Brief Papers

Self-Punishment and Reward Backfill for Deep Q-Learning

Mohammad Reza Bonyadi, Rui Wang, and Maryam Ziaei

Abstract—Reinforcement learning (RL) agents learn by encouraging behaviors, which maximizes their total reward, usually provided by the environment. In many environments, however, the reward is provided after a series of actions rather than each single action, leading the agent to experience ambiguity in terms of whether those actions are effective, an issue known as the credit assignment problem. In this brief, we propose two strategies inspired by behavioral psychology to enable the agent to intrinsically estimate more informative reward values for actions with no reward. The first strategy, called self-punishment (SP), discourages the agent from making mistakes that lead to undesirable terminal states. The second strategy, called the reward backfill (RB), backpropagates the rewards between two rewarded actions. We prove that, under certain assumptions and regardless of the RL algorithm used, these two strategies maintain the order of policies in the space of all possible policies in terms of their total reward and, by extension, maintain the optimal policy. Hence, our proposed strategies integrate with any RL algorithm that learns a value or action-value function through experience. We incorporated these two strategies into three popular deep RL approaches and evaluated the results on 30 Atari games. After parameter tuning, our results indicate that the proposed strategies improve the tested methods in over 65% of tested games by up to over 25 times performance improvement.

Index Terms—Deep neural networks, Q-learning, reinforcement learning (RL), temporal difference (TD).

I. INTRODUCTION

A reinforcement learning (RL) agent [1] aims to make optimal decisions in an environment from which it receives rewards for its actions. The agent optimizes a relationship (policy) between actions and rewards, which is later used to make plausible actions. One of the frequently used techniques to form this relationship is through learning the forward quality of actions in any given state, known as Q-learning [2]. Recently, deep Q-learning networks (DQN) [3] have been introduced and successfully applied to complex RL tasks, such as Atari 2600 and Star Craft II [4].

There exist a range of environments in which there is no reward (or zero reward) corresponding to the majority of actions, posing a significant challenge to RL algorithms [5], [6]. In this brief, we introduce two strategies, namely, the self-punishment (SP) and reward backfill (RB), which provide additional reward signals for the agent to learn from. Inspired by the operant conditioning [7], SP provides undesirable values (punishment) for agent’s undesirable actions (e.g., actions that lead to a terminal state) to discourage it from making mistakes. This strategy provides additional information about the state and enables the agent to find better gradient trajectories toward avoiding a loss and, consequently, improve faster. Inspired by the “clicker training” strategy used for animal training [7], [8], the RB strategy backpropagates nonzero rewards received from the environment (or from SP strategy) to the previous state-action pairs. This strategy provides additional information on how much each state and action with zero reward contributes to a state and action with nonzero reward in the future.

This brief is organized as follows. Section II provides an overview of RL as well as the related works. Section III describes our approaches and Section IV presents experimental results and discussions. We conclude our work with an outlook to the future work in Section V.

II. BACKGROUND

A brief review on RL, Q-learning, deep architectures, and credit assignment problem is provided in this section.

A. Reinforcement and Q-Learning

We define an RL environment (sometimes referred to as an RL problem in this brief) by a tuple (S, A, ε, and r), where S is the set of states an agent can be in, A is the set of actions an agent can choose from, ε(s, a) : S × A → S is a function that takes the agent from state s ∈ S to s′ ∈ S given the action a ∈ A, and r(s, a) : S × A → R is the reward provided for the agent given the state s and the action a. An RL agent (also called RL algorithm) interacts with an environment, such as an Atari emulator, to learn how to behave optimally. The learning is done by optimizing a (usually deterministic) policy π(s) : S → A in a way that the aggregated rewards onward (expected value if nondeterministic), denoted by ∑∞i=0 r(π, s)[all possible π], is an “ordered” set under the operator “≤.”

Value-based RL algorithms define Q(s, a) : S × A → R that represents the total discounted reward the agent may receive by taking action a at the state s onward following a policy π. If the best Q, called Q*, is known, then the optimal policy, π*, can be represented by argmaxa∈A Q*(s, a) for any given s. One of the most commonly used methods to estimate Q is the n-step temporal difference (TD) update [5]

Q(s, a) ← Q(s, a) + α(Rn(t) − Q(s, a))

where Rn(t) is referred to as TD target, defined by

Rn(t) = γ ∑i=0 n−1 r(st+i, at+i)

where n ∈ {1, 2, ..., T−t} and γ is the discount factor. TD target is set to r(st, at) if st+1 is a terminal state, T. Q-learning [2], [5] is a special case of n-step TD with n = 1.

B. Deep Q-Learning Network

In order to interact with the environment through raw vision information, deep Q network parameterizes the Q function as \( Q(s, a; \theta) \) [3]. The parameter set \( \theta \) is a convolutional neural network (CNN) that transforms a given state \( s \) and an action \( a \) to their \( Q \) values. The DQN agent takes \( n \) frames (with a skip parameter \( k \) that only selects observation on every \( k \)th frame) as one state that is subsequently processed by the CNN with \( n \) input channels. Given a state, the network decides on the action with probability \( 1 - \epsilon \) (or performs a random action with probability \( \epsilon \) for exploration purposes), and the environment provides the reward and the next state accordingly. This interaction continues until a terminal state emerges. The value of \( \epsilon \) is closer to 1.0 at the earlier stages of the learning process to encourage exploration. Each interaction produces a transition tuple \( < s, a, r(s, a), s' > \) that is stored in the replay memory. At each step, a batch of samples is randomly selected from these memorized samples to train the network. The learning objective is to minimize a loss function \( L(\theta) = \mathbb{E}[Q(s, a; \theta) - R^{(i)}]^2 \), where \( R^{(i)} = r(s, a) + \gamma \max_{a' \in A} Q(s_{t+1}, a') \) is the TD target [2], [5], [9].

DQN uses a greedy policy to approximate \( Q \) defined as \( \pi(s) = \text{argmax}_{a \in A} Q(s, a; \theta) \). While this is correct if \( Q \) is equal to \( Q^* \), this approximation may lead to overestimation of the \( Q \) values for nonoptimal actions that are regularly selected [10]. This issue stems from dependency between weights used to calculate the target and the \( Q \) values. Double DQN [10] (D2QN) addresses this problem by employing two networks to decouple the action selection and the target value, where the \( Q \)-network decides the best action and the target network computes the TD target as \( r(s, a) + \gamma Q'(s', \text{argmax}_{a' \in A} Q(s', a'; \theta); \theta') \). Dueling DQN [11] (D3QN) decomposes the \( Q \) value estimation function into state-value function and action advantage function updated separately. The \( Q \) values are then estimated as the sum of state-value function and action advantage function. Dueling architecture improves the learning in two ways. First, the estimation of state value instead of \( Q \) value explicitly indicates more valuable states. Second, the action advantage function provides additional information to the estimation that decreases noise stemming from overestimation as two functions make independent estimations. DQN was further extended by other approaches, such as the use of a noisy model with trainable noise parameters [12]. Again, the TD target in these variants is set to \( r(s_t, a_t) \) if \( s_{t+1} \) is a terminal state [3], [10], [11].

C. Credit Assignment Problem

Not all actions receive a nonzero reward in many RL environments. Nevertheless, a sequence of these mostly zero-rewarded actions may lead the agent to a state for which a reward is received. It is, however, not straightforward to estimate the contribution of these zero-rewarded actions to a future reward, an issue known as the credit assignment problem [5]. The severity of this issue increases with the sparsity of nonzero rewards. \( Q \)-learning update rule (\( n = 1 \) in \( n \) step TD update), in particular, is prone to the credit assignment problem as it considers a rather short sight of actual future rewards [5], [6], leading to a large bias and a longer learning time. In the context of DQN and environments with sparse rewards, some of the states in the replay memory would be associated with zero-rewarded actions. When the rewards are sparse, the value of \( R^{(i)} \) is equal to \( \gamma^n \max_{a \in A} Q(s_{t+n}, a) \) in most cases, especially if \( n = 1 \) (i.e., \( Q \)-learning), which encourages the loss function to converge to zero quickly. One obvious approach to address the credit assignment problem in a sparse reward space is to increase the value of \( n \), which in turn increases the chances of having nonzero actual rewards in \( R^{(n)} \) [13]. Incorporating this strategy in DQN is, however, extremely challenging and would require heavy calculations [6]. There have been other approaches targeting this issue for DQN, including defining prioritization for replay memory items [14], curiosity-driven prioritization for replay memory items [15], and hybrid supervised reinforcement learning [16]–[18].

D. Reward Shaping

Reward shaping [19]–[21], the approach that our proposed methods are most related to, replaces the original reward provided by the environment, \( r(s, a) \), by an estimation, \( z(s, a, s') = r(s, a) + f(s, a, s') \), which not only represents the reward but also assigns rewards to subgoals by using \( f : S \times A \times S \rightarrow \mathbb{R} \). The method can potentially address the credit assignment problem by introducing a function \( f(s, a, s') \) that returns nonzero values when \( r(s, a) \) is zero. It has been proven [19] that if there exists a function \( \Phi : S \rightarrow \mathbb{R} \) such that \( f(s, a) = \gamma \Phi(s') - \Phi(s) \), \( \gamma \in [0, 1] \), then the optimal \( Q \) function with the modified reward is the same as the optimal \( Q \) function using the original reward function. Such a reward shaping function is called the potential-based reward shaping function. It has also been proven that this form of reward shaping is both necessary and sufficient to guarantee that the optimality of policies is preserved when \( Q \)-learning is used. The proof provided in [19] mainly relies on the recursive nature of the \( Q \)-learning formulation.

A reward shaping function was proposed in [22] based on a Lyapunov function. The method replaced the reward at each state with a weighted average of the current reward and the reward in the next state received if the best action (provided by the current \( Q \) function) is taken. It was proven that the proposed shaping function is an instance of the potential-based reward shaping. Results showed improvement when this shaping function was used. Another approach based on similarity between decision trajectories was proposed in [23]. In this method, if the current trajectory was “similar” (based on a distance measure) to high-quality ones from the memory, then the reward given to the agent was increased. The increment was calculated based on a weighted average over most successful trajectories (similar to the \( k \)-nearest neighbor) stored in the memory. With the length of the stored trajectories was limited to 100 (i.e., storing the last 100 actions as a trajectory) and the size of the memory to 20 (i.e., storing the top 20 trajectories), it was shown that the proposed method offers an improvement over D2QN on some RL problems.

Leveraging pretrained reward models and improving them during a given task has been a popular way to implement reward shaping. An approach based on a Bayesian framework was proposed in [24] in which the “belief” about the reward distribution of the environment was used to shape the reward. The original reward distribution belief was updated along optimization of the RL policy by collecting more evidence about each transition. The mean of the belief distribution was then used in a \( Q \)-learning framework, replacing the environment reward at each state. A meta-learning approach, implemented by a neural network, was introduced in [25]. The idea was to train the meta-learner on a wide variety of tasks to learn estimating the value of a given state and then use the pretrained meta-learner in a new task to estimate the value of each given state, added to the reward provided by the environment at that state. As the distribution of the states in the tasks on which the meta-learner was trained might not represent the distribution of the states in a new task, it was proposed to use the pretrained meta-learner as a prior and calculate a posterior during learning of the new task. The method was most efficient on tasks that had shared state space, making it less effective on tasks with a wide variate of state spaces such as the ones that use vision inputs. In [26], it was proposed to use a Bayesian model combination framework to merge expert opinion, available through external inputs, at each state in an RL task to make the final decision. It was assumed that each expert opinion is a potential-based reward shaping function and it was decided that the final combination is also a
potential-based reward shaping function, preserving the optimality of the solutions. Results showed that the method could automatically leverage the best expert opinion more, without being aware which opinion is actually the best. The final performance is dependent on the provided expert models to combine.

III. PROPOSED APPROACH

We propose two strategies, namely, the SP and reward backfill (RB), to deal with the credit assignment problem. Both strategies provide easy to implement approaches to establish extra reward information, which leads to finding better solutions quicker.

A. Self-Punishment

RL has a root in a framework of animal psychology called the operant conditioning [7]. Operant conditioning argues that four main types of feedback from the environment can be used to train animals to shape a behavior as follows:

1) positive reinforcement by which a favorable outcome is presented after a desirable behavior;
2) negative reinforcement by which an unfavorable outcome is removed after a desirable behavior;
3) positive punishment by which an unfavorable outcome is presented after an undesirable behavior;
4) negative punishment by which a favorable outcome is removed after an undesirable behavior.

By using these four signals, behaviors are likely to be repeated if followed by a reward (pleasant consequences) or less likely to be repeated if followed by punishment (unpleasant consequences). The rewards provided for the DQN agents, discussed in Section II, are received from the environment with no major alterations. Hence, as majority of environments reward the desirable states only,1 the agent does not receive other types of operant conditioning signals. The lack of positive punishment, in particular, makes it impossible for the agent to distinguish between a neutral state (a state with no reward, but not necessarily a bad state) and an undesirable one. Even in the case of a terminal state where a life is lost, the target value is calculated by \( r(s, a) \). As \( r(s, a) \) is usually zero if the state is an undesirable terminal one, this reward does not provide any information for the agent to avoid this state.

In this brief, we propose a strategy by which the agent shapes an intrinsic auxiliary reward to “self-punish” at a terminal state, without the environment explicitly providing that value. In particular, if the next state after the current state by taking action \( a \) is terminal, then the agent modifies the received reward to \( r(s, a) - p \), where \( p \in \mathbb{R}^+ \) is a constant. Otherwise, the agent does not modify the reward received from the environment. We set the value of \( p \) experimentally in Section IV. One should note that not all terminal states are undesirable. If the terminal state is an undesirable one, then the SP strategy reduces the reward, which would make the distinction between a neutral and an undesirable terminal state more apparent. For a desirable terminal state (e.g., game won and task done successfully), on the other hand, the environment is unlikely to provide a zero reward and is expected to provide a large positive reward. In this case, the proposed SP strategy only slightly shifts the total reward, which would not impact the overall reward as it is applied to all terminal states (see the proof in the following).

Let us exemplify how SP strategy may improve the RL agent’s learning ability in the game of Breakout in Atari 2600. Let us first assume that SP is not used in Breakout and consider a situation where the ball is very close to the right side of the moving paddle but outside of the paddle and approaching. In this setting, although choosing to “move right” or to “move left” leads to a zero immediate reward by the environment, the latter leads to terminating the game, while the former leads to continuing the game. The zero reward provided by the environment makes it impossible for the agent to distinguish between the terminal state and a zero reward state, and hence, the game may be lost without any signal for the agent why it happened. In contrast, if the SP strategy was used, an additional immediate signal for the agent was provided to separate a terminal decision from a “neutral” one, which would guide the agent to avoid this mistake from the early stages and improve faster. One should note that if the \( Q \) function is accurate \( (Q = Q^* \) where \( Q^* \) is the optimal \( Q \)-function), then the \( Q \) value of the action “right” would be larger than any other action, which would lead to choosing the action “right.” This function, however, is optimized by playing the game over and over, hence, expected to be inaccurate especially at the early stages of the learning.

SP modifies the rewarding strategy of a given RL problem. For such a strategy, it is important to ensure that the modification preserves the optimal policy of the given RL problem [19]. To do so, we first introduce some definitions and remarks and then prove that the order of the solutions (policies) is not impacted when SP is used.

**Definition 1**: Policy-Independent Reshaping Function Let \( R \) an RL environment, defined by \((S, A, e, r)\), \( r(s, \pi(s)) \) being the reward received at a state \( s \) by taking an action \( \pi(s) \) and \( \pi \) being a policy used by an RL agent. Assume that we reshape this reward by a function \( \phi(s, \pi(s)) \), \( \phi : S \times A \rightarrow \mathbb{R} \). A reward reshaping function is an instance of policy-independent reshaping function (PIRF) if and only if

\[
\text{for any arbitrary } \pi_1 \text{ and } \pi_2, \quad \phi((\pi_1, s_0)) \leq \phi((\pi_2, s_0))
\]

where \( \phi((s, s_0)) = \sum_{i=0}^{n} \gamma \phi^i(s_i, \pi_i) \), \( \phi^i = \sum_{i=0}^{n} \gamma \phi^i(s_i, \pi_i) \) is the initial state, \( s_{n+1} = \text{a terminal state, and } \gamma \in [0, 1] \) is the discount factor.

Essentially, a reward reshaping function is an instance of a PIRF if and only if it does not change the order of policies in terms of their total reward under the operator \( \prec \). For example, the reward reshaping function \( \phi(s, \pi(s)) = r(s, \pi(s)) + a \in \mathbb{R} \) (any arbitrary value) is not an instance of PIRF in general as it may change the order of the solutions when some rewards are smaller than \( a \). The intuition here is that, when this reshaping function is used, the rewards that are smaller than \( a \) decrease, while the ones that are larger than \( a \) increase.

**Remark 1**: Let \( R \) an RL environment defined by \((S, A, e, r)\) and \( R' \), another RL environment, defined by \((S, A, e, \phi)\). If \( \phi(.) \) is an instance of PIRF, then the optimal policy for \( R \) and \( R' \) is the same.

**Proof**: The proof is trivial and can be done by contradiction (assuming that the function \( \phi \) changes \( \pi^* \)).

There are multiple conclusions one can draw out of Definition 1 and Remark 1. First, a reward reshaping function that is an instance of PIRF preserves optimal and near-optimal policies. Hence, an algorithm that is provably able to find an optimal solution for an RL problem (e.g., Q-learning implemented by neural networks under certain conditions [27]) would perform similarly if the reward is reshaped by a function that is an instance of the PIRF. Second, Definition 1 and Remark 1 do not make any assumption about the algorithm used for finding the optimal policy. Finally, Definition 1
where  \( \hat{\pi} \) denotes the total rewards calculated by 
\[ \hat{v}(\pi, s_0) = \sum_{n=0}^{\infty} \gamma^n r_{i+1} + \gamma \sum_{n=1}^{\infty} \gamma^n r_i \]
where \( \gamma = 1 \) and \( \tau = 1 + \gamma + \gamma^2 + \ldots \) are terminal states. Without loss of generality, we 
assume that \( v(\pi(s_0)) \leq v(\pi(s_2)) \). In the case of incorporating the 
SP strategy, these total rewards are calculated by 
\[ \beta(\pi(s_0)) = \sum_{n=0}^{\infty} \gamma^n r_{i+1} + \gamma \sum_{n=1}^{\infty} \gamma^n r_i \]
where \( n_{i+1} \) and \( n_{i+1} \) are terminal states. The definition of sparsity length 
depends on the sampling frequency of non-zero rewards. In some cases, the vision data are used as samples, then the number of frames between two frames 
in the agent's reward defines the sparsity length (see Section IV-C for details).

Theorem 2: Let \( s_0 \) be an initial state of an RL problem, \( R \), defined by \( (S, A, r, v) \). If \( \sum_{i=0}^{\infty} f(i) \) is a constant for all \( t \) and \( \tau \), then RB strategy (3) is an instance of PIRF.

Proof: For simplicity, we define \( r_A \) the reward the agent receives 
by taking action \( \pi(s_i) \) at state \( s_i \). The total reward received by the 
following arbitrary policies \( \pi_1 \) and \( \pi_2 \) is calculated by 
\[ v(\pi_1(s_0)) = \sum_{n=0}^{\infty} \gamma^n r_{i+1} + \gamma \sum_{n=1}^{\infty} \gamma^n r_i \]
and \( v(\pi_2(s_0)) = \sum_{n=0}^{\infty} \gamma^n r_{i+1} + \gamma \sum_{n=1}^{\infty} \gamma^n r_i \)
where \( n_{i+1} \) and \( n_{i+1} \) are terminal states. The assumption here is that there is always a terminal state (good 
or bad), which means that the episodes are finite (see Section II-A). Based on Remark 1 and Theorem 1, one can conclude that the 
SP strategy can be used in combination with any RL algorithm that learns 
the value or an action-value function.

B. Reward Backfill

The issue of credit assignment has been observed in training 
animals, i.e., the time delay between the action and the reward must 
be minimal in order for the animal to associate the consequence 
with the response effectively \([7], [8]\). As this may not be possible in many environments, a strategy called “clicker training” has 
been used and shown to be effective \([7], [8]\). In this strategy, a new 
reward is shaped, which is used to “bridge” the potential time delay 
of a desirable behavior by the animal and receiving the reward.

We mimic a similar strategy to improve DQN. For each state 
and action with nonzero reward, we propose to backpropagate 
that reward to previously performed actions in their corresponding states, 
namely, reward backfill and RB. This strategy provides information 
for the learning algorithm on how much a state and action with zero 
immediate reward may contribute to a future state and action with 
nonzero reward. We intuitively assume that the actions taken 
to backpropagate reward can be used to reward any action 
for a particular state. Also, we assume that an action with zero reward contributes 
to the closest future state and action with nonzero reward only and 
not further.

Assume that the policy \( \pi \) is used to generate actions for each 
given \( s \). Given the initial state \( s_0 \), the policy generates a sequence of 
actions by which the agent visits \( s_1, s_2, \ldots, s_n \), where \( s_{n+1} \) is a 
terminal state, and receives the rewards \( r_{0}, r_{1}, \ldots, r_{n} \). We propose 
to modify the reward received at a state \( 0 < i < n \) (the episode length) 
by 
\[ r_i = f(i) r_{\pi(s_i)} \]  
where \( f(i) \) is the index of the closest next state to \( i \) with nonzero 
reward in the current sequence of states, and \( f : N \rightarrow R \) is a 
decreasing function. By using this formula, a fraction of the reward 
at a nonzero reward state next to a given state is backpropagated 
to modify previous zero rewards. This strategy reflects the impact of 
actions and states with no rewards in receiving the reward at the state.
instance selected from the replay memory for training, the reward is replaced by the value of \( p \) if the next state (i.e., \( s'_m \), where \( m \) is the index of the memory) in that instance is terminal. If the state is not terminal, then (3) (RB strategy) is used to estimate the reward. For an efficient implementation, one can store the number of states for which the agent has not received any reward and use that to backcalculate \( \hat{r}_i \) in \( O(1) \).

IV. EXPERIMENTS

In this section, we first investigate the impact of the value of \( p \) and \( \lambda \) on D2QN and then compare the final results using a hybrid RB and SP strategy.

A. Test Environment and Experiment Settings

We used 30 Atari 2600 games for our comparisons, including UpNDown, BankHeist, MsPacman, Qbert, Zaxxon, Alien, Amidar, Tutankham, AirRaid, Kangaroo, Jamesbond, Gravitar, Seaquest, Hero, WizardOfWor, Frostbite, Venture, Centipede, Freeway, Berzerk, RoadRunner, Carnival, Asterix, Solaris, SpaceInvaders, KungFuMaster, Assault, Krull, Riverraid, and Breakout. The deterministic version of all games was used with four frames’ action repetition. We used Python 3 (source codes and detailed analyses are available as Supplementary Material) to implement DQN variants with the discount factor \( \gamma \) of 0.99, the learning rate of 0.0001, the learning method of RMSprop, the maximum number of training episode of 4000, the replay memory size of 1 M, the memory update of every four steps, the minibatch size of 32, the initial epsilon of 1.0 that decays to 0.1 over 100k steps after the exploration step (first 50k), Huber as the loss function, and the maximum episode length of 18k frames. The number of steps between target network updates was 10000 when double targeting strategy was used. In terms of hardware, we used a GPU cluster, each node equipped with two NVIDIA GPU Volta V100 and two skylake Intel Xeon 6132 processor, and over 300 GB of RAM. We allocated four cores, one GPU, and 30 GB of RAM to each run. We run all tests for 4000 episodes unless explicitly specified otherwise.

B. Evaluation Metrics

We measured the performance of each method for each environment by averaging the total reward the agent received in the last 100 episodes during the training. The use of this measure allows evaluating the number of times a method would need to play the game to learn it. We used three evaluation matrices for comparisons: average rank, average improvement percentage, and percentage of improved games. The average rank provides the ranking of different methods according to the performance measure. To calculate the average rank for each environment, we ranked the results of different settings (including the original algorithm) by sorting their performances descendingly and then averaged the ranks across all environments. This gives us an indication of how would each setting perform in comparison with others across all environments. The average improvement percentage measures the average percentage of improvement over the original algorithm across all environments on the performance measure. We calculated the average percentage of performance improvement, where each strategy with different settings was compared against the original version (the improvement is \( 100(P^o - P^s)/P^o \), where \( P^o \) is the performance of the original version of the algorithm and \( P^s \) is the performance of the algorithm with SP or RB strategies incorporated in it).

C. Sparsity Length

It was discussed in Section III-B that the sparsity length in environments has a direct impact on the efficiency of RB strategy. Fig. 1 shows the mean sparsity length of 30 Atari games when D3QN was applied to find the optimal policy. It is seen that this length is larger than 25 in most of the environments tested (23 out of 30 tested), which was used in our experiments. In the cases where the sparsity length is small, there would be a need for a smaller \( \lambda \) to compensate.

One should note that the RB approach is not expensive [done in \( O(1) \)] as it backpropagates reward signals and does not need any forward calculation of a neural network.

D. Parameters Setting

We incorporated SP and RB strategies to D2QN and tested the performance of the algorithm for \( p \in \{1, 10, 50, 100, 200\} \), \( \lambda \in \{.15, .65, .75, .85, .95\} \) and environments UpDown, Carnival, Gravitar, MsPacman, Qbert, Spaceinvaders, Berzerk, and Breakout. Results for SP settings are reported in Fig. 2. Fig. 2(a) shows the average ranks (the smaller, the better) of D2QN with and without SP and different values of \( p \). The D2QN without SP in most episodes ranked worse than D2QN with SP (“original” bar in the graph), demonstrating the effectiveness of this strategy. From Fig. 2(a), it is clear that \( p = 1 \) and \( p = 10 \) provide the best average rank across all tested environments. Fig. 2(b) shows that the average improvement is maximized across tested environments for \( p = 1 \).

Fig. 3 shows the results of incorporating RB to D2QN tested on the same set of environments. Fig. 3(a) and (b) shows that, for some values of \( \lambda \), RB improves D2QN (in terms of average rank and improvement percentage). The parameter \( \lambda \) decides that the amount of the reward propagated backward with a larger value of \( \lambda \) leads to a larger portion of the reward backpropagated. In these subfigures, it is seen that the maximum improvement and best rank takes place when \( \lambda = .65 \) across all tested settings.

E. Comparison Results

Three different deep Q-learning algorithms were tested as shown in Fig. 4(a) and (b) when SP and RB were incorporated to the base methods (\( p = 1 \) and \( \lambda = 0.65 \)). It is seen that the proposed strategies could improve the DQN methods in over 26 out of 30 tested environments by up to 2800% in some cases. The improvement for D2QN and D3QN was in 19 out of 30 games for up to 1900% and 700%, respectively. In some cases, however, the proposed strategies
lead to a performance drop up to 50% for all methods. These results well demonstrate the effectiveness of our proposed strategies.

In addition, Fig. 4(b) shows the performance comparison between our proposed strategies, the Lyapunov reward shaping strategy [22], \(k\)-nn-based trajectory selection shaping strategy [23], and a noisy neural network structure used in \(Q\)-learning [12]. The figure shows that the proposed reward shaping strategies could improve D2QN more effectively in comparison to other shaping strategies tested. Noisy structure improved the performance of D2QN in 27 out of 30 Atari games compared to 19 out of 30 when the proposed strategies were used. This shows that the noisy D2QN could provide a better baseline to benefit from our proposed shaping strategies, which is left as future work.

V. CONCLUSION AND FUTURE WORKS

In this brief, we introduced two strategies, called the SP and the reward backfill, to deal with the credit assignment problem. The strategies were inspired by the psychology of conditioning and behavior shaping, namely, the operant conditioning and clicker training. SP signals the agent mistakes to enable quicker learning to avoid such mistakes. The reward backfill propagates the value of a rewarded state back to the previous actions to signal the contribution of those previous actions to the action which explicitly rewarded. We proved that both of these two strategies maintain the order of policies in the space of all possible policies in terms of their total reward and, by extension, maintain the optimal policy. Hence, our proposed strategies integrate with any RL algorithm that learns a value or action-value function through experience. We further showed how to effectively implement these strategies to achieve a \(O(1)\) complexity in their calculations. Finally, we experimentally showed that these strategies can improve the ability of Deep \(Q\)-learning methods in 30 Atari 2600 games.

Both SP and reward backfill methods should be viewed as a supplementary strategy to the family of deep \(Q\)-learning algorithms, which are designed for overcoming the credit assignment problem. Because these strategies do not modify the internal computational mechanism of a deep \(Q\)-learning algorithm, they are also applicable in conjunction with other algorithms developed for overcoming sparse reward problem, such as prioritized experience replay [14] or curiosity-driven exploration [15] mentioned in Section II.

For the SP strategy, we realized that the improvement is not consistent across all environments, i.e., some environments are improved and some not. One potential reason is that some environments have more complicated terminal states where an agent reaching the terminal states is not directly caused by the latest actions it takes but a longer term strategy. In MsPackman, for example, an agent walks into a state where the enemies come from both sides, where the agent is going to reach the terminal state regardless of the action it takes. Another potential reason, also observable in our results, is that the optimal value for \(p\) can be different across environments, which encourages an adaptive strategy to control the value of \(p\) automatically for different iterations and environments. Finally, we observed that a larger \(p\) would not improve the results. One potential reason behind this event is that larger \(p\) potentially generates larger gradient value, which may lead to a delay in convergence or even divergence. Hence, based on our experiments, one simple criterion to make this strategy beneficial is to avoid using large \(p\) values, which again could be adjusted given the environment.

For the reward backfill strategy, we observed that the best \(\lambda\) is sensitive to the sparsity length in the environments, as it was predicted by Theorem 2. For example, in the game MsPackman, the agent receives rewards very frequently. Hence, according to Theorem 2, there is no guarantee that the incorporation of RB would not change the best solution of the RL problem. We actually observed that \(\lambda = 0.95\) and 0.85 leads to the worst results in MsPackman, indicating the negative impact the RB strategy may have on the learning when the sparsity length is short. Note, however, an environment with frequent rewards would not have the problem of sparse rewards, dimming the need for the RB strategy. We also noticed that the best value for \(\lambda\) is environment-dependent. Hence, one criterion to successfully use this approach is to ensure that the sparsity length is long enough or reduce the value of \(\lambda\) (or \(l_{\text{max}}\)) to ensure the consistency in the order of the optimality of policies.
The impact of the proposed methods appears to be environment-dependent, evidenced by our results. Thus, a natural extension to our work is to design an adaptive approach to adjust the relevant parameters of the methods during the learning procedure in a way that the addition of SP or RB is more likely to be beneficial. One example is to leverage the fact that the impact of RB is directly related to the value of $\lambda$ and sparsity of the rewards provided by the environment.

One interesting result is that there is a huge improvement (about ten times more than others) on the original DQN algorithm. A known issue with DQN is the overestimation of $Q$ value due to the greedy policy of approximation, and D2QN and D3QN subsequently mitigate the problem by applying additional weights and estimators. Although the reason behind such big improvement in DQN is unclear, it would be worthwhile to investigate whether the SP and RB strategies can help the overestimation issue in DQN.

ACKNOWLEDGMENT

The authors would like to acknowledge the use of GPU cluster, Wiener, at the Queensland Brain Institute, The University of Queensland, Brisbane, QLD, Australia, for running the experiments. They would also like to thank Jake Carroll who assisted in optimizing the codes to make the best use of that cluster.
