Supporting Information

ABSTRACT: The combination of photonics and spintronics opens new ways to transfer and process information. It is shown here that in systems in which organic molecules and semiconductor nanoparticles are combined, matching these technologies results in interesting new phenomena. We report on light induced and spin-dependent charge transfer process through helical oligopeptide–CdSe nanoparticles (NPs) architectures deposited on ferromagnetic substrates with small coercive force (~100–200 Oe). The spin control is achieved by the application of the chirality-induced spin-dependent electron transfer effect and is probed by two different methods: spin-controlled electrochemistry and photoluminescence (PL) at room temperature. The injected spin could be controlled by excitation of the nanoparticles. By switching the direction of the magnetic field of the substrate, the PL intensity could be alternated.

KEYWORDS: Charge transfer, chirality, spin transport, oligopeptide, spin selectivity, ferromagnet

The concept of controlling magnetism by light has attracted much attention in recent years. Specifically, the controlling of spin transport by light combines two interesting technologies, photonics and spintronics. Having organic material makes the coupling of the two technologies easier because the light-absorbing properties of organic molecules can be modified relatively easily. Recently, it was found that the transmission of electrons through chiral molecules depends on the electrons’ spin orientation; this effect is referred to as chirality-induced spin selectivity (CISS). The CISS effect makes it possible to construct spintronic devices without ferromagnetic spin injectors because the chiral molecules themselves serve to select a specific spin to transport across the molecules. In the hybrid system studied herein, helical oligopeptide molecules were attached on one end to CdSe nanoparticles (NPs) and on the other end to ferromagnetic substrates. Two experimental configurations were applied; in the first, the photoemission intensity from the NPs was monitored as a function of the magnetization direction of the substrate (Figure 1A). In addition, electrochemical measurements were conducted (Figure 1B) when the ferromagnetic working electrode was coated with the oligopeptide–CdSe NP system. The Faradic current through the adsorbed layer was measured as a function of the direction of the magnetic field when the system was illuminated. It was established that when an electron is transmitted through a chiral molecule, a specific spin orientation is preferred. Here, we utilized the effect to control the photoluminescence (PL) intensity from the NPs by controlling the direction of the magnetic field of the substrate. We also demonstrated control by light of the preferred spin transmitted through the structures of hybrid chiral molecules–NPs.

RESULTS AND DISCUSSION

The hybrid system studied is based on a self-assembled monolayer (SAM) of a helical oligopeptide17 HS–CH2–CH2–NHCO(Ala–Aib)8–NH2, (known as Ala8, where Ala = Alanine, Aib = 2-aminoisobutyric acid) adsorbed on a specially prepared thermally grown SiO2 substrate. In all cases, a 5 nm Ta adhesive layer was deposited on the substrates, followed by a 2 nm Pt layer on it. Co and Pt were repetitively (three or five times) deposited onto the substrates. The substrate exhibits soft magnetization were prepared either on glass or on a 300 nm thermally grown SiO2 substrate. In all cases, a 5 nm Ta adhesive layer was deposited on the substrates, followed by a 2 nm Pt layer on it. Co and Pt were repetitively (three or five times) deposited onto the substrates. The substrate exhibits soft magnetization with a perpendicular easy axis (Figure S1). The FM materials become readily oxidized under aerobic conditions and specifically in an electrochemical cell having an aqueous solution as the electrolyte. To address this problem, we...
coated the FM substrates with a very thin and smooth overlayer of Au (1 nm). More details on the layer preparation and characterization are given in Methods and Supporting Information.

CdSe NPs of 6–7 nm diameter are covalently attached to the SAM through its free primary amine (−NH₂) of Ala8. The NPs absorb light at 514 nm, whereas the excited NPs emit at about 650 nm. The Ala8–CdSe NP assembly was characterized using polarization modulation-infrared reflection–absorption spectra (PM-IRRAS), atomic force microscopy (AFM) images, and X-ray photoelectron spectroscopy (XPS) spectroscopy. It was found to be stable under ambient conditions and did not deteriorate upon mild sonication (see Figures S2–S6 in the Supporting Information). An external static magnetic field of 0.35 T was applied to switch the magnetization of the ferromagnetic substrate. Two different experimental setups were employed. The first one is based on measuring fluorescence from the NPs under ambient conditions (Figure 1A), whereas in the second one electrochemical measurements were performed in a custom-made electrochemical cell (Figure 1B).

In the fluorescence setup, upon photoexcitation of the NPs either electron or hole transfer to the substrate may occur and their rates determine the intensity of the fluorescence. As it was established, whereas the lifetime of the isolated CdSe NPs is of the order of 20 to 30 ns, when the NPs are able to transfer electrons from the oligopeptide to a metal substrate, the lifetime is shortened to below 1 ns. Hence, the fast charge transfer results in lowering the fluorescence intensity because it hampers the radiative electron–hole recombination process. As was determined by surface photovoltage (SPV) measurements, in the current Ala8–CdSe hybrid system, hole transfer from the excited NPs to the substrate across the hybrid structures is more efficient than by electron transfer. Figure 2A shows that photoluminescence intensity is affected by the direction of the magnetization of the substrate. Because the quenching of the fluorescence is due to the transfer of electrons from the substrate to the NPs (hole transfer from NPs to substrate),

![Figure 1](https://example.com/figure1.png)

**Figure 1.** (A) Schematic presentation of the experimental setup for the spin-dependent photoluminescence measurements. (B) Schematic presentation of the light-induced spin-dependent electrochemical measurements recorded in a homemade electrochemical cell in the presence of tris buffer containing 5 mM K₃[Fe(CN)₆]/K₄[Fe(CN)₆]. The ferromagnetic substrate was the working electrode (WE), whereas platinum wire and KCl-saturated calomel electrode (SCE) were used as the counter (CE) and reference (RE) electrodes, respectively. The working electrode was based on multiple ferromagnetic layers, and it was coated with the Ala8–CdSe NP assemblies. In both cases, a permanent magnet (H = 0.35 T) was placed underneath the modified ferromagnetic substrate and the direction of the magnetic dipole was flipped either pointing “UP” or “DOWN” (white and yellow arrows, respectively). In all cases, a green laser (λexc = 514 nm) was used for exciting the CdSe NPs.

![Figure 2](https://example.com/figure2.png)

**Figure 2.** (A) Photoluminescence spectra of CdSe NPs attached to an oligopeptide monolayer (Ala-8) adsorbed onto magnetic substrates, as measured in the presence of an external magnetic field of 0.35 T pointing either UP (blue curve) or DOWN (red curve). (B) Photoluminescence spectra of CdSe NPs attached to an achiral 1,16-hexadecane dithiol monolayer adsorbed onto the magnetic substrate measured under identical conditions. The nanoparticles were excited with a green laser at 514 nm.
when the electron’s spin is parallel to the adsorbed molecule axis (when the magnet was pointing “UP”), its transfer is more efficient and as a result photoluminescence intensity get quenched. This observation is consistent with former data showing the same spin preference also in spin-dependent photoelectron transmission through oligopeptides.\textsuperscript{21} The average ratio of the PL intensity, as estimated by the area under the curve measured for two different directions (the magnet pointing “DOWN” vs “UP”), was found to be $1.4 \pm 0.2$. These results are highly reproducible among five different samples prepared under identical conditions. Several control experiments were performed where Ala-8 was replaced by achiral 1,16-hexadecane dithiol (DT), biphenyl-4,4′-dithiol (BD), and 4-aminothiophenol; an external magnetic field was applied, keeping the experimental setup identical. The achiral SAM−CdSe NP assemblies did not exhibit any effect of the external magnetic field on the PL intensity, as shown in Figure 2B and Figure S7, corroborating that the CISS effect arises exclusively from chiral structures.\textsuperscript{4}

Spin-dependent electrochemical measurements were performed using both the oligopeptide and oligopeptide-NP structures assembled on the ferromagnetic substrates in the presence of a chemically robust redox probe such as $K_{\text{a}}[\text{Fe(CN)}_6]_4/K_{\text{a}}[\text{Fe(CN)}_6]_3$ in Tris(hydroxymethyl)-aminoethane (TRIS) buffer (see Figure 1B). The SAM-modified ferromagnetic substrate was used as the working electrode (WE), platinum wire as the counter electrode (CE), and a KCl-saturated calomel electrode as the reference electrode (RE). A permanent magnet having a field of $0.35$ T was placed underneath the ferromagnetic working electrode, which can be flipped by changing its direction by $180^\circ$ so that the magnetic field points either toward the surface (UP) or away from it (DOWN). The NPs in the hybrid structures could be excited at $514$ nm during the electron conduction measurements. The dependence of the CV curves on the direction of the magnetic field and on the illumination is shown in Figure 3. In the dark, the substrate was coated only with the SAM (Figure 3A) and one was coated both with SAM and NPs (Figure 3B); both show magnetic field-dependent CV curves with a higher current when the magnet points DOWN. The spin polarization (SP) is defined as $\text{SP} = \frac{I(V_\text{up}) - I(V_\text{down})}{I(V_\text{up}) + I(V_\text{down})} \times 100$, where $I(V_\text{up})$ and $I(V_\text{down})$ represent the currents obtained through monolayers with the magnetic field pointing “DOWN” or “UP”, respectively, at a specific applied potential (V). The SP for transmission through the chiral Ala8 monolayers is $+11 \pm 1\%$ at

Figure 3. Spin-dependent cyclic voltammograms recorded for (A) Ala8 monolayers adsorbed over ferromagnetic substrates, (B) Ala8−CdSe hybrid structures under dark conditions, and (C) under light conditions. The voltammograms were obtained when the ferromagnetic cobalt (used as the working electrode) is magnetized either with its magnetic moment pointing UP (the solid blue line), or pointing DOWN (the solid red line). Voltammograms were recorded in Tris buffer containing 5 mM $K_{\text{a}}[\text{Fe(CN)}_6]_4/K_{\text{a}}[\text{Fe(CN)}_6]_3$ at pH 9 at a scan rate of $50$ mV s$^{-1}$, keeping the area of the ferromagnetic working electrode the same in all cases.

Figure 4. Chronoamperometric measurements (current versus time) for (A) Ala8 and (B) Ala8−CdSe structures on a magnetic cobalt working electrode in the presence of an external static magnetic field either pointing UP (solid blue line) or DOWN (solid red line) in a Tris buffer containing 5 mM $K_{\text{a}}[\text{Fe(CN)}_6]_4/K_{\text{a}}[\text{Fe(CN)}_6]_3$ at pH 9. The samples were illuminated with a green laser having a 514 nm wavelength. Magnetic field-dependent current versus time measurements were recorded at $+0.32$ V (oxidation process) and 0 V (reduction process) versus a saturated calomel electrode (SCE).
The present study demonstrates the interaction between light and electrons’ spin as manifested when light controls the spin-
selective electron transport through chiral molecules. By attaching a fluorophore, the NPs to the chiral molecule the actual spin orientation being transmitted can be flipped with significant efficiency. Thus, when combining light and a magnetic field the chirality-induced electron transfer process may find increased interest in the field of light-controlled biospintronic research.\textsuperscript{23} It is important to appreciate that the effect observed here relates to weak magnetic fields applied on the ferromagnetic substrate and hence differ significantly from the known magneto-chiral anisotropy in charge transfer, in which very high fields (many Tesla) are applied.\textsuperscript{24} The combination of systems, like those presented here, and molecular magnets\textsuperscript{25,26} may result in a new type of photospintronics devices that are all molecular.

\section*{METHODS}

\textbf{Preparation of Soft Ferromagnetic Substrates.} The ferromagnetic films with a perpendicular easy axis were prepared on soda lime glass slides and on silicon substrate (100) on which 5 \textmu m of tantalum and 2 nm of platinum were deposited using a magnetron sputtering system with a base pressure of \(<3 \times 10^{-9}\) Torr. Cobalt and platinum deposition were repeated thrice on top of the 2 \textmu m platinum layer. A thin layer of cobalt, followed by 1 nm gold, was grown on top. The stacking structure of the magnetic substrates was Si/SiO\textsubscript{2}/Ta 5/1 nm/Co 5/5/Co 30 nm/1 nm/Co 30 nm/Au 1 nm (in nm). All metal layers were deposited at a working pressure of Ar 1.5 mTorr at room temperature.

\textbf{Preparation of Oligopeptide Monolayer and Oligopeptide–CdSe Nanoparticle Structures.} Magnetic substrates with a 1 nm Au overlayer were cleaned with boiling acetone followed by ethanol for 15 min in each. The substrates were dried carefully under N\textsubscript{2} and used for IR, XPS, and electrochemical measurements.

The substrates were immersed into a solution containing CdSe in anhydrous toluene for 4 h under dark conditions. In order to remove unreacted NPs, the substrates were lightly sonicated for 5 s in toluene and dried gently under N\textsubscript{2} for 45 min) for 48 h in order to achieve maximum surface coverage. The functionalized substrates were rinsed with the same solvent mixture and mildly sonicated for 5 s to remove any unreacted materials. Consequently, the monolayers were dried at a working pressure of Ar 1.5 mTorr at room temperature.

\textbf{Characterization.} The magnetic properties of perpendicular magnetized [Co/Pt] films were characterized by using a vibrating sample magnetometer (VSM, VersaLab Quantum Design). Saturation magnetization (Ms) is 827 \pm 96.7 emu/cm\textsuperscript{3} (measured moment/volume of Co and Pt) and the coercivity is 145 and 270 Oe for substrate 1 and substrate 2, respectively (Figure S1).

The formation of monolayers in the polypeptide and its CdSe nanoparticles structures were characterized by recording the polarization modulation infrared-reflection–absorption spectra (PM-IRRAS) using a Nicolet 6700 FTIR equipped with a PEM-90 photoelastic modulator (Hinds Instruments, Hillsboro, OR) at an incidence angle of 80°. In all cases, vibrational stretching frequencies of amide I and amide II bonds in the SAMs were monitored.

\textbf{X-ray Photoelectron Spectroscopy (XPS) and Chemically Resolved Electrical Measurements (CREM).} freshly prepared SAMs of oligopeptide (Aal8) and peptide–CdSe architectures on the ferromagnetic substrates were analyzed by XPS measurements using a Kratos Axis Ultra DLD spectrometer equipped with a monochromatic Al K\textalpha\ X-ray source (\(h\nu = 1486.6\) eV) operating at a power of 75 W. Two emission angles (65° and 0° with respect to the surface normal) were compared. Detection pass energies ranged between 20 and 80 eV. Elemental concentrations and layer thicknesses were deduced from the relative intensities of overlayer (N, C, O, and S 2p) versus substrate (Ta, Pt, Co, Au, and O) signals. Special care was devoted to eliminate beam-induced effects and damage to molecules in particular. This was achieved by conducting repeated measurements, starting with very fast scans at fresh spots, in order to evaluate the exposure-dependent spectral changes.

The coverage by CdSe nanoparticles (NPs) was estimated based on the NP average size, 6–7 nm in diameter, which was determined independently. Work function measurements were performed prior to any XPS scan, by inspecting the photoelectron onset at low kinetic energies under a source power of 0.3 W. Site-specific photovoltages were extracted by evaluating the energy shifts of representative lines (Cd, N, C, and Au) under a 630 nm diode source.\textsuperscript{27} The advantage of these measurements over standard SPV experiments stems from the fact that one can resolve local electrostatic potential changes and in particular those developing specifically on the CdSe NPs.

The formation of Aal8–CdSe nanoparticle structures on ferromagnetic substrates was further confirmed by AFM images recorded on a Multimode/Nanoscope (Bruker-Nano, Santa Barbara, CA, U.S.A.). The AFM images were acquired in noncontact mode and a Si probe having a resonance frequency of 70–90 kHz was used. The topographic images were recorded at a scan rate of 1 Hz. Several images (at least at four different points) of each sample were taken from different fields of view (0.5–2.0 \textmu m) to confirm the uniformity and reproducibility of the samples. The formation of homogeneous distributions of CdSe nanoparticles in the monolayer was confirmed by AFM imaging.

The PL measurements were carried out by using a LabRam HR800-PL spectrometer microscope (Horiba Jobin-Yvon). Typically, 514 nm laser light (argon-ion CW laser at \(\sim 15\) mW/cm\textsuperscript{2}) has been used for excitation of CdSe NPs. The incident light was impinged on the sample surface at an angle 90° to the sample surface. Prior to collecting the PL spectra, an area (typically, 20 au \times 20 au) and number points (25 points) within this area were defined in order to map the surface. Afterward, the PL spectra were collected using a microscope (with a 5× high working distance lens). During the measurement, a confocal aperture (1100 \mu m) was fully opened and the integration time was maintained at 15 s. Finally, the spectra were presented after averaging out the PL of individual points within the defined area at two different magnetic orientations.

Cyclic voltammetry (CV) and chronocoulometric measurements were carried out using a Bio-Logic potentiostat SAS (Model SP-200) with an integrated software EC Lab (V 10.36) by employing a typical three-electrode electrochemical cell. A SAM-modified Co substrate, a Pt wire, and KCl-saturated...
calomel electrodes were used as the working, counter, and reference electrodes, respectively, in the presence of Tris buffer containing 5 mM K₄[Fe(CN)]₆/K₃[Fe(CN)]₆ taken into a custom-made electrochemical cell. Spin-dependent electrochemical measurements were carried out in the presence of a permanent magnet having a magnetic field strength of 0.35 T, which was placed underneath the Co working electrode, followed by changing the magnet’s direction (UP/DOWN).
