnching and StAr formation (ALMaQUEST) project is one of the first resolved studies to systematically investigate galaxies across the $\Sigma_1$–$\Sigma_{\text{SFR}}$ plane at $z \sim 0$ (Lin et al., in preparation). Lin et al. (2019) use a sample of star-forming ALMA QUEST galaxies to calibrate three resolved relationships: the spatially resolved star formation main sequence (rSFMS, $\Sigma_1$–$\Sigma_{\text{SFR}}$; e.g. Cano-Díaz et al. 2016), the molecular gas main sequence (rMGMS, $\Sigma_1$–$\Sigma_{\text{H}_2}$), and the Schmidt–Kennicutt star formation law (rSK, $\Sigma_{\text{H}_2}$–$\Sigma_{\text{SFR}}$; Kennicutt 1998). Offsets from these relationships can therefore be used to quantify quenching in the GV on kpc scales.

In this letter, we investigate quenching of star formation by comparing the distribution of molecular gas and star formation in a sample of seven massive GV galaxies. Five galaxies were selected to lie in the GV in NUV – $r$ colours ($4 < \text{NUV} – r < 5$), to have large central 4000 Å breaks (indicative of the old
central stellar populations found in bulges), not to host a Seyfert AGN, and to have axial ratios larger than 0.5 to avoid inclination effects. The large selected central 4000 Å breaks are representative of massive \( (M_\odot > 10^{10} M_\odot) \) GV galaxies, lying within 1σ of the population mean. We also reanalyse two GV galaxies without AGN from the Lin et al. (2017) ALMaQUEST pilot study. This work uses a larger sample size than the pilot study and performs a radial stacking analysis to avoid biases due to non-detection of either SFR or molecular gas tracers. We assume a Kroupa (2001) initial mass function (IMF) and Lambda cold dark matter cosmology throughout, with \( H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}, \Omega_M = 0.3, \) and \( \Omega_\Lambda = 0.7. \)

2 DATA

2.1 MaNGA integral field spectroscopy

Mapping Nearby Galaxies at Apache Point Observatory (MaNGA) is an IFU survey targeting 10 000 nearby galaxies \( (z \sim 0.03; \) Bundy et al. 2015; Yan et al. 2016). Mounted on the Sloan Digital Sky Survey (SDSS) 2.5 m telescope (Gunn et al. 2006), the IFU system simultaneously targets 17 galaxies, covering them out to at least 1.5 effective radii \( (R_e). \) The fibres are fed into the Baryon Oscillation Spectroscopic Survey spectrographs (Smee et al. 2013), which fully cover the wavelength range of 3600–10 000 Å with spectral resolution \( R \sim 2000. \) Reduced data cubes have 0.5 arcsec spaxels and a spatial resolution (full width at half-maximum) of 2.5 arcsec (Yan et al. 2015; Law et al. 2016). The MaNGA data used in this work are taken from data release 15 (Aguado et al. 2019).

We analyse the data both spaxel by spaxel and in bins of deprojected radius, generated using the position angles and inclinations from the NASA-Sloan catalogue (Blanton et al. 2011), derived from SDSS photometry. The spaxel-by-spaxel analysis is used to obtain an initial view of the data (as shown in Fig. 1) and to obtain the velocity field used to stack spectra in radial bins. We describe the stacking analysis in detail below since it forms the basis of our result. The spaxel-by-spaxel analysis follows roughly the same steps.

We first centre and coadd the spectra of spaxels in bins of width 0.25\( R_e \) using the H\( \alpha \) velocity field from the data analysis pipeline (DAP) v2.2.1 (Belfiore et al. 2019; Westfall et al. 2019). We construct a grid of 72 SSP templates spanning 12 ages \((0.001–15 \text{ Gyr})\) and 6 metallicities \( ([Z/H] = -2.0 \text{ to } 0.0)\) using the PEGASE-HR code (Le Borgne et al. 2004) together with the ELODIE v3.1 stellar library (Prugniel & Soubiran 2001; Prugniel et al. 2007), and then use penalized pixel fitting (PPXF; Cappellari & Emsellem 2004; Cappellari 2017) to simultaneously fit the gas and stellar emission while assuming a Calzetti (2001) attenuation curve. We refit the spectra after adding noise, producing a distribution of 1000 estimates for the emission-line fluxes and the mass in each SSP template. We have checked that the H\( \alpha \) fluxes obtained in this way are consistent with those obtained by summing the individual spaxel flux estimates from the DAP. The H\( \alpha \) flux is corrected for dust extinction using the theoretical case B Balmer ratio \((H\alpha/H\beta = 2.87)\) and the Calzetti (2001) attenuation curve with \( R_V = 4.05. \) \( \Sigma_{\text{SFR}} \) is derived from the extinction-corrected H\( \alpha \) flux using the Kennicutt & Evans (2012) calibrations for a Kroupa (2001) IMF for spectra classified as star forming in the \( ([S\text{II}]/H\alpha)_{6717,31} \) versus \( ([O\text{III}]/H\alpha) \) BPT diagram (Baldwin, Phillips & Terlevich 1981; Veilleux & Osterbrock 1987). We have checked that the radial and spaxel-by-spaxel BPT classifications are consistent; less than 10 percent of the spaxels in LIER radial bins are star forming.

\[ \Sigma_{\text{SFR}} = \text{estimated from the average reconstructed star formation history in each spaxel, defined as the mean mass over all MC runs in each age slice. We correct } \Sigma_{\text{SFR}} \text{ for the mass fraction returned to the interstellar medium (ISM). In regions that are BPT-classified as LIER, we also use the SSP analysis to test for the presence of young stars. We define } \Sigma_{\text{SFR}} \text{ in LIER regions as the average rate of star formation in the last } 10 \text{ Myr, consistent with the star formation time-scale probed by H\( \alpha \) (Kennicutt & Evans 2012). We define a conservative sensitivity limit to young stars using the 10th percentile of spatially resolved sSFR for all annular fits with non-zero weights for young stars: } \log(s\text{SFR}/\text{yr}^{-1}) \sim -12 \text{. We choose an sSFR limit, rather than } \Sigma_{\text{SFR}}, \text{ since the sensitivity to young stars is strongly affected by the total mass budget. The sensitivity limit is combined with } \Sigma_{\text{SFR}} \text{ to place constraining upper limits on } \Sigma_{\text{SFR}} \text{ in annuli lacking evidence of recent star formation.} \]

2.2 CO(1–0) data

\( ^{12}\text{CO}(1–0) \) observations have been performed for a sample of five galaxies using the NOEMA. Each galaxy was observed for \( \sim \) 5.5 h total on-source time in two array configurations: C (observed 2017 June–July, typically with } 10 < \text{ precipitable water vapor (PWV) 15 mm}) and D (observed 2018 April, typically with } 5 < \text{ PWV}
we measure the line flux by integrating across the channels above
MNRASL 498, later in this section are based on binning in radial annuli. Fig. 1
We show maps obtained by deriving physical properties on spaxel-
formation efficiency \(SFE = \frac{\Sigma_{\text{SFR}}}{\Sigma_{\text{H}_2}}\), with and star
fraction \(f_{\text{gas}} = \frac{\Sigma_{\text{H}_2}}{\Sigma_{\text{H}_2}}\), and/or star formation efficiency
SFE since our sSFR detection limit leads to
central SFE upper limits are consistent with a relatively flat profile
none the less, star formation tends to be less efficient at small galactocentric
3 RESULTS
Quenching is the suppression of star formation (often quantified by
sSFR = \(\Sigma_{\text{SFR}}/\Sigma_{\ast}\), with ‘quenched’ regions having sSFR \(\sim 10^{-12}\) yr\(^{-1}\), consistent with the population of passive galaxies)
and can occur because of a reduced molecular gas content, often
quantified in terms of gas fraction \(f_{\text{gas}} = \Sigma_{\text{H}_2}/\Sigma_{\ast}\), and/or star
formation efficiency \(SFE = \Sigma_{\text{SFR}}/\Sigma_{\text{H}_2}\), where
log(sSFR) = log(SFE) + log(f_{\text{gas}}).
(1)
In this framework, a reduction in SFE probes quenching through inefficient conversion of gas into stars while low \(f_{\text{gas}}\) signifies quenching through a depleted gas reservoir. We note that sSFR, SFE, and \(f_{\text{gas}}\) denote spatially resolved quantities unless otherwise stated.
In Fig. 1, we show maps of SFE and \(f_{\text{gas}}\) for galaxy 8550–12704. We show maps obtained by deriving physical properties on spaxel-by-spaxel basis purely for display purposes. All the results presented later in this section are based on binning in radial annuli. Fig. 1 demonstrates the centrally suppressed SFR typical of GV galaxies, and a central decrease in both \(f_{\text{gas}}\) and SFE. The other six galaxies show qualitatively similar trends (see Section B of the online supplementary material).

3.1 Radial profiles
Fig. 1 highlights the limitations and challenges of a fully resolved analysis: we obtain a biased view of the galaxy by restricting our analysis to pixels, where one of the two key tracers (SFR or \(M_{\text{H}_2}\)) is well detected. For example, low-\(f_{\text{gas}}\) regions may be hidden in Fig. 1 because of molecular gas non-detections. We therefore derive radial profiles based on the annular averaged spectra described in the previous section to get a comprehensive view of GV galaxies.

Fig. 2 shows radial profiles of sSFR, \(f_{\text{gas}}\), and SFE for the galaxies in our sample. The radial bins have widths of 0.25R_e, which corresponds approximately to the sizes of the MaNGA and NOEMA beams. 7977–3704 is an exception, where 0.25R_e only corresponds to half the size of the NOEMA/MaNGA beam. The radial bins in this galaxy are therefore not independent, and the profiles are better viewed as moving averages.
sSFR profiles are consistent with previous GV studies (e.g. Belfiore et al. 2018; Spindler et al. 2018): the sSFR shows a clear decrease moving from the outer to the inner regions, most of which is driven by the increase in \(\Sigma_{\ast}\) in the central regions. We also find that the SFE shows a radial gradient, being lower at smaller galactocentric distances. This suggests that the decreasing sSFR is not only due to a stellar bulge. Rather, star formation is being suppressed. In agreement with Lin et al. (2017), we observe reduced gas fractions in the central regions of GV galaxies with respect to their outskirts. The reduction is very significant (1 dex on average), except in 7977–12705. In this galaxy, the central star formation is at least partially driven by a large gas reservoir.

It is difficult to infer the full extent of any central suppression in SFE since our sSFR detection limit leads to \(\Sigma_{\text{SFR}}\) upper limits that are not strongly constraining in the high \(\Sigma_{\ast}\) central regions. In fact, the central SFE upper limits are consistent with a relatively flat profile as well as a rapidly decreasing efficiency at small radii. None the less, star formation tends to be less efficient at small galactocentric radii, and this effect compounds the reduction of \(f_{\text{gas}}\) to leave central regions quenched, i.e. sSFR \(\sim 10^{-12}\) yr\(^{-1}\).
Assuming a metallicity-dependent $\alpha_{CO}$ conversion factor in the presence of a metallicity gradient would reduce the measured central gas densities, thereby steepening radial profiles of $f_{gas}$ while flattening those of SFE. In the outer, star-forming regions, where the gas-phase metallicity can be measured using standard diagnostics (here we use the O3N2 calibration from Pettini & Pagel 2004), the metallicity profiles are flat ($8.6 < 12 + \log(O/H) < 8.8$) with $1\sigma$ scatter smaller than 0.05 for all seven galaxies. Assuming the metallicity profiles remain flat in the LIER regions, where the metallicity cannot be directly measured, we expect $\alpha_{CO}$ variations smaller than $\sim 0.1$ dex using the metallicity-dependent conversion factor adopted in Sun et al. (2020). This is insufficient to alter the trends shown in Figs 2 and 3.

### 3.2 What is driving the reduced sSFR in GV galaxies?

We have shown that $f_{gas}$ and SFE vary within GV galaxies and that both effects drive reductions in sSFR. The key goal of this work is, however, to investigate the transition from the star-forming main sequence to the GV, and understand why GV galaxies form fewer stars than their star-forming counterparts. We therefore examine offsets from three relationships connecting $\Sigma_*$, $\Sigma_{SFR}$, and $\Sigma_{HI}$ in MS galaxies on kpc scales, i.e. the rSFMS, rMGMS, and rSK (Lin et al. 2019; Fig. 3). We correct for the different IMFs used in Lin et al. (2019) (Salpeter) when calculating the offsets.

GV galaxies lie below the rSFMS at all radii, but the difference is largest inside $0.5R_e$, where the LIER regions form stars $\sim 100$ times more slowly than star-forming regions. This is partially explained by offsets from the rMGMS: for the same $\Sigma_*$, the gas fraction is slightly reduced in the disc but $\sim 10$ times lower in the inner bulge (relative to the gas fraction found in typical annuli in star-forming galaxies). These offsets are at least partially driven by the growth of the central bulge and may not be associated with a change in the gas content of the disc. We also observe offsets from the rSK, and a mild radial trend. In particular, the efficiency of forming stars relative to normal star-forming galaxies also decreases with decreasing galactocentric radius. As with profiles of SFE, much of the suppression lies below the detection limit. None the less, we demonstrate that the efficiency of star formation at the centre of GV galaxies is generally three times lower than expected from the rSK, and some galaxies are up to 10 times less efficient. This confirms that the offset from the rSFMS is not only caused by the growth of the central bulge and that star formation is suppressed at the centres of GV galaxies.

The bottom row in Fig. 3 compares offsets from the rMGMS and rSK relationships and enables a ranking of the two drivers: which is more significant for quenching star formation? Neither factor dominates beyond $\sim 0.6R_e$, and we conclude that changes in the gas reservoir and efficiency are equally responsible for reduced star formation in the disc. Offsets from the rMGMS appear to dominate in the central regions, but the full extents of the corresponding offsets from the rSK are unconstrained. We are therefore unable to rank the two drivers in these regions.

We review the offsets from the rMGMS and rSK for all annuli in Fig. 4. The majority of data points lie in the bottom-left quadrant with suppressed gas reservoirs and star-forming efficiencies. Small galactocentric radii have significantly suppressed gas fractions and star formation efficiencies, but the upper limits on $\Delta_{SK}$ highlight our inability to identify the dominant mechanism. While these data points generally lie below the 1:1 line where suppression of the gas reservoir dominates, our data are also consistent with the remarkable scenario in which GV galaxies are predominately quenched through reduced SFE.

### 4 SUMMARY AND DISCUSSION

We investigated the spatial distribution of molecular gas and star formation on kpc scales within GV galaxies. We find that both $f_{gas}$ and SFE drive quenching. In particular, they are roughly equally responsible for quenching star formation in the outer disc. We are unable to determine the dominant mechanism in the central, strongly quenched regions, because of the difficulty to measure low levels of star formation, below roughly $\log(SFR/\text{yr}^{-1}) \sim -12$; but the data demonstrate that both $f_{gas}$ and SFE certainly contribute.
Our analysis is consistent with the results of global studies in which SFE and \( f_{\text{gas}} \) both regulate sSFR (Saintonge et al. 2011a, b, 2017; Huang & Kaufmann 2014; Piotrowska et al. 2019; Zhang et al. 2019). Although \( f_{\text{gas}} \) is the main driver of offsets from the global MS (Saintonge et al. 2012), the distribution of galaxies in the SFR–M* plane also depends on variations in SFE (Saintonge et al. 2016). Our resolved analysis is consistent with \( f_{\text{gas}} \), driving quenching in the central regions of GV galaxies, but we have not ruled out a scenario in which SFE is significantly suppressed and is the main cause of quenching.

A number of mechanisms may reduce the central \( f_{\text{gas}} \). The SIMBA hydrodynamical simulation requires an AGN ejective mode to reproduce the central suppression in sSFR observed in GV galaxies, a success other simulations like ILLUSTRIS and EAGLE have not yet achieved (Appleby et al. 2020). However, quenching in SIMBA is driven by \( f_{\text{gas}} \) in inner regions and SFE in the outskirts. This is inconsistent with our findings. From an observational perspective, while it is natural to invoke large-scale AGN-driven outflows to expel gas and reduce \( f_{\text{gas}} \) (Maiolino et al. 2012), molecular outflow velocities are generally found to be below the escape velocity, therefore raising doubts about their quenching ability (Fluet sch et al. 2019). Furthermore, much of the suppression in \( f_{\text{gas}} \) is driven by the large central bulge rather than reduced gas content (Fig. 2d). Radial profiles of \( \Sigma_{\text{H}} \) tend to increase slightly with decreasing galactocentric radius. This may point towards preventive, rather than ejective feedback. Star-forming galaxies, with their centrally elevated \( \Sigma_{\text{SFR}} \), will subsequently build up their central \( \Sigma_* \), decreasing \( f_{\text{gas}} \). Thus, centrally suppressed \( f_{\text{gas}} \) may simply be a consequence of star formation in a galaxy starved of its gas supply.

AGNs may also suppress SFE by injecting thermal energy directly into the ISM and supporting molecular clouds against gravitational collapse. Magnetic fields and turbulence may provide alternative sources of pressure support (Federrath & Klessen 2012). Finally, the galaxies in our sample have prominent bulges, which may support the disc against gravitational instabilities and suppress SFE (Martig et al. 2009).

James, Bretherton & Knapp (2009) discuss the possibility of bars sweeping out ‘star formation deserts’, often accompanied by excess star formation at the centre of the bar. 7977–12705 and 7990–12704 show the clearest evidence of bars in our sample, and both have the largest central sSFR (Fig. 2). While these central regions have SFE consistent with the other five galaxies, they have increased \( f_{\text{gas}} \), supporting a scenario in which bars encourage the inflow of gas towards a galaxy’s centre (Regan & Teuben 2004).

It is tempting to assess the two drivers, \( f_{\text{gas}} \) and SFE, by comparing their correlations with sSFR (Lin et al. 2017; Ellison et al. 2020). This approach runs into two potential issues. First, it relies on constraining all parameters (sSFR, \( f_{\text{gas}} \), and SFE) throughout the galaxy. Lin et al. (2017), on the other hand, only consider star-forming regions that have emission-line and \(^{12}\text{CO}(1\rightarrow0)\) fluxes exceeding the detection limits. This biases the results towards less quenched regions. Though we have improved the analysis by constraining all radii, some measurements of SFE are upper limits that cannot trivially be included in a correlation analysis. Secondly, the three derived parameters actually rely on only two independent measurements: sSFR and SFE both include a \( \Sigma_{\text{SFR}} \) term, and sSFR and \( f_{\text{gas}} \) both include a \( \Sigma_* \) term. Strong correlations are therefore to be expected. In fact, the strength of the correlation increases as the confounding measurements become more noisy. Correlation analyses should therefore be treated with caution.

In the near future, the ALMAQuest sample will be further expanded, allowing the study of secondary correlations (e.g. the role of stellar mass). HCN observations will also be forthcoming, aimed at directly investigating the true site of star formation: dense molecular gas (Gao & Solomon 2004).

ACKNOWLEDGEMENTS

The authors thank the anonymous referee for their insightful comments that have helped to improve the discussion in this work.
