Abstract

We review the main achievements of the research programme for the study of nuclear forces in the framework of chiral symmetry and discuss some problems which are still open.

PACS numbers:
The research programme for the study of nuclear forces, based on the idea that long and medium range interactions are dominated by one and two-pion exchanges, was formulated more than fifty years ago in a seminal paper by Taketani, Nakamura and Sasaki[1]. Nevertheless, only in the last fifteen years it has achieved its full strength, due to the consistent use of chiral symmetry. This led to a considerable improvement in our knowledge of the basic mechanisms underlying nuclear interactions. For a comprehensive discussion of the subject, the reader is directed to the recent review produced by Epelbaum[2]. Here we describe the main topics in which progress has been made towards clarifying dynamics and outline some problems which still remain open, in a perspective biased by the work done by our group[3].

The works by Weinberg[4] in the early nineties motivated the systematic use of chiral symmetry in the study of nuclear forces. The rationale for this approach is the fact that nuclear interactions are dominated by low-energy processes involving the quarks $u$ and $d$, which have small masses. This allows one to work with a two-flavor version of QCD and to treat these masses as a perturbation in a chiral symmetric massless lagrangian. The procedure for the systematic inclusion of the effects associated with the quark masses is known as chiral perturbation theory (ChPT). In order to be able to perform chiral expansions, one uses a typical scale $q$, set by either pion four-momenta or nucleon three-momenta, such that $q < 1$ GeV.

Chiral symmetry is especially suited for dealing with multipion processes. Hence, in the case of the one-pion exchange potential ($OPEP$), it becomes relevant only when form factors are taken into account. On the other hand, it is essential to the accurate description of the two-pion exchange potential ($TPEP$), which is closely related to the $\pi N$ scattering amplitude. In the sequence, we concentrate on this component of the force.

The leading contribution to the $TPEP$ is $O(q^2)$ and, at present, there are two independent expansions of the potential up to $O(q^4)$ in the literature, based on either heavy baryon[5] or covariant[3] ChPT. These results allow one to put the problem in perspective and note that the following aspects of the problem have been tamed:

- Quite generally, asymptotic (large $r$) expressions for the potential have the status of theorems and are written as sums of chiral layers, with little model dependence.
- The minimal realization of the symmetry is implemented by just pions and nucleons, but realistic potentials require other degrees of freedom, either hidden within the-low energy
constants (LECs) of effective lagrangians or represented as explicit deltas.

- The dynamical content of the \textit{TPEP} is associated with three families of diagrams, shown in the figure below. Diagrams of family I correspond to the minimal realization of chiral symmetry and involve only the $\pi N$ coupling constants $g_A$ and $f_\pi$. Family II describes effects associated with pion-pion correlations, whereas the interactions in family III depend on the LECs, represented by black dots.

- The relation of these diagrams with $\pi N$ scattering is well understood and may be used to fix the (LECs) in family III. When this procedure is adopted, the \textit{TPEP} does not contain any free parameters and becomes fully determined.

- There is no room for scalar mesons, such as the $\sigma$, in the long and medium range parts of the \textit{TPEP}.

- Relativistic effects are visible in the final form of the \textit{TPEP} and arise from the proper covariant treatment of loop integrals. Therefore they are present even when the external nucleon momenta are small.

- Due to the treatment of loop integrals, heavy baryon and relativistic derivations of the potential do not coincide. This problem is conceptually important, since it is related with the form of the asymptotic chiral theorems. From the point of view of internal theoretical consistency, the covariant procedure is favored. On the other hand, heavy baryon calculations have the advantage of producing analytical results. As far as numerical applications are concerned, the differences between both approaches are small.
• The chiral picture is well supported by partial wave analyses[6]. In the figure above we compare the chiral TPEP $V_C^+$ and $V_{LS}^+$ components with results from the Argonne group[7].
• The dominant features of the isospin independent component of the central potential are directly related with the QCD vacuum through the nucleon scalar form factor[8].

• As far as dynamics is concerned, the various channels of the potential are clearly dominated by isolated contributions arising from either family I or III and intermediate $\pi\pi$ scattering processes in family II are almost completely irrelevant. This is in sharp contrast with older models for the TPEP, which were not based on chiral symmetry. As typical instances, in the preceding figure we show the ratios of the individual contributions from families I, II and III by their sum, in the case of the components $V_C^+$ and $V_{LS}^+$. 
• The relative importances of $O(q^2)$, $O(q^3)$ and $O(q^4)$ terms in all the components of the potential has been assessed. At distances of physical interest, they are consistent with converging series, with the exception of the isospin independent central potential. In the figure that follows we display the relative contribution of each chiral order to the $TPEP$ for $V_C^+$ and $V_{LS}^+$. The black dots in the curves correspond to the points where the ratio is 0.5.

The clear picture of the $TPEP$ dynamics promoted by chiral symmetry allows one to identify some problems that remain open and deserve being tackled in order to put the potential in a yet firmer basis.

• The construction of the potential involves loop integrals, which must be regularized. At present, the best regularization procedure for chiral symmetry in the baryon sector is the infrared scheme[9], which gives rise to power counting. Even if indications are that the influence of the regularization scheme is restricted to distances smaller than 1 fm, the $TPEP$ problem remains in the want of a full calculation based on the infrared method.

• A rather puzzling aspect of the chiral $TPEP$ is that its leading terms are formally predicted to be $O(q^2)$, whereas the all important central isospin independent component $V_C^+$ begins at $O(q^3)$. This may be associated with the poor convergence of the chiral series for this term, as shown in the preceding figure. The numerical reasons for its odd behavior can be traced back to the large size of the LECs that are used in the first two diagrams of family III. These LECs, in turn, are dynamically generated by processes involving delta intermediate states. Therefore the explicit inclusion of delta degrees of freedom in a covariant calculation could prove useful in shedding light into this problem.
The relation of the potential with data is very important. At present, one has good indications that the chiral $TPEP$ is able to reproduce well empirical phase shifts. However, a problem that occurs in this kind of testing is that the theoretical potential can only be directly used in the study of peripheral waves, which are small and carry large uncertainties. In order to study a larger set of waves and energies, theoretical expressions have to be corrected at short distances by means of cutoffs or form factors, which also influence numerical results. As this problem cannot be avoided, a proper assessment of the merits of the $TPEP$ could be obtained by mapping in detail the influence of cutoffs and form factors over numerical results.

A related problem concerns the determination of the numerical values of the LECs present in the effective lagrangians. Many of the LECs relevant to the $NN$ interaction also contribute to elastic $\pi N$ scattering and it would be useful to know whether values extracted from these two processes are compatible. In doing this comparison, it is important to bear in mind that the numerical values for the LECs depend on the chiral order of the expansion one is working with.

In the long run, it would be interesting to consider the extension of the chiral picture to potentials used in many-body calculations which, for technical reasons, tend to be more schematic. Usually, they rely heavily on scalar-isoscalar interactions inspired in the linear $\sigma$ model. However, the chiral $TPEP$ does not support this assumption, especially as far as the $O(q^3)$ nature of the central potential is concerned.
