Abstract—The term stack safety is used to describe a variety of compiler, run-time, and hardware mechanisms for protecting stack memory. Unlike “the heap,” the ISA-level stack does not correspond to a single high-level language concept: different compilers use it in different ways to support procedural and functional abstraction mechanisms from a wide range of languages. This protean nature makes it difficult to nail down what it means to correctly enforce stack safety.

We propose a new formal characterization of stack safety using concepts from language-based security. Rather than treating stack safety as a monolithic property, we decompose it into an integrity property and a confidentiality property for each of the caller and the callee, plus a control-flow property: five properties in all. This formulation is motivated by a particular class of enforcement mechanisms, the “lazy” stack safety micro-policies studied by Roessler and DeHon [1], which permit functions to write into one another’s frames but taint the changed locations so that the frame’s owner cannot access them. No existing characterization of stack safety captures this style of safety; we capture it here by stating our properties in terms of the observable behavior of the system.

Our properties go further than previous formal definitions of stack safety, supporting caller- and callee-saved registers, arguments passed on the stack, and tail-call elimination. We validate the properties by using them to distinguish between correct and incorrect implementations of Roessler and DeHon’s micro-policies using property-based random testing. Our test harness successfully identifies several broken variants, including Roessler and DeHon’s lazy policy; a repaired version of their policy passes our tests.

I. INTRODUCTION

Functions in high-level languages (and related abstractions such as procedures, methods, etc.) are units of computation that invoke one another to define larger computations in a modular way. At a low level, each function activation manages its own local variables, spilled temporaries, etc., as well as information about the caller to which it will return. The call stack is the fundamental data structure used to implement functions, aided by an Application Binary Interface (ABI) that defines how registers are shared between activations.

From a security perspective, attacks on the call stack are attacks on the function abstraction itself. Indeed, the stack is an ancient [2] and perennial [3–8] target for low-level attacks, sometimes involving control-flow hijacking via corrupting the return address, sometimes memory corruption more generally.

The variety in attacks on the stack is mirrored in the range of software and hardware protections that aim to prevent them, including stack canaries [9], bounds checking [10–12], split stacks [13], shadow stacks [14, 15], capabilities [16–20], and hardware tagging [1, 21]. But enforcement mechanisms can be brittle, successfully eliminating one attack while leaving room for others. To avoid an endless game of whack-a-mole, we seek formal properties of safe behavior that can be proven, or at least rigorously tested. Such properties can be used as the specification against which enforcement can be validated—even enforcement mechanisms that do not fulfill a property can benefit from the ability to articulate why and when they may fail.

Many of the mechanisms listed above are fundamentally ill-suited for offering formal guarantees: they may impede attackers, but they do not provide universal protection. Shadow stacks, for instance, aim to “restrict the flexibility available in creating gadget chains” [15], not to categorically rule out attacks. Other mechanisms, such as SoftBound [10] and code-pointer integrity [13], do aim for stronger guarantees, but not formal ones. To our knowledge, the sole line of work making a formal claim to protect stack safety is the study of secure calling conventions by Skorstengaard et al. [19] and Georges et al. [20].

Some of the other mechanisms listed above should also be amenable to strong formal guarantees. In particular, Roessler and DeHon [1] present an array of tag-based micro-policies [22] for stack safety that aim to offer universal protection. But the reasoning involved can be subtle: they include micro-policy optimizations, Lazy Tagging and Lazy Clearing (likely to be deployed together, which we hereafter refer to as Lazy Tagging and Clearing, or LTC). LTC allows function activations to write improperly into one another’s stack frames, but ensures that the owner of the corrupted memory cannot access it afterward, avoiding expensive clearings of the stack frame. Under this policy, one function activation can corrupt another’s memory—just not in ways that affect observable behavior. Therefore, LTC would not fulfill Georges et al.’s property (adapted to the tagged setting). But LTC does arguably enforce stack safety, or as Roessler and DeHon describe it informally, a sort of data-flow integrity tied to the stack. A looser, more observational definition of stack safety
is needed to fit this situation.

We propose here a formal characterization of stack safety based on the intuition of protecting function activations from each other and using the tools of language-based security [23] to treat function activations as security principals. We decompose stack safety into a family of properties describing the integrity and confidentiality of the caller’s local state and the callee’s behavior during (and after) the callee’s execution, together with the well-bracketed control flow (WBCF) property articulated by Skorstengaard et al. [19].

Our properties are stated abstractly in the hope that they can also be applied to other enforcement mechanisms besides LTC. However, it does not seem feasible to give a universal definition of stack safety that applies to all architectures and compilers. While many security properties can be described purely at the level of a high-level programming language and translated to a target machine by a secure compiler, stack safety cannot be defined in this way, since “the stack” is not explicitly present in the definitions of most source languages but rather is implicit in the semantics of features such as calls and returns. But neither can stack safety be described coherently as a purely low-level property; indeed, at the lowest level, the specification of a “well-behaved stack” is almost vacuous. The ISA is not concerned with such questions as whether a caller’s frame should be readable or writable to its callee. Those are the purview of high-level languages built atop the hardware stack.

Thus, any low-level treatment of stack safety must begin by asking: which high-level features are supported in a given setting using the stack, and how does their presence influence the expectation of well-bracketed control flow, confidentiality, and integrity? We begin with a simple system with very few features, then move to a more realistic one supporting tail-call elimination, argument passing on the stack, and callee-saves registers. Our properties are factored so that the basic structure of each of our five properties remains constant while the presence or absence of different features leads to subtler differences in how they behave.

We demonstrate the usefulness of our properties for distinguishing between correct and incorrect enforcement using QuickChick [25], [26], a property-based random testing tool for Coq. Indeed, we find that the published version of LTC is flawed in a way that undermines both integrity and confidentiality; after correcting this flaw, LTC satisfies all of our properties. Further, we modify LTC to protect the features of our more realistic system and apply random testing to validate this extended protection mechanism against the extended properties.

In summary, we offer the following contributions:

- We give a novel characterization of stack safety as a conjunction of security properties—confidentiality and integrity for callee and caller—plus well-bracketed control flow. The properties are parameterized over a notion of external observation, allowing them to characterize lazy enforcement mechanisms.

- We extend these core definitions to describe a realistic setting with argument passing on the stack, callee-saves registers, and tail-call elimination. The model is modular enough that adding these features is straightforward.

- We validate a published enforcement mechanism, Lazy Tagging and Clearing, via property-based random testing, find that it falls short, and propose and validate a fix.

The following section offers a brief overview of our framework and assumptions. Section III walks through a function call in a simple example machine, discusses informally how each of our properties applies to it, and motivates the properties from a security perspective. Section IV formalizes the machine model, its security semantics, and the stack safety properties built on these. Section V describes how to support an extended set of features. Section VII describes the micro-policies that we test, Section VIII the testing framework itself, and Sections IX and X related and future work.

The accompanying artifact [2] contains formal definitions (in Coq) of our properties, plus our testing framework. It does not include proofs, since we use Coq primarily for the QuickChick testing library and to ensure that our definitions are unambiguous. Formal proofs are left as future work.

II. FRAMEWORK AND ASSUMPTIONS

Stack safety properties need to describe the behavior of machine code, but they naturally talk about function activations and stack contents—abstractions that are typically not visible at machine level. To bridge this gap, our properties are defined in terms of a security semantics layered on top of the standard execution semantics of the machine. The security semantics identifies certain state transitions of the machine as security-relevant operations, which update a notional security context. This context consists of an (abstract) stack of function activations, each associated with a view that maps each machine state element (memory location or register) to a security class (active, sealed, etc.) specifying how the activation can access the element. The action of a security-relevant operation on the context is defined by a function that characterizes how the operation’s underlying machine code ought to implement the function abstraction in terms of the stack and registers.

Given the security classes of the elements of the machine state, we define high-level security properties—integrity, confidentiality, and well-bracketed control flow—as predicates that must hold on each call. These predicates draw on the idea of variant states from the theory of non-interference, plus a notion of observable events, which might include specific function calls (e.g., system calls that perform I/O), writes to special addresses representing memory-mapped regions, etc. For example, to show that certain locations are kept secret, it suffices to compare executions starting at machine states which vary at those locations and check that their traces of observable events are the same. This structure allows us to

1 Contrast Azevedo de Amorim et al.’s work on heap safety [24], where the concept of the heap figures directly in high-level language semantics and its security is therefore amenable to a high-level treatment.

2 https://github.com/SNoAnd/stack-safety
talk about the eventual impact of leaks or memory corruption without reference to internal implementation details and, in particular, to support lazy enforcement by flagging corruption of values only when it can actually impact visible behavior.

We introduce these properties by example in Section [III] and formally in Section [IV]. In the remainder of this section we introduce the underlying semantic framework in more detail.

**Machine Model:** We assume a conventional ISA (e.g., RISC-V, x86-64, etc.), with registers including a program counter and stack pointer. We make no particular assumptions about the provenance of the machine code; in particular, we do not assume any particular compiler. If the machine is enhanced with enforcement mechanisms such as hardware tags [21], [27] or capabilities [16], we assume that the behavior of these mechanisms is incorporated into the basic step semantics of the machine, with a notion of “compatible” states that share security behavior that may be defined based on the enforcement mechanism. Failstop behavior by enforcement mechanisms is modeled as stepping to the same state (and thus silently diverging).

**Security Semantics:** A security semantics extends the core machine model with additional context about the identities of current and pending functions (which act as security principals) and about their security requirements on registers and memory. This added context is purely notional; it does not affect the behavior of the core machine. The security context evolves dynamically through the execution of security-relevant operations, which include calls, returns, and frame manipulation. Our security properties are phrased in terms of this context, often as predicates on future states (“when control returns to the current function, X must hold...”) or as relations on traces of future execution (hyper-properties).

Security-relevant operations abstract over the implementation details of the actions they take. Since the same machine instruction may be used by compilers for different purposes, we assume that the compiler or another trusted source has provided labels to identify the security-relevant purpose of each instruction, if any. For instance, in the tagged RISC-V architecture that we use in our examples and tests, calls and returns are conventionally performed using the architecture that we use in our examples and tests, calls and returns, and local memory is introduced in the example in Section [III] and formalized in Section [IV]. An extended set covering simple memory sharing and tail-call elimination is described in Section [V] and tested in Section [VIII]. The remaining operations are needed for the capability-based model in Section [VI].

**Views and Security Classes:** The security context consists of a stack of views, where a view is a function mapping each state element to a security class—one of public, free, active, or sealed.

State elements that are outside of the stack—general-purpose memory used for globals and the heap, as well as the code region and globally shared registers—are always labeled public. We place security requirements on some public elements for purposes of the well-bracketed control flow WBCF property, and a given enforcement mechanism might restrict their access (e.g., by rendering code immutable), but for integrity and confidentiality purposes they are considered accessible at all times.

When a function is newly activated, every stack location that is available for use but not yet initialized is free. From the perspective of the caller, the callee has no obligations regarding its use of free elements.

Arguments are marked active, meaning that their contents may be used safely. When a function allocates memory for its own stack frame, that memory will also be active. Then, on a call, active elements that are not being used to communicate with the callee will become sealed—i.e., reserved for an inactive principal and expected to be unchanged when it becomes active again.

**Instantiating the Framework:** Conceptually, the following steps are needed to instantiate the framework to a specific machine and coding conventions: (i) define the base machine semantics, including any hardware security enforcement features; (ii) identify the set of security-relevant operations and

rules required by the coding conventions; (iii) determine how to label machine instructions with security-relevant operations as appropriate; (iv) specify the form of observable events.

**Threat Model and Limitations:** When our properties are used to evaluate a system, the threat model will depend on the details of that system. However, there are some constraints that our design puts on any system. In particular, we must trust that the security-relevant operations have been correctly labeled. If a compiled function call is not marked as such, then the caller’s data might not be protected from the callee; conversely, marking too many operations as calls may cause otherwise safe programs to be rejected.

We do not assume that low-level code adheres to any single calling convention or is being used to implement any particular source-language constructs. Indeed, if the source language is C, then high-level programs might contain undefined behavior, in which case they might be compiled to arbitrary machine code.

In general, it is impossible to distinguish buggy machine code from an attacker. In examples, we often identify one function or another as an attacker, but our framework does not require any static division between trusted and untrusted code, and we aim to protect even buggy code.

This is a strong threat model, but it does omit some important aspects of stack safety in real systems: in particular, it does not address concurrency. Hardware and timing attacks are also out of scope.

### III. Properties by Example

In this section, we introduce our security properties by means of small code examples, using a simple set of security-relevant operations for calls, returns, and private allocations.

Figure 1 gives C code and possible corresponding compiled 64-bit RISC-V code for a function main, which takes an argument secret and initializes a local variable sensitive to contain potentially sensitive data. Then main calls another function f, and afterward it performs a test on sensitive to decide whether to output secret. Since sensitive is initialized to 0, the test should always fail, and main should instead output the return value of f. Output is performed by writing to the special global out, and we assume that such writes are the only observable events in the system.

The C code is compiled using the standard RISC-V calling conventions [28]. In particular, the function’s first argument and its return value are both passed in a0. Memory is byte addressed, and the stack grows towards lower addresses. We assume that main begins at address 0 and its callee f at address 100. The annotations in the right-hand column are security-relevant operations, described further below. The assembly is a simplified but otherwise typical compilation of the source code into RISC-V; its details are less important than the positions of the security-relevant operations.

Now, suppose that f is actually an attacker seeking to leak secret. It might do so in a number of ways, shown as snippets of assembly code in Fig. 2. Leakage is most obviously viewed as a violation of main’s confidentiality. In Fig. 2a volatile int out;
void main(int secret) {
  int sensitive = 0;
  int res = f();
  if (secret == 42)
    out = secret;
  else
    out = res;
}

In Fig. 2b, f takes an offset from the stack pointer, accesses secret, and directly outputs it. More subtly, even if it is somehow prevented from outputting secret directly, f can instead return its value so that main stores it to out, as in Fig. 2b. Beyond simply reading secret, the attacker might overwrite sensitive with 42, guaranteeing that main publishes its own secret unintentionally (Fig. 2c), this does not violate main’s confidentiality, but rather its integrity. In Fig. 2d, the attacker arranges to return to the wrong instruction, thereby bypassing the check and publishing secret regardless; this violates the program’s well-bracketed control flow (WBCF). In Fig. 2e, a different attack violates WBCF, this time by returning to the correct program counter but with the wrong stack pointer. (We pad some of these variants with nops just so that all the snippets have the same length, which keeps the step numbering uniform in Fig. 3.)

The security semantics for this program is based on the security-relevant events noted in the right columns of Figs. 1 and 2; namely execution of instructions that allocate or deallocate space (specified by an SP-relative offset and size), make a call (with a specified list of argument registers), or make a

```
volatile int out;
void main(int secret) {
  int sensitive = 0;
  int res = f();
  if (secret == 42)
    out = secret;
  else
    out = res;
}
```

![Fig. 1: Example: C and assembly code for main and layout of its stack frame (the stack grows to the left).](image)
Our security semantics attaches a security context to the machine state, consisting of a view $V$ and a stack $σ$ of pending activations’ views. Figure 3 shows how the security context evolves over the first few steps of the program. (The formal details of the security semantics are described in Section $\Gamma$ and the context evolution rules are formalized in Fig. 7.) Execution begins at the start of main, with the program counter ($PC$) set to zero and the stack pointer ($SP$) at address 1000. State transitions are numbered and may be labeled with a security operation, written $\downarrow ψ$, between steps.

The initial view $V_0$ maps all stack addresses below $SP$ to $free$ and the remainder of memory to $public$. The sole used argument register, $a0$, is mapped to $active$; other caller-save registers are mapped to $free$ and callee-save registers to $sealed$. Step 1 allocates a word each for $secret$, $sensitive$, and $res$, as well as two words for the return address; this has the effect of marking those bytes $active$. We use $V[...]$ to denote updates to $V$.

At step 5, the current principal’s record is pushed onto the inactive list. The callee’s view is updated from the caller’s such that all $active$ memory locations become $sealed$. (For now we assume no sharing of stack memory between activations; data is passed only through argument registers, which remain active. In the presence of memory sharing, some memory would remain active, too.) Function $f$ does not take any arguments; if it did, any registers containing them would be mapped to $active$, while any non-argument, caller-saved registers are mapped to $free$. In the current example, only register $a0$ changes security class. All callee-save registers remain $sealed$ for all calls, so if, in the example, we varied the assembly code for main so that $secret$ was stored in a callee-save register (e.g., $s0$) rather than in memory, its security class would still be $sealed$ at the entry to $f$. At step 9, $f$ returns and the topmost inactive view, that of main, is restored.

We now show how this security semantics can be used to define notions of confidentiality, integrity, and correct control flow in such a way that many classes of bad behavior, including the attacks in Fig. 2, are detected as security violations.

Well-Bracketed Control Flow: To begin with, if $f$ returns to an unexpected place (i.e., $PC \neq 20$ or $SP \neq 980$), we say that it has violated WBCF. WBCF is a relationship between call steps and their corresponding return steps: just after the return, the program counter should be at the next instruction below the call, and the stack pointer should have the same value that it had before the call. Both of these are essential for security. In Fig. 2d the attacker adds 16 to the return address and then returns; this bypasses the if-test in the code and outputs $secret$. In Fig. 2e the attacker returns with $SP' = 988$ instead of the correct $SP = 980$. In this scenario, given the layout of main’s frame,

\[
\begin{array}{cccccc}
\text{res} & \text{sens} & \text{sec} & \text{ra}_1 & \text{ra}_2 \\
\downarrow & \downarrow \\
\end{array}
\]

main’s attempt to read $secret$ may instead read part of the return address, and its attempt to output $res$ will instead output $secret$.

Before the call, the program counter is 16 and the stack pointer is 980. So we define a predicate on states that should hold just after the return: $Ret m \triangleq m[PC] = 20 \land m[SP] = 980$. We can identify the point just after the return (if a return occurs) as the first state in which the pending call stack is smaller than it was just after the call. WBCF requires that, if $m$ is the state at that point, then $Ret m$ holds. This property is formalized in Table 11 line 1.

Stack Integrity: Like WBCF, stack integrity defines a condition at the call that must hold upon return. This time the condition applies to all of the memory in the caller’s frame. In Fig. 3 we see the lifecycle of an allocated frame: upon allocation, the view labels it $active$, and when a call is made, it instead becomes $sealed$. Intuitively, the integrity of $main$ is preserved if, when control returns to it, any $sealed$ elements are identical to when it made the call. Again, we need to know when a caller has been returned to, and we use the same mechanism of checking the depth of the call stack. In the case of the call from main to $f$, the $sealed$ elements
are the addresses 980 through 999 and callee-saved registers such as the stack pointer. Note that callee-saved registers often change during the call—but if the caller accesses them after the call, it should find them restored to their prior value.

While it would be simple to define integrity as “all sealed elements retain their values after the call,” this would be stricter than necessary. Suppose that a callee overwrites some data of its caller, but the caller never accesses that data (or only does so after re-initializing it). This would be harmless, with the callee essentially using the caller’s memory as scratch space, but the caller never seeing any change.

For a set of elements \( K \), a pair of states \( m \) and \( n \) are \( K \)-variants if their values an only disagree on elements in \( K \). We say that the elements of \( K \) are irrelevant in \( m \) if they can be replaced by arbitrary other values without changing the observable behavior of the machine. All other elements are relevant.\(^3\)

We define caller integrity (CLR1) as the property that every relevant element that is sealed under the callee’s view is restored to its original value at the return point. (This property is formalized in Table II line 2).

In our example setting, the observation trace consists of the sequence of values written to \( \text{out} \). In Fig. 2c the states before and after the call differ in the value of sensitive. Figure 2 shows the states before and after the call, which disagree on the value at sensitive. If we consider a variant of the original return state in which sensitive is 0 (orange) as opposed to 42 (blue), that state will eventually output 1, while the actual execution outputs 5. This means that sensitive is relevant.

\( ^3 \) This story is slightly over-simplified. If an enforcement mechanism maintains additional state associated with elements, such as tags, we don’t want that state to vary. This is touched on in Section IV-D.

To be more explicit, similar to WBCF, we define \( \text{Int} \) as a predicate on states that holds if all relevant sealed addresses in \( m \) are the same as after step 5. We require that \( \text{Int} \) hold on the state following the matching return, which is reached by step 9. Here sensitive has obviously changed, but we just saw that it is relevant.

**Caller Confidentiality:** We treat confidentiality as a form of non-interference as well: the confidentiality of a caller means that its callee’s behavior is dependent only on publicly visible data, not the caller’s private state. This also requires that the callee initialize memory before reading it. As we saw in the examples, we must consider both the observable events that the callee produces during the call and the changes that the callee makes to the state that might affect the caller after the callee returns.

---

**Fig. 3:** Execution of example up through the return from \( f \). In stack diagrams, addresses increase to the right, stack grows to the left, and boxes represent 4-byte words.

**Fig. 4:** Integrity Violation: sensitive changed, and if varied, changes future outputs.
and has not changed during the call, which does not represent
which the variant states disagree must carry some information
derived from the original varied elements. In most cases, that
is because the element is one of the original varied elements
and has not changed during the call, which does not represent
Confidentiality (formalized in Table II, line 3a).

Consider the state after step 5, shown at the top of Fig. 5
with the attacker code from Fig. 2a and the assumption that
secret has the value 5. We take a variant state over the set
of elements that are sealed in V2 (orange), and compare it to
the original (blue). During the execution, the value of secret
is written to the output, and the information leak is evidenced
by the fact that the outputs do not agree—the original outputs
5, while the variant outputs 3. This is a violation of internal
confidentiality (formalized in Table II, line 3).

But, in Fig. 2b we also saw an attacker that exfiltrated the
secret by reading it and then returning it, in a context where
the caller would output the returned value. Figure 6 shows
the behavior of the same variants under this attacker, but in
this case, there is no output during the call. Instead the value
of secret is extracted and placed in a0, the return value
register.

At the end of the call, we can deduce that every element on
which the variant states disagree must carry some information
derived from the original varied elements. In most cases, that
is because the element is one of the original varied elements
and has not changed during the call, which does not represent
a leak. But in the case of a0, it has changed during the call, and
the return states do not agree on its value. This represents
data that has been leaked, and should not be used to affect
future execution. Unless a0 happens to be irrelevant to the
caller, this example is a violation of what we term return-time
confidentiality (formalized in Table II, line 3b).

Structurally, return-time confidentiality resembles integrity,
but now dealing with variants. We begin with a state immedi-
ately following a call, m. We consider an arbitrary variant
state, n, which may vary any element that is sealed or free, i.e.,
any element that is not used legitimately to pass arguments.
Caller confidentiality therefore can be thought of as the callee’s
insensitivity to elements in its initial state that are not part of
the caller-callee interface.

We define a binary relation Conf on pairs of states, which
holds on eventual return states m' and n' if all relevant elements are uncorrupted relative to m and n. An element is
corrupted if it differs between m' and n', and it either changed
between m and m' or between n and n'.

Finally, we define caller confidentiality (CLRC) as the com-
bination of internal and return-time confidentiality (Table II,
line 3).

The Callee’s Perspective: We presented our initial ex-
ample from the perspective of the caller, but a callee may
also have privilege that its caller lacks, and which must be
protected from the caller. Consider a function that makes a
privileged system call to obtain a secret key, and uses that
key to perform a specific task. An untrustworthy or erroneous
caller might attempt to read the key out of the callee’s memory
after return, or to influence the callee to cause it to misuse the
key itself!

Where the caller’s confidentiality and integrity are con-
cerned with protecting specific, identifiable state—the caller’s
stack frame—their callee equivalents are concerned with en-
forcing the expected interface between caller and callee. Com-
munication between the principals should occur only through
the state elements that are designated for the purpose: those
labeled public and active.

Applying this intuition using our framework, callee con-
fidentiality (CLEC) turns out to resemble CLRI, extended to
every element that is not marked active or public at call-time.
The callee’s internal behavior is represented by those elements
that change over the course of its execution, and which are not
part of the interface with the caller. At return, those elements
should become irrelevant to the subsequent behavior of the
caller.

Similarly, in callee integrity (CLEI), only elements marked
active or public at the call should influence the behavior of the
callee. It may seem odd to call this integrity, as the callee does
not have a private state. But an erroneous callee that performs
a read-before-write within its stack frame, or which uses a
non-argument register without initializing it, is vulnerable to
its caller seeding those elements with values that will change
its behavior. The fact that well-behaved callees have integrity
by definition is probably why callee integrity is not typically
discussed.
IV. Formalization

We now give a formal description of our machine model, security semantics, and properties. Our definitions abstract over: (i) the details of the target machine architecture and ABI, (ii) the set of security-relevant operations and their effects on the security context, (iii) the set of observable events, and (iv) a notion of value compatibility.

A. Machine

The building blocks of a machine are words and registers. Words are ranged over by $w$ and, when used as addresses, $a$, and are drawn from the set $W$. Registers in the set $R$ are ranged over by $r$, with the stack pointer given the special name $SP$; some registers may be classified as caller-saved (CLR) or callee-saved (CLE). Along with the program counter, $PC$, these are referred to as state elements $k$ in the set $K ::= PC|W|R$.

A machine state $m \in M$ is a map from state elements to a set $V$ of values. Each value $v$ contains a payload word, written $|v|$. We write $m[k]$ to denote the value of $m$ at $k$ and $m[|v|]$ as shorthand for $m[|v|]$. Depending on the specific machine being modeled, values may also contain other information relevant to hardware enforcement (such as a tag). When constructing variants (see Section IV-D) this additional information should not be varied. To capture this idea, we assume a given compatibility equivalence relation $\sim$ on values, and lift it element-wise to states. Two values should be compatible if their non-payload information (e.g., their tag) is identical.

The machine has a step function $m \xrightarrow{\psi,e} m'$. Except for the annotations over the arrow, this function just encodes the usual ISA description of the machine’s instruction set. The annotations serve to connect the machine’s operation to our usual ISA description of the machine’s instruction set. The state elements are referred to as their non-payload information (e.g., their tag) is identical.

B. Security semantics

The security semantics operates in parallel with the machine. Each state element (memory word or register) is given a security class $l \in \{\text{public}, \text{active}, \text{sealed}, \text{free}\}$. A view $V \in VIEW$ maps elements to security classes. For any security class $l$, we write $l(V)$ to denote the set of elements $k$ such that $V k = l$. The initial view $V_0$ maps all stack locations to $\text{free}$, all other locations to $\text{public}$, and registers based on which set they belong to: $\text{sealed}$ for callee-saved, $\text{free}$ for caller-saved except for those that contain arguments at the start of execution, which are active, and public otherwise.

A (security) context is a pair of the current activation’s view and a list of views representing the call stack (pending inactive principals), ranged over by $\sigma$.

$$e \in C ::= VIEW \times \set{\text{list VIEW}}$$

The initial context is $\alpha_0 = (V_0, \varepsilon)$.

Section III describes informally how the security context evolves as the system performs security-relevant operations. Formally, we combine each machine state with a context to create a combined state $s = (m, c)$ and lift the transition to $\Rightarrow$ on combined states. At each step, the context updates based on an assumed given function $Op : M \rightarrow C \rightarrow \Psi \rightarrow C$. Since a single step might correspond to multiple operations, we apply $Op$ as many times as needed, using foldl.

$$m \xrightarrow{\psi,c} m' \xrightarrow{\text{foldl}} (Op m) c \psi = c'$$

$$ Op m \xrightarrow{\text{return}} (\_ (V, \sigma')) = (V, \sigma') $$

Fig. 7: Basic Operations

C. Events and Traces

We abstract over the events that can be observed in the system, assuming just a given set $EVENTS$ that contains at least the element $\tau$, the silent event. Other events might represent certain function calls (i.e., system calls) or writes to special addresses representing memory-mapped regions. A trace is a nonempty, finite or infinite sequence of events, ranged over by $\mathcal{E}$. We use “::” to represent “cons” for traces, reserving “::” for list-cons.

We are particularly interested in traces that end just after a function returns. We define these in terms of the depth $d$ of the security context’s call stack $\sigma$. We write $d \rightsquigarrow s$ for the trace of execution from a state $s$ up to the first point where the stack depth is smaller than $d$, defined inductively by these rules:

$$ |\sigma| < d \Rightarrow d \rightsquigarrow (m, (V, \sigma)) = \tau \quad \text{DONE}$$
\[ |\sigma| \geq d \quad d \rightarrow (m', c') = \mathcal{E} \]

\[
\text{STEP} \quad (m, (V, \sigma)) \xrightarrow{(m', c')} (d \Rightarrow (m, (V, \sigma))) = e \cdot \mathcal{E}
\]

When \( d = 0 \), the trace will always be infinite because the machine never halts; in this case we omit \( d \) and just write \( \Downarrow \).

Two event traces \( \mathcal{E}_1 \) and \( \mathcal{E}_2 \) are similar, written \( \mathcal{E}_1 \approx \mathcal{E}_2 \), if the sequence of non-silent events is the same. That is, we compare up to deletion of \( \tau \) events. Note that this results in an infinite silent trace being similar to any trace. So, a trace that silently diverges due to a failstop will be vacuously similar to all other traces.

\[ \mathcal{E} \approx \mathcal{E} \quad \text{SIMREFL} \]

\[ \mathcal{E}_1 \approx \mathcal{E}_2 \quad \text{SIMLEFT} \]

\[ \tau \cdot \mathcal{E}_1 \approx \mathcal{E}_2 \quad \text{SIMRIGHT} \]

D. Variants, corrupted sets, and “on-return” assertions

Two (compatible) states are variants with respect to a set of elements \( K \) if they agree on the value of every element not in \( K \). Our notion of non-interference involves comparing the traces of such \( K \)-variants. We use this to define sets of irrelevant elements. Recall that \( \approx \) is a policy-specific compatibility relation.

Definition 1. The difference set of two machine states \( m \) and \( m' \), written \( \Delta(m, m') \), is the set of elements \( k \) such that \( m[k] \neq m'[k] \).

Definition 2. Machine states \( m \) and \( n \) are \( K \)-variants, written \( m \approx_K n \), if \( m \sim n \) and \( \Delta(m, n) \subseteq K \).

Definition 3. An element set \( K \) is irrelevant to state \((m, c)\), written \((m, c) \parallel K\), if for all \( n \) such that \( m \approx_K n \), \( \Downarrow (m, c) \approx \Downarrow (n, c) \).

When comparing the behavior of variant states, we need a notion of how their differences have influenced them.

Definition 4. The corrupted set \( \hat{\Delta}(m, m', n, n') \) is the set \((\Delta(m, m') \cup \Delta(n, n')) \cap \Delta(m', n') \).

If we consider two execution sequences, one from \( m \) to \( m' \) and the other from \( n \) to \( n' \), then \( \hat{\Delta}(m, m', n, n') \) is the set of elements that change in one or both executions and end up with different values. Intuitively, this captures the effect of any differences between \( m \) and \( n \), i.e., the set of values that are “corrupted” by those differences.

Our “on-return” assertions are defined using a second-order logical operator \( d \rightarrow P \), pronounced “\( P \) holds on return from depth \( d \)” where \( P \) is a predicate on machine states. This is a coinductive relation similar to “weak until” in temporal logic—it also holds if the program never returns from depth \( d \).

\[ |\sigma| < d \quad (d \Rightarrow P) (m, (V, \sigma)) \quad \text{RETURNED} \]

Similarly, we give an analogous binary relation for use in confidentiality. We define \( \uparrow \) so that \((m, c) (d \Rightarrow R) \) \((m', c') \) holds if \( R \) holds on the first states that return from depth \( d \) after \((m, c) \) and \((m', c') \). Once again, \( \uparrow \) is coinductive.

\[ |\sigma| < d \quad (d \Rightarrow P) (m, (V, \sigma)) \quad \text{RETURNED} \]

E. Properties

Finally, the core property definitions are given in Table I arranged to show their commonalities and distinctions. Each definition gives a criterion quantified over states \( s \) that immediately follow call steps. If an execution includes a transition \( s' \xrightarrow{\tau} s \) where call \( a \tau \in \hat{\psi} \), then \( s \) is the target of a call. As a shorthand, we write that each property is defined by a criterion that must hold “for all call targets \( s \)” or, in the case of WBCF, “for all call steps \( s \Rightarrow s' \)”.

1. WBCF: Given a call step \((m, (V, \sigma)) \Rightarrow (m', (V', \sigma'))\), we define the predicate \( \text{Ret} \) to hold on states \( m'' \) whose stack pointer matches that of \( m \) and whose program counter is at the next instruction. A system enjoys WBCF if, for every call transition, \( \text{Ret} \) holds just after the callee returns (i.e., the call stack shrinks).

2. CLRI: When the call target is \((m, (V, \sigma))\), we define the predicate \( \text{Int} \) to hold on states \( m' \) if all elements that are both sealed in \( V \) and in the difference set between \( m \) and \( m' \) are irrelevant. A system enjoys CLRI if, for every call, \( \text{Int} \) holds just after the corresponding return.

3. CLRC: When the call target is \((m, (V, \sigma))\), we begin by taking an arbitrary \( n \) that is a \( K \)-variant of \( m \), where \( K \) is the set of sealed elements in \( V \). We require that two clauses hold. On line 3a, the behavior of a trace from \((m, (V, \sigma)) \) up to its return must match that of \((n, (V, \sigma)) \). On line 3b, we define a relation \( \text{Conf} \) that relates states \( m' \) and \( n' \) if their corrupted set (relative to \( m \) and \( n \)) is irrelevant, and require that it hold just after the returns from the callees that start at \((m, (V, \sigma)) \) and \((n, (V, \sigma)) \). A system enjoys CLRC if both clauses hold for every call.

4. CLEC: We consider the callee’s private behavior to be any changes that it makes to the state outside of legitimate channels—elements marked active or public. The remainder should be kept secret, which is to say, irrelevant to future execution. Similar to CLRI, given a call target \((m, (V, \sigma))\), we define a predicate \( \text{CConf} \) to hold on states \( m' \) if the difference set between \( m \) and \( m' \), excluding active or public locations,
is irrelevant. A system enjoys CleC if, for every call, CConf holds just after the corresponding return.

5. CleI: Callee integrity means that the caller does not influence the callee outside of legitimate operations. The caller’s influence can be seen internally, or in corrupted data on return, just after the corresponding return.

The rules for the extended security semantics are given in Fig. 4; the rules in Fig. 3 can be recaptured by instantiating call with $\text{sp}$ as the empty set, and alloc with flag f.

A. Sharing Stack Memory

In our examples, we have presented a vision of stack safety in which the interface between caller and callee is in the registers that pass arguments and return values. This is frequently not the case in a realistic setting. Arguments may be passed on the stack because there are too many to pass in registers, as variadic arguments, or because they are composite types that inherently have pass-by-reference semantics. The caller may also pass a stack-allocated object by reference in the C++ style, or take its address and pass it as a pointer.

We refine our call operation to make use of the information that we have about which stack memory locations contain arguments. The new annotation $\text{sp}$ is a set of triples of registers, an offset from the value of that register, and a size. We first define the helpful set $\text{sp}$, then extend the call operation to keep all objects in $\text{sp}$ marked as active and seal everything else (Fig. 5).

Using this mechanism, a call-by-value argument passed on the stack at an $\text{sp}$-relative offset is specified by the triple $\text{sp, off, sz}$. In this case, only the immediate callee gains access to the argument location. A C++-style call-by-reference argument where the reference is passed in r is instead specified by the triple $(r, 0, \text{sz})$. Such a call-by-reference argument could be passed through multiple calls, provided that it is in $\text{sp}$ each time.

TABLE II: Properties

| Rule | Description |
|------|-------------|
| 1 WBCF $\equiv (|\sigma| \uparrow \text{Ret}) (m', (V', \sigma'))$ | where $\text{Ret} m'' \equiv m'[\text{sp}] = m[\text{sp}]$ and $m''[\text{pc}] = m[\text{pc}] + \text{sz}$ for all calls $(m, (V, \sigma)) \rightarrow (m', (V', \sigma'))$ where sz is the size of instruction at m[pc] |
| 2 ClrI $\equiv (|\sigma| \uparrow \text{Int}) (m, (V, \sigma))$ | where $\text{Int} m' \equiv m' \parallel (\text{sealed}(V) \cap \Delta(m, m'))$ for all call targets $(m, (V, \sigma))$ |

| 4 CleC $\equiv (|\sigma| \uparrow \text{CConf}) (m, (V, \sigma))$ | where $\text{CConf} m' \equiv m' \parallel (\Delta(m, m') - K)$ for all call targets $(m, (V, \sigma))$ |
| 5 CleI $\equiv \forall n \text{ s.t. } m \equiv K n$, where $K = K - (\text{public}(V) \cup \text{active}(V))$ | for all call targets $(m, (V, \sigma))$ |

VI. PROVENANCE, CAPABILITIES, AND PROTECTING OBJECTS

Lastly, what if we want to express a finer-grained notion of safety, in which stack objects are protected unless the function that owns them intentionally passes a pointer to them? This can be thought of as a capability-based notion of security. Capabilities are unforgeable tokens that grant access to a region of memory, typically corresponding to valid pointers to that region. As such, this capability safety relies on some preexisting notion of pointer validity, i.e., pointer provenance. Memarian et al.’s PVI [29] (provenance via integer) memory model is a good option: it annotates pointers with the
\[ K = \text{range } \pi \text{ off sz m } \cap \text{free}(V) \]
\[ V' = V[a \mapsto \text{active } | \ a \in K] \]
\[ \text{Op m } (\text{alloc f (off, sz)}) (V, \sigma) = (V', \sigma) \]  
\[ \text{ALLOCF} \]

(b) Calls with Argument Passing on the Stack

Fig. 8: Operations supporting tail calls and argument passing on stack.

We implement and test two micro-policies inspired by Roessler and DeHon [1]: Depth Isolation without lazy optimizations (DI) and with both Lazy Tagging and Lazy Clearing optimizations (LTC). (The connection between our properties and Roessler and DeHon’s work is discussed below.) They share a common structure: each function activation is assigned a “color” \( n \) representing its identity. Stack locations belonging to that activation are tagged STACK \( n \), and while the activation is running, the tag on the program counter (PC tag) is PC \( n \). Stack locations not part of any activation are tagged UNUSED.

In DI, \( n \) always corresponds to the depth of the stack when the function is called. A function must initialize its entire frame upon entry in order to tag it, and then clear the frame before returning. During normal execution, the micro-policy rules only permit load and store operations when the target memory is tagged with the same depth as the current PC tag, or, for store operations, if the target memory is tagged UNUSED.

In LTC, a function neither initializes the frame at entry nor clears it at exist; instead, it simply sets each location’s tag to the PC tag when that location is written. It does not check if those writes are legal! If the PC tag is PC \( n \), then any stack location that receives a store will be tagged STACK \( n \). On a load, the micro-policy failstops if the source memory location is tagged UNUSED or STACK \( n \) for some \( n \) that doesn’t match the PC tag.
To implement this discipline, *blessed instruction sequences* appear at the entry and exit of each function, which manipulate tags as just described while performing the usual tasks of saving/restoring the return address to/from the stack and adjusting the stack pointer. A blessed sequence uses further tags to guarantee that the full sequence executes from the beginning—no jumping into the middle.

**Applicability to Roessler & DeHon [1]:** Roessler and DeHon (henceforward R&D) R&D differentiate between memory safety policies (without lazy optimization) and *data-flow integrity* policies (with lazy optimization). Our properties are phrased in terms of data flow, and we apply them to both optimized and non-optimized Depth Isolation. R&D do not attempt to define explicit formal properties, but they do list the behaviors that they expect their data-flow integrity policies to prevent, namely: reads from sealed objects (our CLR), writes to sealed objects if they are later read (our CLR1), and reads from deallocated objects (our CLEC). They also note that Lazy Clearing prevents uninitialized reads, which corresponds roughly to our CLE1.

R&D note a flaw in Depth Isolation: because function activations are identified by depth, a dangling pointer into a stack frame might be usable when a new frame is allocated at the same depth. Our testing does not discover this flaw, because we do not test address-taken objects, but it discovers a related flaw under Lazy Tagging and Clearing that does not require an object’s address to be taken. If an activation reads a location that was previously written by an earlier activation at the same depth, it will violate callee confidentiality. If that location was in a caller’s frame, it also violates caller integrity and confidentiality.

They propose addressing the dangling-pointer issue by tracking both the depth of the current activation and the static identity of the active function. This would not eliminate all instances of this issue, but it would require the confidentiality-violating activation to be of the same function that wrote the data in the first place, which is a significantly higher bar. We propose instead tracking every activation uniquely, which should eliminate the issue entirely—and does in our tests.

**Protecting Registers:** R&D do not need to protect registers, since they include the compiler in their trusted computing base, but we target threat models that do not. In particular, CLRI requires callee-saved registers to be saved and restored properly. We extend DI and LTC so that callee-saved registers are also tagged with the color of the function that is using them. In DI they are tagged as part of the entry sequence, while in LTC they are tagged when a value is placed in them.

**VIII. Validation through Random Testing**

There are several ways to evaluate whether an enforcement mechanism enforces the above stack safety properties. Ideally such validation would be done through formal proof over the semantics of the enforcement-augmented machine. However, while there are no fundamental barriers to producing such a proof, it would be considerable work to carry out for a full ISA like RISC-V and complex enforcement mechanisms like Roessler and DeHon’s micro-policies. We therefore choose to systematically test their Depth Isolation and Lazy Per-Activation Tagging and Clearing micro-policies.

We use a Coq specification of the RISC-V architecture [30], extend it with a runtime monitor implementing a stack safety micro-policy, and test it using QuickChick [26], a randomized
property-based testing framework. QuickChick works by generating random programs, executing them, and checking that they fulfill our criteria.

Such testing is sound—it will not produce false positives—but necessarily incomplete. We might test a flawed policy but fail to generate a program that exploits the flaw. Additionally, detecting violations of noninterference-style properties is dependent on choosing appropriate variant states, so it is possible to generate a dangerous program but have it pass the test due to variant selection. We increase our confidence in our test coverage by mutation testing, in which we intentionally inject flaws into the policies and demonstrate that testing can find them.

A. Test Generation

To use QuickChick, we develop random test-case generators that produce an initial RISC-V machine state tagged appropriately for the micro-policy (see Section VII), including a code region containing a low-level program. They also produce the meta-information about how instructions in that program map to security-relevant operations, which would normally be provided by the compiler.

Our generators build on the work of Hritcu et al. [31], [32], which introduced generation by execution, a technique that produces programs that lead to longer executions—and hopefully towards more interesting behaviors as a result. Each step of generation by execution takes a partially instantiated machine state and attempts to generate an instruction that makes sense locally (e.g., jumps go to a potentially valid code location, loads read from a potentially valid stack location). The generator repeats this process for an arbitrary number of steps, or until it reaches a point where the machine cannot step any more. Each time it generates a call or return, it places the appropriate policy tags on the relevant instruction(s) and records the operation.

We extend Hritcu et al.’s technique with additional statefulness to avoid early failstops. For example, immediately after a call, we increase the probability of generating code that initializes any stack-allocated variables. To allow for potential attack vectors to manifest, the generator periodically relaxes those constraints and generates potentially ill-formed code, such as failing to initialize variables, writing outside of the current stack frame, or attempting an ill-formed return sequence.

B. Property-based Testing

Once a test program is generated, QuickChick tests it against a property. A typical hyperproperty testing scheme might do this by generating a pair of initial variant states, executing them to completion, and comparing the results. We extend this procedure to handle the nested nature of confidentiality.

For our setup to naively test the confidentiality of every call, it would need to create a variant state at each call point, execute it until return, then generate a post-call variant based on any tainted values. The post-call variant would execute alongside the “primary” execution until the test is finished. This results in tracking a number of variant executions that is linear in the total number of calls!

For better performance, we instead maintain a single execution that combines all of the variants that would be spawned at returns. So, at any given time, we need only simulate (1) the original execution, (2) the tainted execution, and (3) one variant execution for each call on the call stack. This approach makes testing longer executions substantially faster, at the cost of making it harder to identify which call is the source of a failure.

C. Mutation Testing

To ensure the effectiveness of testing against our formal properties, we use mutation testing [33] to inject errors (mutations) in a program that should cause the property of interest (here, stack safety) to fail, and ensure that the testing framework can find them. The bugs we use for our evaluation are either artificially generated by us (deliberately weakening the micro-policy in ways that we expect should break its guarantees), or actual bugs that we discovered through testing our implementation. We elaborate on some such bugs below.

For example, when loading from a stack location, Depth Isolation needs to enforce that the tag on the location being read is STACK $n$ for some number $n$ and that the tag of the current PC is PC $n$ for the same depth $n$. We can relax that restriction by omitting the check (bug LOAD_NO_CHECK). Similarly, when storing to a stack location, the correct micro-policy needs to ensure that the tag on the memory location is either UNUSED or has again the same depth as the current PC tag. Relaxing that constraint causes violations to the integrity property (bug STORE_NO_CHECK).

In additional intentional mutations, our testing catches errors in our own implementation of the enforcement mechanism, including one interesting bug where the initial function’s frame included space allocated for its return address, but this uninitialized (and therefore UNUSED-tagged) space was treated as private data but left unprotected. We added this to our set of mutations as HEADER_NO_INIT.

For LTC, the original micro-policy, implemented as PER_DEPTH_TAG, fails in testing, in cases where data is leaked between sequential calls. To round out our mutation testing we also check LOAD_NO_CHECK, equivalent to its counterpart in depth isolation, and a version where stores succeed but fails to propagate the PC tag, STORE_NO_UPDATE.

The mean-time-to-failure (MTTF) and average number of tests for various bugs can be found in Table [III] along with the average number of tests it took to find the failure. Experiments were run in a desktop machine equipped with i7-4790K CPU @ 4.0GHz with 32GB RAM.

IX. RELATED WORK

The centrality of the function abstraction and its security are behind the many software and hardware mechanisms proposed for its protection [11, 20–21]. Many enforcement techniques focus purely on WBCF; others combine this with some degree of memory protection, chiefly focusing on integrity. Roessler
and DeHon’s \textit{Depth Isolation} and \textit{Lazy Tagging and Clearing} \cite{LRC} both offer protections corresponding to WBCF, CLRI, and CLRC, though they do not give a formal description of this. They are generally not concerned with protecting callees.

To our knowledge, the only other line of work that aims to rigorously characterize the security of the stack is the StkTokens-Cerise family of CHERI-enforced secure calling conventions \cite{LRC1, LRC2, LRC3}. The authors define stack safety as overlay semantics and related stack safety properties, phrased in terms of logical relations instead of trace properties. Originally, they define an informal notion of stack safety as the combination of WBCF and “local state encapsulation” \cite{LRC2}, and describe the latter in terms of integrity only (but it has confidentiality, equivalent to CLRI and CLRC). StkTokens \cite{LRC2} makes this conception of stack safety explicit through an overlay semantics which (1) on call mints new a stack frame from a capability representing the available stack space, and (2) on return merges the current frame back into the stack capability, under the assumption that there are no capabilities left on the stack. The underlying unary logical relation does not capture confidentiality proper, although it does capture some of its facets.

Their latest paper \cite{LRC3} was inspired by the properties presented in this paper to extend their formalism to include confidentiality through a binary logical relation. When checking if our properties applied to their old calling convention, they noted that it did not enforce CLEC, and made sure that their new version would in addition to building it into their formalism.\footnote{A. L. Georges, personal communication.} To do so, they redesign the overlay semantics to actually pop stack frames on return and have them disappear from the stack. This demonstrates the benefit of our choice to explicitly state properties in security terms: specifying security is hard, and when the spec takes the form of a “correct by construction” machine, it is easy to neglect a non-obvious security requirement.

In terms of direct feature comparison with Georges et al. \cite{LRC3} (the most recent work in the line), with the addition of confidentiality to their formalism, we are roughly at parity in terms of the expressiveness of our properties. We have additionally proposed callee-integrity, but it is probably the least practical of our properties. We extend our model to tailcalls, which they do not, and to the passing of pointers to stack objects. They discuss stack objects and the interaction between stack and heap, but their calling convention does not guarantee safety in the presence of pointer passing without additional checks. We test a limited degree of pointer passing, which does not guarantee memory safety for the passed pointer but which does not undermine the security of its frame, and we offer an untested formalism for memory-safe passing of pointers. On the other hand, their properties are validated by proof, while ours are only tested.

### X. Future Work

We plan to test our properties against multiple enforcement mechanisms. The top priority is capability machines, namely CHERI \cite{cheri}, a modern architecture designed to provide efficient fine-grained memory protection and compartmentalization. We want to test the most recent work by Georges et al. \cite{LRC3}, which is designed to enforce analogues of all of our properties except for CLEI.

It would also be interesting to test a software enforcement approach. Under a bounds checking discipline \cite{bounds}, all the pointers in a program are extended with some disjoint metadata used to gate memory accesses. These approaches enforce a form of \textit{memory safety}, and we would therefore expect them to enforce CLRI and CLRC. They aim to enforce WBCF by cutting off attacks that involve memory-safety violations, but that may not be sufficient. Bounds checking approaches require substantial compiler cooperation. This is not a problem for our properties in general, but it is not very compatible with generation-by-execution of low-level code. A better choice might be to generate high-level code using a tool like CSmith \cite{smith}, or prove the properties instead.

Several popular enforcement mechanisms are not designed to provide absolute guarantees of security. For example, stack canaries \cite{canary} and shadow stacks \cite{shadow, shadow2} are chiefly hardening techniques: they increase the difficulty of some control-flow attacks on the stack, but cannot provide absolute guarantees on WBCF under a normal attacker model. Interestingly, these are lazy enforcement mechanisms, in that the attack may occur and be detected some time later, as long as it is detected before it can become dangerous. That would make our observation-based formalism a good fit for defining their security, if we could find a formal characterization of what they do achieve (perhaps in terms of a base machine with restricted addressing power).

We have preliminary work on extending our model to handle C++-style exceptions, which, like tailcalls, obey only a weakened version of WBCF. We are also exploring extensions to concurrency, starting with a model of statically allocated coroutines. These extensions will also require non-trivial testing effort. We also plan to test the model in Section \ref{sec:future} for arbitrary memory-safe pointer sharing.
