Adipose triglyceride lipase
Triacylglycerol
Lipotoxicity
Mitochondrial function

A B S T R A C T

Lipolysis is defined as the catabolism of triacylglycerols (TGs) stored in cellular lipid droplets. Recent discoveries of essential lipolytic enzymes and characterization of numerous regulatory proteins and mechanisms have fundamentally changed our perception of lipolysis and its impact on cellular metabolism. Adipose triglyceride lipase (ATGL) is the rate-limiting enzyme for TG catabolism in most cells and tissues. This review focuses on recent advances in understanding the (patho)physiological impact due to defective lipolysis by ATGL deficiency on mitochondrial (dys)function. Depending on the type of cells and tissues investigated, absence of ATGL has pleiotropic roles in mitochondrial function.

1. Introduction

Lipolysis provides free fatty acids (FFAs) depending on metabolic need (e.g. during fasting). FFAs are essential substrates for energy production and lipid synthesis, including membrane lipids and lipid intermediates involved in cellular signaling. Despite their fundamental physiological importance, an excess of FFAs results in lipotoxicity. Lipotoxic effects impair membrane function and induce endoplasmic reticulum (ER) stress, mitochondrial dysfunction, inflammation, and cell death. Essentially all cells are able to detoxify FFAs by esterification within triacylglycerols (TGs). Since most cells have a limited capacity to accumulate excess fat, adipose tissue stores TGs during feeding and supplies FFAs to other tissues during calorie restriction [1]. When the limit of adipose tissue expansion to store excess nutrients has been reached lipids accumulate in other tissues [2]. Thereby adipose tissue protects non-adipose tissues from ectopic lipid spillover, which otherwise would result in cell death and impaired organ function.

2. Role of ATGL in neutral lipolysis

Intracellular lipid catabolizing enzymes degrade neutral lipids such as TGs and cholesteryl esters and their metabolic intermediates, which are stored in cytosolic lipid droplets. Lipid droplet-associated cholesteryl esters are hydrolyzed by neutral cholesteryl ester hydrolase(s) including hormone-sensitive lipase [3]. In 2004, three groups independently published the discovery of an enzyme able to hydrolyze TGs and named it adipose triglyceride lipase (ATGL) [4], desnutrin [5], or calcium-independent phospholipase A2 (iPLA2) [6]. ATGL selectively performs the first step in TG hydrolysis, resulting in the formation of diacylglycerol (DG) and FFA. For maximal lipolytic activity ATGL requires CGI-58 as a co-activator [7]. G0S2 (predominantly expressed in adipose tissue and liver) has been identified as a selective inhibitor of ATGL [8]. It has been proposed recently that CGI-58 and G0S2 regulate ATGL via non-competing mechanisms [9].

ATGL is so far the only known lipase that hydrolyzes TGs selectively at the sn-2 position of the glycerol backbone [10]. Upon stimulation of the enzyme by its co-activator CGI-58, the stereo- and regioselectivity of ATGL broadens to the sn-1 position, leading to increased FA release. sn-1,3 DG is the preferred substrate for the consecutive hydrolysis by hormone-sensitive lipase. ATGL exhibits 10-fold higher substrate specificity for TGs than for DGs [4] and shows low transacylase and phospholipase activity [6]. In contrast...
to hormone-sensitive lipase, ATGL lacks the ability to hydrolyze DGs, monoacylglycerols, cholesteryl esters, or retinyl esters [4].

ATGL is expressed in most tissues of the body with highest mRNA levels and enzyme activity found in white (WAT) and brown adipose tissue (BAT) [reviewed in Ref. [11]]. The important role of ATGL in lipolysis became evident from observations in Atgl-deficient (−/−) mice, which accumulate TGs in essentially all organs [12]. Massive TG accumulation caused by impaired TG mobilization in cardiac myocytes results in cardiac failure and premature death of Atgl−/− mice, starting at the age of 12 weeks. Due to the reduced availability of FFAs as energy substrate, Atgl−/− mice show an increased utilization of carbohydrates as energy source, leading to improved glucose tolerance and insulin sensitivity. Atgl−/− male mice are fertile, whereas females lack the ability to suckle their offspring due to impaired milk production. Plasma FA, TG, total cholesterol, HDL-cholesterol and ketone body concentrations are decreased in both fed and fasted Atgl−/− mice [12]. Major findings in various Atgl−/− tissues and cells are summarized in Table 1.

### 3. ATGL deficiency and mitochondrial dysfunction

#### 3.1. Cardiac muscle

Although TG accumulation occurs in essentially all organs, none of them is as much affected as the heart (Fig. 1). Although the overall morphology of mitochondria and the structure of mitochondrial cristae appear intact in electron micrographs (Fig. 1), mitochondrial size compared to that of wild-type (Wt) mice is increased [14]. The drastic cardiac phenotype with massive lipid accumulation and cardiomyopathy was initially thought to result in the premature death of Atgl−/− mice [12]. Mice lacking ATGL in all tissues except cardiac muscle (Atgl-ko/CM) have normal life expectancy and no physiological difficulties [13]. Haemmerle et al. have very recently shown that heart failure in Atgl−/− mice is not caused by lipid accumulation per se but is a net result of a severe impairment of cardiac mitochondrial function [14]. ATGL-mediated lipolysis of cellular TG depots, thereby delivering lipids for the PPARα–PGC-1 complex, is crucial for normal cardiac functioning. Severely reduced oxygen consumption under both basal and succinate-stimulated conditions in heart homogenates of Atgl−/− mice indicate mitochondrial defect regardless of the presence of glucose or palmitate, suggesting that the substrate energy source does not rescue the mitochondrial defect. The authors proposed the following mechanism: after entering the cell, exogenous FFAs are activated and either enter mitochondria for oxidation or are reesterified and stored within lipid droplets. ATGL-mediated hydrolysis of TG stores is critical to provide ligands for functional signaling by the PPARα–PGC-1 complex, which activates mitochondrial biogenesis and oxidative phosphorylation. Importantly, the lipolytic defect in the heart of Atgl−/− mice is able to be bypassed by PPARα agonist treatment. Fenofibrate and/or Wy14653 restores the cardiac expression of PGC-1α and PGC-1β, reverses systemic lipid accumulation, normalizes oxidative function in mitochondria, improves cardiac performance, and prevents lethal cardiomyopathy [14]. These data open the possibility of clinical application of PPARα or non-selective PPAR agonists for the treatment of patients with neutral lipid storage disease with myopathy.

#### 3.2. Skeletal muscle

Compared with other non-adipose tissues, ATGL mRNA expression in murine skeletal muscle is quite high [4], suggesting an important role for ATGL in this metabolically active tissue. Intramyocellular TGs localized within cytoplasmic active lipid droplets serve as a reservoir for lipoprotein-derived FFAs [15], which are esterified into TGs [16,17] prior to mobilization by ATGL. Whole body ATGL deficiency in mice leads to 44% decrease in TG hydrolyase activity and concomitant significant TG accumulation in myocytes, predominantly in oxidative fibres [12]. In line with these data, ATGL siRNA in myotubes reduces TG hydrolyase activity and increases TG content, whereas retroviral-mediated ATGL overexpression induces the reciprocal response and increases the oxidation of FFAs liberated from TGs and DGs [18]. Endurance exercise training increases skeletal muscle ATGL protein by 2-fold and reduces intramyocellular TG content in healthy young men [19]. These data confirm the importance of ATGL for lipid and energy metabolism in skeletal muscle.

The localization of lipid droplets in close proximity to the ER and mitochondrial network [20] might be crucial for the cellular economy of myocytes. Skeletal muscle is quantitatively the most prominent site for FA uptake [18]. Of particular importance is the activity of skeletal muscle during exercise, which increases the mitochondrial volume up to 50% after only few weeks in previously untrained subjects [21]. Similar data showing stimulating effect of exercise on mitochondrial biogenesis are observed in rats [22] and mice [23]. ATGL is essential for efficient lipolysis of intramyocellular TGs and supply of FFAs for mitochondrial β-oxidation [13,24,25]. An impaired capacity for exercise-induced lipolysis despite increased oxidative capacity is observed in skeletal muscles of Atgl−/− mice [24]. Being unable to efficiently hydrolyze TGs in the absence of ATGL carbohydrate metabolism is induced, resulting in elevated muscle and liver glycogen depletion. Reduced maximal running velocity and endurance capacity in Atgl−/− mice is not due...
to defective muscle contraction [24]. Intact cardiac function is essential for maintaining normal physiology, especially during exercise training. To exclude cardiac malfunction, the most prominent phenotype of Atgl/C0/C0 mice [12], Schoiswohl et al. have generated Atgl/C0/C0 mice that express ATGL only in cardiac muscle (Atgl-ko/CM) [13]. In contrast to whole body Atgl/C0/C0 mice, Atgl-ko/CM mice do not accumulate TGs in the heart and have a normal life expectancy. However, both mouse lines are unable to increase circulating FA levels during exercise. The reduced availability of FAs is compensated by an increased use of carbohydrates for energy conversion, leading to rapid depletion of liver glycogen stores during exercise [13]. To explain decreased force production and higher muscle relaxation times of Atgl/C0/C0 mice Nunes et al. measured mitochondrial oxidative phosphorylation [25]. Despite a highly increased intramyocellular lipid pool skeletal muscles from Atgl-/-/ mice show a comparable energy status and overall muscular in vivo mitochondrial oxidative capacity as Wt mice. According to these data mitochondrial dysfunction is likely not responsible for poor Atgl-/- muscle performance.

3.3. Liver

Inconsistent results are published on TG accumulation in livers of Atgl-/- mice with almost identical [26], 2.3-fold [12] or at least 3-fold increased hepatic TG concentrations [27] compared with Wt livers. Electron microscopy reveals lipid droplet accumulation in Atgl-/-/ livers with morphologically intact mitochondria surrounded by rough ER (Fig. 2). Using an adenovirus-mediated approach, Watt et al. [28] have very recently demonstrated that hepatic ATGL deficiency leads to hepatic steatosis without impairing hepatic insulin sensitivity. Intraportal injections of tunicamycin induce hepatic steatosis in Atgl-/- but not in Wt mice [26]. Thus deficiency of liver ATGL causes progressive hepatic steatosis but inflammatory and fibrotic responses are reduced compared with those reported in other obesity models with similar degrees of steatosis [27]. Livers from Atgl-/- mice might be protected from hepatic ER stress and inflammation through alterations in FA composition. The authors conclude that ATGL-mediated TG hydrolysis might be a novel target in the treatment of hepatic ER stress [26], which is typically present in patients suffering from non-alcoholic fatty liver disease and steatohepatitis. Hepatic ATGL deficiency leads to lowering of mitochondrial β-oxidation without affecting very low-density lipoprotein secretion [29]. Mice deficient in liver ATGL exhibit 40–70% reduced mRNA expression of hepatic PPARα and its target genes involved in FA utilization and glucose production [29]. Consistent with these data, hepatic mitochondrial oxidation is down-regulated in high fat diet-fed mice administered Atgl shRNA adenovirus in comparison with controls [28]. Treatment with the PPARα agonist fenofibrate, however, cannot overcome the decreased expression of PPARα target genes in mice transduced with Atgl shRNA, suggesting that in the liver ATGL regulates PPARα through a ligand-independent mechanism. Knockdown of hepatic ATGL by adenoviral infection results in a higher respiratory quotient during food withdrawal, indicating that

**Fig. 1.** Transmission electron micrographs of heart sections from Wt and Atgl-/- mice. Heart tissue was dissected using a Zeiss OPI1 surgical microscope (Carl Zeiss, Oberkochen, Germany). Small tissue fragments were fixed in 2.5% glutaraldehyde and 2% paraformaldehyde in 0.1 M phosphate buffer (pH 7.4) for 2 h, postfixed in 2% osmium tetroxide for 2 h at room temperature, dehydrated in graded series of ethanol, and embedded in a TAAB epoxy resin. Sections (70 nm thick) were contrasted with uranyl acetate and lead citrate. Images were taken using an FEI Tecnai G² 20 transmission electron microscope (FEI Eindhoven, Eindhoven, Netherlands) with a Gatan ultrasound 1000 CCD camera. Acceleration voltage used was 120 kV. Wt cardiac muscle sections (upper panels) show a intermyofibrillar network containing mitochondria (M). Atgl-/- cardiac muscle (lower panels) show a massive lipid droplet (LD) accumulation within the intermyofibrillar network. Overall morphology of mitochondria and the structure of mitochondrial cristae appeared normal. Mitochondrial size compared to that of Wt mice is increased [14]. Left panels: scale bars 1 μm; right panels: scale bars 0.5 μm.
the main source of energy is glucose oxidation, resulting in improved glucose tolerance [28]. In contrast to cardiac ATGL deficiency, hepatic ATGL deficiency leads to an upregulation of PGC-1α and PGC-1β, indicating unchanged or even increased hepatic mitochondrial biosynthesis [14]. Liver-specific Atgl−/− mice have an increased number of lipolysosomes, suggesting that lysosomal TG degradation might reduce hepatic steatosis under conditions of ATGL deficiency [27].

In summary, absence of hepatic ATGL results in steatosis without inflammation [27], downregulation of PPARα target genes and consequently reduced β-oxidation [29]. Improved hepatic glucose tolerance but normal hepatic insulin signaling [28] and protection from tunicamycin-induced ER stress [26] argue for beneficial effects of ATGL deficiency on the liver.

3.4. Adipose tissues

Atgl−/− mice have enlarged fat depots, which is mostly pronounced in BAT [12]. In WAT, hormone-stimulated lipolysis is drastically reduced, indicating that ATGL is hormone-regulated via direct or indirect mechanisms. The transcriptional response to products of lipolysis in WAT and BAT reflects the functional differences of lipolysis in these tissues. In WAT mobilized FAs are released, whereas in BAT FAs activate uncoupling protein 1 and provide fuel for thermogenesis [30]. Thus Atgl−/− mice exhibit defective thermogenesis. ATGL may also affect PPARγ function since rosiglitazone-mediated PPARγ activation and lipid accumulation are associated with increased lipolysis and ATGL expression in rat adipose tissue [31]. Although increases in WAT mass and adipocyte volume have broad metabolic consequences including reduced mitochondrial function and increased ER stress [32,33], microarray studies in WAT of Atgl−/− mice revealed only moderate changes in the levels of transcripts associated with identifiable biological processes [34]. To our knowledge, no studies investigating mitochondrial function in Atgl−/− white adipocytes have been published so far. In contrast, microarray results from BAT indicate that ATGL deficiency results in decreased mRNA expression of genes involved in FA β-oxidation [34] and leads to downregulation of PPARα target genes in BAT [35]. Another study confirms that knockdown of ATGL significantly reduces the induction of the rate-limiting enzymes for mitochondrial FA β-oxidation [36]. Lipolysis is required for maximal induction of thermogenic genes by β-adrenergic receptor activation in BAT. Brown adipocytes lacking ATGL are fully responsive to exogenous PPARα and PPARγ ligands for increasing the expression of genes involved in FA oxidation and oxidative phosphorylation, indicating that the defect in gene regulation involves ATGL-dependent production of PPAR ligands. The authors conclude that in BAT ATGL is required for the maximal induction of genes involved in FA oxidation and mitochondrial electron transport [36].

3.5. Macrophages

Efficient FA oxidation and ATP synthesis depend on substrate availability, effective FA transport into the mitochondria, and efficient mitochondrial function. The marked downregulation of the PPAR target genes carnitine palmitoyltransferase 1α and long chain acyl-CoA dehydrogenase, the decrease of total acyl-CoA concentrations,
and the reduction in essentially all middle and long chain carnitine esters [37] are indicators of mitochondrial dysfunction in Atg1-/- macrophages. Decreased concentrations of acetyl-CoA suggest defective mitochondrial β-oxidation, implicating that less NADH and FADH₂ are available for oxidative phosphorylation to drive ATP synthesis. In fact, ATP levels are reduced in Atg1-/- macrophages, suggesting that the lipolytic defect affects the usage of FAs as energy fuel. As a consequence, decreased mitochondrial membrane potential, reduced mitochondrial O₂ consumption, elevated cytosolic Ca²⁺, and intracellular reactive oxygen species concentrations are observed in Atg1-/- macrophages [38]. Mitochondria in Atg1-/- macrophages are clustered around lipid droplets, are less electron dense and smaller in size with aberrant cristae (Fig. 3), which provides evidence of considerable mitochondrial dysfunction [38], indicating a highly compromised mitochondrial function as a consequence of defective lipolysis.

Fragmented mitochondria are defining features of apoptosis. Impaired mitochondria generate reactive oxygen species, which are capable of acting as second messengers that mediate multiple cellular responses, including apoptosis. Loading of macrophages with unesterified cholesterol in vitro induces programmed cell death via activation of the mitochondrial apoptosis pathway [39]. The absence of ATGL in macrophages, accompanied by TG accumulation, also results in an increase of typical markers of apoptosis [38] and ER

![Fig. 3](image-url)

**Fig. 3.** Transmission electron micrographs of macrophages from Wt and Atg1-/- mice. Wt macrophages show mitochondria (M) with intact cristae. Atg1-/- macrophages, which accumulate lipid droplets (LD), exhibit smaller, electron-light mitochondria with aberrant cristae. Treatment of Atg1-/- macrophages with the ceramide synthase inhibitor fumonisin B1 (FB1) normalizes mitochondria size and morphology [40]. Scale bars: 0.2 μm.

![Fig. 4](image-url)

**Fig. 4.** Transmission electron micrographs of small intestinal sections from Wt and intestine-specific Atg1-/- mice. Section from Wt (upper panels) and Atg1-/- (lower panels) small intestinal cells show intact mitochondria (M) albeit lipid droplet (LD) accumulation in Atg1-/- small intestine. Scale bars: 0.5 μm.
stress [40]. In contrast with these results, TG accumulation in macrophages might also be cytoreductive [41,42]. Differences between the studies could be explained by additional mechanisms being activated in Atgl−/− macrophages. A highly increased concentration of the pro-apoptotic ceramide C16:0 might be responsible for induction of apoptosis and mitochondrial dysfunction in Atgl−/− macrophages [40]. The findings that Atgl−/− macrophages can be rescued from mitochondria fragmentation (Fig. 3), mitochondrial dysfunction and apoptotic cell death but not from ER stress by inhibition of ceramide synthesis by fumonisin B1 treatment indicate that C16:0 ceramide is essential and sufficient for apoptosis and mitochondrial dysfunction of Atgl−/− macrophages [40].

3.6. Other tissues

In the brain, intracellular FAs mediate the conversion into signaling lipid molecules, including eicosanoids, DGs, phospholipids, TGs, and fatty acyl carnitine species [43–45]. ATGL is expressed in various brain regions, including pyramidal cells of the hippocampus and the dentate gyrus, ependymal cells, and the choroid plexus [46]. Recent data from brains of Atgl−/− mice indicate that ATGL affects cerebral TG catabolism, in particular in hippocampus and the dentate gyrus, ependymal cells, and the expressed in various brain regions, including pyramidal cells of the hippocampus and the dentate gyrus, ependymal cells, and the choroid plexus [46]. Intracellular TG lipolysis by ATGL may be important to maintain FA supply and represents another mechanism of cerebral lipid management. Since FA β-oxidation in the brain occurs only at very low levels the impact of ATGL is expected to hardly influence this process. Atgl−/− mice show no sign of neurodegeneration, which might be due to the fact that 12–16 week old mice were used for the study [46].

ATGL has very recently been identified as an important TG hydrolase of the small intestine [47]. Absence of intestinal ATGL modulates PPARα signaling, thereby influencing the rate of FFA and cholesterol uptake from the intestinal lumen. Further data from this study revealed that intestinal ATGL deficiency has no influence on chylomicron production, suggesting that lipolytic products generated by ATGL are not used for intestinal lipoprotein production. The effects of intestinal ATGL deficiency on mitochondrial function are still elusive. However, as observed in liver and heart [14], genes involved in β-oxidation are down-regulated in the small intestine of fasted intestine-specific Atgl−/− mice, arguing for a decrease in β-oxidation rate [47]. Intact mitochondria albeit lipid droplet accumulation (Fig. 4) and unchanged mRNA expression of PGC-1α in Atgl−/− intestine (Obrowsky et al., unpublished observation) indicate normal mitochondrial biogenesis and function in Atgl−/− enterocytes. Downregulation of glutathione-S-transferases [47], which are important for the detoxification of xenobiotics and lipid peroxidation products [48,49], suggest that intestinal ATGL might play a role in the protection from oxidative stress.

Knockdown of ATGL in pancreatic INS832/13 cells and its absence in pancreas of Atgl−/− mice results in ~3-fold increased TG concentrations [50]. All findings published in this report (unchanged glucose oxidation, mitochondrial membrane potential, glucose usage, FA oxidation, and insulin content) illustrate that moderate increases in TG content within the pancreas protect against lipotoxicity, resulting in intact mitochondrial function.

4. Conclusion

Despite TG accumulation in all investigated Atgl−/− cells and tissues, current data on ATGL deficiency demonstrate that ATGL has pleiotropic roles in mediating mitochondrial function, depending on the type of cell or tissue. It is likely that ATGL-mediated lipolysis in cardiac muscle, BAT, and macrophages activates PPARα and β through ligand-dependent and ligand-independent mechanisms to regulate mitochondrial gene expression and FA oxidation, thereby strongly influencing mitochondrial function. In the liver, ATGL deficiency leads to an upregulation of PGC-1α and PGC-1β, suggesting unchanged or even increased hepatic mitochondrial biosynthesis. According to studies performed so far definite lipolysis in skeletal muscle, WAT, small intestine, and pancreas has no impact on mitochondrial function. Numerous questions, including why ATGL exerts mitochondrial dysfunction in some but not all tissues, remain unanswered. Additional studies are necessary to answer the question whether tissue- or cell-specific targeting of ATGL might be a potential drug target for pharmaceutical intervention in humans.
