(August 13, 2018)

We report on extensive numerical simulations on the Bak-Sneppen model in high dimensions. We uncover a very rich behavior as a function of dimensionality. For \(d > 2\) the avalanche cluster becomes fractal and for \(d \geq 4\) the process becomes transient. Finally the exponents reach their mean field values for \(d = d_e = 8\), which is then the upper critical dimension of the Bak Sneppen model.

The Bak-Sneppen (BS) model \(^{[1]}\), since its introduction, has attracted much attention in statistical physics. Thanks to its simplicity, it has lead to a much deeper understanding of the nature of self organized criticality \(^{[2]}\) and of extremal dynamics \(^{[3]}\) in general. The rules of the BS dynamics, in \(d\) dimensions, are very simple: the state of the model is completely defined by \(L^d\) numbers \(f_i\) arranged on a \(d\)-dimensional lattice of edge size \(L\). At every time step the smallest of these numbers and its 2d nearest neighbors are replaced with new uncorrelated random numbers, drawn from the uniform distribution. Such very simple dynamics, based on the selection of the global minimum, is generally called extremal dynamics. It was first introduced in invasion percolation \(^{[4]}\) and it results in a remarkably rich and interesting critical behavior.

The self-organized critical nature of the BS model (as well as of other extremal models) is revealed in its ability to naturally evolve towards a critical state where almost all of the variables \(f_i\) are above a threshold \(f_e\). The dynamics in this state is characterized by scale-free bursts of activity or avalanches, which form a hierarchical structure \(^{[4,5]}\) of sub-avalanches within bigger avalanches. This critical state is described by critical exponents. The distribution of avalanche duration \(s\) behaves as a power law \(P(s) \sim s^{-\tau}\) with exponent \(\tau\). An avalanche of duration \(s\) covers a number of sites \(V(s) \sim s^\mu\). The set of avalanche sites is generally fractal \(V(s) \sim R(s)^D\), where \(R(s)\) is the gyration radius and \(D_f\) is the (spatial) fractal dimension. The active site (the one with the global minimum \(f_i\)) has a dynamical wandering that can be described in terms of return times: The distribution \(P_f(t) \sim t^{-\tau_f}\) of first return times is characterized by an exponent \(\tau_f\), whereas the distribution of all return times \(P_a(t) \sim t^{-\tau_a}\) defines the exponent \(\tau_a\). For a random walk these two exponents take the values \(\tau_f = 3/2\) and \(\tau_a = 1/2\) in \(d = 1\), whereas for \(d \geq 2\) one finds \(\tau_f = \tau_a = d/2\). Note that with respect to previous literature \(^{[4,3]}\), our notation is slightly different: The exponent \(\mu\) in ref. \(^{[3]}\) is defined as \(\mu = d/D\), where \(D\) was called “fractal dimension”. Here we regard \(\mu\) as a fundamental exponent (not a composite one) and reserve the name fractal dimension to describe the spatial geometrical properties of the avalanches. This choice, as we shall see, avoids ambiguities which can arise in higher dimensions, where the avalanche cluster becomes fractal.

A scaling theory was proposed in \(^{[3]}\) which shows that scaling relations allow to reduce the number of critical exponents to two, for example \(\mu\) and \(\tau\). Numerical simulations in \(d = 1\) and \(2\) fully confirm the validity of the scaling theory \(^{[3]}\). The mean field limit, formally corresponding to the limit \(d \to \infty\), has also been solved exactly \(^{[3]}\): the exponents, in this limit take the values \(\tau = \tau_f = \tau_a = 3/2\), \(\mu = 1\) and \(D_f = 4\). Finally, it was recently shown \(^{[3,4]}\) that a further non-trivial relation, of a different nature, exists between \(\mu\) and \(\tau\). This suggests that the BS universality class is characterized by a single exponent, e.g. \(\mu(d)\), as a function of \(d\).

In this Letter we analyze the behavior of the BS model as a function of dimensionality. The understanding of the critical behavior of a model, as a function of dimensionality, is a central issue in statistical physics. In particular the identification of the upper critical dimension \(d_e\), above which the mean field picture applies, is of great importance. Indeed it allows to understand the behavior of a finite dimensional system using the powerful tools of dimensional \((\epsilon)\) expansion. In equilibrium statistical mechanics, this is almost routine work, but for non-equilibrium systems it is a challenging issue. For this reason the understanding of the behavior of simple models as a function of dimensionality is of great importance.

We present extensive numerical simulations for the BS model which show that \(i)\) the upper critical dimension is \(d_e = 8\) \(ii)\) for \(d > 2\) the avalanches are no more compact \(D_f < d\) \(iii)\) in \(d = 3\) we find \(\mu < \tau_a < 1\) and \(iv)\) for \(d \geq 4\) the process becomes transient i.e. \(\tau_a = \tau_f > 1\). The BS model then shows a quite rich behavior, with four qualitatively different regimes \((d \leq 2, 2 < d < 4, 4 \leq d < 8\) and \(d \geq 8\), as a function of dimensionality. In particular we find that the relation \(\mu = \tau_a\) holds only up to \(d = 2\) (note that this relation is in any case problematic close to the mean field limit \(\mu = 1, \tau_a = 3/2\)). A possible interpretation of our results is that “geometric” exponents, such as \(\tau_a, \tau_f\) and \(D_f\) become independent

\[05.40+j, 64.60Ak, 64.60Fr, 87.10+e\]
from “avalanche” or “memory” (see later) exponents for \(d > 2\) and the number of independent exponents changes with dimension. We shall first discuss in detail the numerical procedure, defining operationally the quantities we measure. Then we present the numerical results and finally we discuss them.

The BS dynamics can be simulated very efficiently using a tree like search and replace algorithm. This decreases greatly computation times, so that memory is the only limitation to the system sizes studied. The numerical procedure was first tested in \(d = 1\) and \(d = 2\) and we found complete agreement with refs. In order to compute the exponents \(\mu\) and \(\tau\), following ref. we introduce an age variable \(k_i\) on each site. The age \(k_i\) of site \(i\) measures the time elapsed since the last update of the variable \(f_i\). This method enables us to give a precise evaluation of the exponent \(\mu\). Indeed at each time the sites with age \(k_i\) less than \(s\) identify the current avalanche of duration \(s\). Therefore \(V(s)\) is simply obtained counting the sites with \(k_i < s\). Age variables also allow for a determination of the avalanche exponent \(\tau\). In systems evolving by an extremal dynamics, it has been found that the probability that the global minimum \(f_i\) occurs on a site with age \(k_i\) behaves as \(\rho(k_i) \sim k_i^{-\alpha}\). The exponent \(\alpha > 0\) implies that older sites are less likely to be selected. This reflects the fact that a very old site has survived many selections, and therefore it has very likely a high value of the variable \(f_i\): the more it survives the higher is its \(f_i\), possibly even greater than the threshold \(f_c\), in which case the site will never be selected before a new update (occurring if one of its neighbors is selected). The exponent \(\alpha\) is related to the avalanche exponent by \(\alpha = 3 - \tau\). The advantage of measuring \(\alpha\), with respect to a direct measure of \(\tau\), is that the statistics of the former is much richer than that of the latter in the same simulation. We measured \(\tau\) in both ways and found good agreement (which also supports the validity of the relation \(\alpha = 3 - \tau\)). Since statistical uncertainty of the exponent \(\alpha\) is much less than that of \(\tau\) we report here only the value \(\tau = 3 - \alpha\). The return times exponents are measured in the usual way: let \(t_i^{(k)}\), \(k = 0, 1, \ldots\) be the (return) times when site \(i\) is visited \((t_i^{(k)} < t_i^{(k+1)})\). The first return exponent is obtained from the statistics of \(t_i^{(k)} - t_i^{(k-1)}\), whereas the all returns exponent is obtained from \(t_i^{(k)} - t_i^{(0)}\). Finally, in order to obtain the fractal dimension \(D_f\), we compute the gyration radius of avalanches of size \(V(s)\).

The numerical results are summarized in Table. As shown in Fig. our numerical results for \(\mu\) and \(\tau\) are in good agreement with the exact relation recently found in ref. This is an important consistency check for the reliability of the simulations. In \(d = 2\) we find a slight difference between \(\tau_0\) and \(\mu\) which is however within error bars. The data are also plotted in Fig. for completeness. For \(d = 3\) the difference between \(\tau_0\) and \(\mu\) is much larger than the error bars (see Fig.2). In Fig. we plot the exponents as a function of dimensionality. For \(d \leq 3\) the process is recurrent, since \(\tau_0 > 1\), i.e. each visited site, in an infinite system, is visited again an infinite number of times (or, stated differently, a selected site will be selected again with probability one). Instead for \(d \geq 4\) the process becomes transient i.e. \(\tau_0 = \tau_f > 1\): each site, in an infinite system, is visited a finite number of times (there is a finite, smaller than one, probability that a selected site will be selected again). The relation \(\tau_0 + \tau_f = 2\) if \(\tau_0 < 1\) and \(\tau_0 = \tau_f\) if \(\tau_0 \geq 1\) (a classical result from renewal theory) is always respected, the former holding for \(d \leq 3\). The return time statistics, in the BS model, is determined both by memory effects and by geometry. Activity can return to site \(i\) either because all sites with variables larger than \(f_i\) are eliminated by the BS dynamics (which we call a memory return) or because the activity returns close to site \(i\) and \(f_i \rightarrow f_i'\) is updated (geometric return). As the dimension \(d\) increases, geometric returns become less and less relevant (see later) and for very large dimensions one expects to recover the mean field result \(\tau_0 = \tau_f = 3/2\). We find that the mean field limit holds for \(d \geq d_c = 8\).

We now turn to the discussion of the onset of fractality of avalanche clusters for \(d > 2\). At \(d = 2\), we found numerically that the fractal dimension is slightly smaller than \(D_f = 2\). We argue, however, that small size effects occur and that \(D_f = 2\) holds. Indeed, as the system size \(L\) is increased the slope of the curve \(\log V(s)\) vs \(\log R(s)\) increases, suggesting that avalanches are compact. The occurrence of small size effects can be understood analyzing the dynamics of the growth of the avalanche cluster in \(d\) dimensions. The growth probability distribution of the cluster is characterized by memory. The problem of cluster growth with memory was recently investigated in ref. In a standard model of growth, new sites can be added only at the surface of the cluster. In this case, it was shown that when \(\alpha > 1\) the cluster has a fractal dimension \(D_f < d\). The difference between cluster growth with memory and the avalanche cluster growth in the BS is that in the latter the activity can return to bulk sites. At the initial stages of growth of BS clusters, however, the analogy is useful, since the ratio between the number of surface sites and that of bulk sites is \(\sim 2d\) so that returns to the bulk are rare. In \(d = 2\), as more and more returns to the bulk occur the surface to volume ratio decreases and the cluster becomes compact (for a fractal cluster the ratio of perimeter sites to bulk sites is finite). Therefore, while small \(s\) avalanches look fractal, for larger sizes they become more and more compact. These small size effects are also visible in the distribution of first return times (see also Fig.4). In \(d \geq 3\) the same size effect should appear, however in this case we find a fractal dimension which is definitely smaller than \(d\). Returns to the bulk are fewer in \(d \geq 3\) than in \(d = 2\) and more importantly the topology of a fractal
The cluster is very different: while the 2-dimensional cluster is characterized by a distribution of holes of all sizes, a fractal in \( d \geq 3 \) is most likely a ramified object. Returns to the bulk can fill the holes of the \( d = 2 \) cluster but it is much more difficult for them to turn the branched fractal structure of the \( d \geq 3 \) avalanche into a compact one. For this reason, we believe that our data are compatible with the occurrence of a compact cluster in \( d = 2 \) and with \( D_f < d \) when \( d \geq 3 \). In any case, numerical data are relatively stable with changes of the system size and we could not detect any small size effect such as the one discussed above for \( d = 2 \).

Geometric returns arise because the avalanche cluster has many self-intersections: indeed the self-intersection set has a fractal dimension \( D_I = 2D_f - d > 0 \) for \( d < 8 \). Note that \( D_I \) is smaller than \( D_f \) which means that the larger the avalanche the smaller is the fraction of intersection sites. Moreover, as mentioned earlier, geometric returns become less and less relevant as \( d \) increases since \( D_f - D_I = d - D_f \) also increases with \( d \). Above \( d = d_c = 8 \) the fractal dimension \( D_f = 4 \) attains its mean field value and the avalanche has no self-intersections \((D_f < 0)\).

The fractality of avalanches implies that some scaling relations must be modified. For example the jump probability distribution \( \rho(r) \) was analyzed in ref. [2] under the hypothesis of a compact cluster. It is defined as the probability that the activity jumps in one time step to a site at a distance \( r \) from the current site and it falls off with a power law behavior: \( \rho(r) \sim r^{-\pi} \). The exponent \( \pi \) was related to \( \tau \) and \( D \) in ref. [2] by \( \pi = 1 + D(2 - \tau) \), under the hypothesis of a compact cluster. The same argument as in ref. [2] led us to the expression

\[
\pi = 1 + \frac{D_f(2 - \tau)}{\mu}.
\]

It is interesting to observe that, for the values quoted in Table I, \( \pi \) is always slightly larger than 3, so that the second moment of \( \rho(r) \) is finite, and its mean field value is \( \pi = 3 \). Were it not for the correlations, the activity would perform a random walk and it would be transient already for \( d > 2 \). Correlations induced by memory effects, shifts the onset of transient behavior to \( d \geq 4 \).

In order to check the full consistency of the results shown in Table I, we are also exploring an alternative way to move away from the mean field limit [6]. Within a \( d = 1 \) system, we choose the “nearest neighbors” of the active site at random over the lattice, with a probability which is a power law decreasing function of the distance from the active site, with exponent \( \omega \). Preliminary results show that the mean field limit is recovered when \( \omega \to 1 \). Varying \( \omega > 1 \) again three different critical regimes appear. In particular we find a region of the values of \( \omega \) where activity is recurrent \( (\tau_a < 1) \) but \( \mu \neq \tau_a \) and a region where activity is transient \( (\tau_a > 1) \) but \( \mu < 1 \). Moreover we find that, whenever \( \mu \) takes the same values listed in Table I, also the other quantities take on the same corresponding values (apart of course from \( D_f \) which is always smaller than 1). Finally, working in \( d = 1 \) allows us to simulate extremely large sizes and to rule out any finite size effects, thus strengthening the reliability of the results shown in Table I.

It has been argued that the mean field limit of BS can be described as a branching process \([8]\). The value \( d_c = 8 \), which coincides with the upper critical dimension of branched polymers, is consistent with this picture \([7]\). We believe that close to \( d = 8 \) branched polymers give a reasonable description of the geometry of the BS process. An \( \varepsilon = d_c - d \) expansion for the BS model could therefore be feasible, also using the recent expansion around the mean field solution of ref. [2]. In this respect, our results allow for a prediction of the first coefficient \( \mu \simeq 1 - 0.017\varepsilon \) of the \( \varepsilon \) expansion.

In summary, we have presented numerical results for the BS model in high dimensions. These allow to conclude that for \( d > 2 \) avalanches become fractal and for \( d \geq 4 \) the process becomes transient. Finally the mean field limit is reached at the upper critical dimension \( d_c = 8 \). This behavior, with three different non-trivial regimes of criticality, is substantially richer that that of equilibrium statistical models, where non-trivial behavior occurs only in one region of dimensionality, limited by the lower and the upper critical dimension. Our results also call for a close analysis of the scaling theory of ref. [2], which has been developed under the implicit assumptions of a recurrent process with compact avalanches.

[14] The measurement of the fractal dimension is the most time consuming and moreover the feasible system sizes are smaller the larger the dimension. For this reason we did not push the calculation of $D_f$ to $d > 4$. Note that the mean field result $D_f = 4$ implies $D_f \leq 4$ and therefore a fractal structure for $d \geq 5$.

[15] The dimension $D_I$ of the intersection of two objects of fractal dimension $D_f$ in $d$ dimensions can be obtained knowing that the codimension of the intersection $(d-D_I)$ is the sum of the codimensions of the two intersecting objects $(d-D_f)$. Therefore $d - D_I = 2(d - D_f)$ from which the relation $D_I = 2D_f - d$ follows.

[16] P. De Los Rios, in preparation.

[17] Indeed $d = 8$ is the upper critical dimension of branched polymers as obtained using simple Flory arguments, see e.g. J. Isaacson and T.C. Lubensky, J. Physique Lett. 41, 469 (1980) and references therein.

| $d$ | 1  | 2  | 3  | 4  | 5  | 6  | 7  | 8  |
