Abstract

Quantum decoherence is the loss of a system’s purity due to its reaction with the surrounding environment. Via AdS/CFT correspondence, we study how a system decoheres when its environment is a strongly-coupled theory. In Feynman-Vernon formalism, we compute the influence functional holographically by relating it to the generating function of Schwinger-Keldysh propagators and thereby obtain the dynamics of the system’s density matrix.

We present two exactly solvable examples: (1) a straight string in a BTZ black hole and (2) a scalar probe in AdS$_5$. We prepare an initial state that mimics Schrödinger’s cat and identify different stages of its decoherence process using the time-scaling behaviors of Rényi entropy. We also relate decoherence to local quantum quench, and by comparing the time evolution behaviors of the Wigner function and Rényi entropy we demonstrate that the relaxation of the local quantum excitation leads to the collapse of its wave-function.

I. MOTIVATION AND SUMMARY

Quantum decoherence is defined as the loss of ‘coherence’ of a quantum state, and its resulting transition to a classical state. What is its mechanism? Is it instantaneous or gradual? If latter is it possible to reduce its speed? The development of the quantum information science during the last twenty years has not only lifted these questions from the philosophical realm to the physical one but also made them pressing issues since a realistic quantum computer requires the qubits to remain coherent long enough for their operations to complete.

The Environment-Induced Decoherence developed by Zurek [1] differs from earlier mechanism of decoherence such as ‘Copenhagen Interpretation’ [2] and ‘Many Worlds’ [3] in that it is defined purely from quantum mechanics itself: the notion of classicality, the boundary between classical and quantum, the process of decoherence can all be defined and computed within the framework of Quantum Mechanics. Adding to its theoretical elegance are numerous experimental support such as [4].

In the framework of Environment-Induced Decoherence, the quantum decoherence problem is characterized by three elements: the ‘system’ of interest, its ‘environment’, and the interaction between the two. Both the ‘system’ and ‘environment’ are quantum, together they form a closed quantum system which evolves unitarily. However, the ‘system’ by itself is open: it starts to decohere the moment the interaction is turned on and eventually loses all its coherence and becomes a classical state. The ‘environment’ plays two crucial roles. First, it determines which states the ‘system’ can decohere into. Second, it causes the decoherence to happen via its interaction with the ‘system’.

---

1 Quantum decoherence is also crucial in resolving the information paradox of black holes and studying the primordial cosmic fluctuations during the inflation era of the Universe.
The natural question is then how to compute the decoherence rate for different combinations of ‘system’, ‘environment’, and the interaction between the two. The canonical formalism to study decoherence in Environment-Induced Decoherence scheme is Feynman-Vernon path-integral \([5, 6]\). Given the difficulty of decoherence problem (a non-equilibrium process of an open ‘system’ possibly at finite temperature), most of the early studies in this formalism is limited to the toy model in which both the ‘system’ and the ‘environment’ are simple harmonic oscillators (SHO), for which the decoherence rate can be computed exactly \([7, 8]\).

However, for non-trivial combinations of ‘system’ plus ‘environment’ with slow decoherence rates we need to extend our search beyond this toy model. Feynman-Vernon formalism is a first-principle method that requires no assumption on the detailed nature of the ‘system’ or the ‘environment’, therefore is capable of dealing with generic non-trivial ‘environment’. This leads to the focus of the present paper: Using Feynman-Vernon formalism, we will study quantum decoherence when the ‘environment’ is a non-trivial strongly-coupled quantum field theory that has a dual descriptions in terms of a gravity theory. More precisely, we will consider conformal field theories that are dual to gravity theories living in anti de Sitter space. In this Gauge/Gravity (or AdS/CFT) correspondence, the strongly-coupled field theory can be much more easily studied in terms of its weakly-coupled gravity dual.

The motivation is two-fold. One comes from experiments: the qubits (the ‘system’) in the lab are usually embedded in a strongly-coupled condensed matter ‘environment’. For instance, a very promising realization of quantum computation is the topological quantum computation \([10, 11]\), which utilizes the topologically-ordered phases of certain condensed-matter systems. Most of the topologically ordered phases \([12]\) are based on the gapped states and hence are robust against ordinary environmental disturbance. However, these gapped states or the localized zero-modes such as Majorana fermions \([13, 14]\) (viewed as ‘system’) still interact with the gapless states on the edge and might decohere via this interaction; and the gapless state should therefore be viewed as the ‘environment’ and they are usually described by strongly-coupled 2D conformal field theories.

The other motivation is theoretical. Even beyond the class of the topological quantum

---

2 In general, to mitigate the effect of decoherence on quantum computation one needs to implement fault-tolerant algorithms; however here we are only interested in the physical aspects of decoherence.

3 There have also been various approximations and reductions starting from the Feynman-Vernon formalism in order to treat more non-trivial ‘environments’ but they are more ad hoc and their validity need to be examined case-by-case (see e.g. \([9]\)).
computation, in general we should search among non-trivial (very likely strongly-coupled) theories for decoherence-suppressing ‘environments’. However, quantum decoherence with non-trivial ‘environment’ is a difficult problem. Therefore, we could start from those with weakly-coupled gravity duals in order to gain some insight to this problem.

In Feynman-Vernon formalism, all effects of the ‘environment’ can be packaged into a certain functional of the fields of the ‘system’ called ‘influence functional’. For the holographic quantum decoherence, the key observation is that the influence functional is nothing but the generating function of non-equilibrium Green’s functions (Schwinger-Keldysh propagator) in the ‘environment’ (for the case of linear coupling). This generating function can then be easily computed from the gravity side via AdS/CFT correspondence.

This holographic quantum decoherence applies to any holographic ‘environment’. In this paper, we demonstrate its power with two cases of ‘system’ plus ‘environment’: (1) the holographic dual of a straight string in a BTZ black hole and (2) that of a scalar probe in AdS\(_5\). In both cases we solve the dynamics of quantum decoherence exactly. Using two quantities (the negative part of Wigner function and the purity) to characterize the quantum decoherence, we then describe the full decoherence process and further distinguish its different stages according to the scaling behavior of the purity. We also write a python code to numerically study more complex cases. These results not only allow us to understand quantum decoherence in more details; more importantly, with our scheme one can study holographic ‘environments’ systematically, thus provide valuable insight for the construction of robust qubits.

We also notice the similarity between the environment-induced decoherence and the local quantum quench. We find that the decoherence and the quench occur around the same time, and match the scaling behaviors (with time) of the entanglement entropy in the quantum quench process with that of the purity in decoherence. This suggests that the quantum quench occurs when local excitations decohere.

This paper is organized as follows. In Section.II we review quantum decoherence and Feynman-Vernon method, and explain how to compute the influence functional from the gravity side. In Sec.III we compute the propagating function and use it to derive the master equation for the reduced density matrix. (The detailed derivations are contained in the Appendices.) In Sec.IV we study Wigner function, the purity, and relation of our setup to the local quantum quench. Sec.V examines the two exactly solvable cases. Sec.VI contains
II. FORMALISM FOR QUANTUM DECOHERENCE AND ITS HOLOGRAPHIC VERSION

A. Quantum Decoherence

If our world is intrinsically quantum mechanical, why does it appear to be classical most of the time? Can the concept ‘classical’ be defined in a purely quantum mechanical framework? How does a quantum mechanical system lose its ‘coherence’ and become classical? Is the process of ‘decoherence’, i.e. the quantum-to-classical transition, instantaneous or gradual? If latter how can we reduce its speed in order to build a real quantum computer?

These are the questions a framework for quantum decoherence need to address. Historically, the most prominent schemes are the following two (for a review see [1]).

1. Copenhagen interpretation [2]: Our world is divided into classical and quantum. A measuring apparatus is macroscopic and classical. A quantum mechanical system loses its coherence (i.e. wave-function collapse) the moment it is probed by a classical measuring apparatus. In this interpretation, the classicality and the boundary between the classical and the quantum cannot be defined within the framework of quantum mechanics but has to be introduced from outside.

2. Many Worlds [3]: Unlike in Copenhagen interpretation, the world does not have a priori classical subsystems and always evolves unitarily. The decoherence is caused by selecting a particular observer or subsystem.

The ‘Environment-Induced Decoherence’ developed by Zurek [4] differs from these earlier attempts in that it does not need a deus ex machina outside quantum mechanics to come in and announce the transition from quantum to classical. All questions asked in the beginning of this section can be answered within the framework of quantum mechanics.

First of all, a closed system is always quantum. Its state evolves unitarily according to the Schrödinger equation, and would never collapse into a classical state by itself. Now, let us divide this closed system into a subsystem (which we refer to as the ‘system’) and its complement ‘environment’, and we allow the interaction (hence the flows of energy and information) between the two. Now the ‘system’ is an open system and due to its interaction
with the ‘environment’, in general it would not evolve unitarily — even though the total
system (‘system’ plus ‘environment’) still does. This non-unitarity, hence the decoherence
of the ‘system’, is caused by the (non-unitary) influence of the environment via a ‘leaking’
of the quantum information from the ‘system’ into the ‘environment’.

The ‘environment’ is also quantum mechanical (unlike in Copenhagen Interpretation) and
plays two roles. First, it selects from the ‘system’ s Hilbert space a subspace of states which
are stable against the disturbance from the ‘environment’. These states are classical states
(also called pointer states) — this is the definition of classicality. Second, by interacting with
the ‘system’ the ‘environment’ causes the ‘system’ to lose its coherence between these pointer
states. The process of decoherence is gradual and its speed can be computed given the
‘system’, the ‘environment’, and the interaction between the two. Finally we can engineer
one or all of these three aspects in order to reduce the speed of decoherence — thereby
improving the robustness (against decoherence) of the quantum computer.

To discuss the quantum decoherence process, we need a language to describe the quantum
and classical states in a unified way. The density matrix \( \hat{\rho} \) is such one. Once we fix a basis,
the quantum coherence manifests itself in the presence of \( \hat{\rho} \)’s off-diagonal elements of \( \hat{\rho} \),
whose disappearance signifies the quantum decoherence process. At the end of decoherence,
a quantum state becomes a classical one, whose density matrix loses all off-diagonal elements.

Therefore we need to study the evolution dynamics of the density matrix \( \hat{\rho}_{sys} \) of the
‘system’. First, let us denote the density matrix of the total system (‘system’ plus ‘environment’) by \( \hat{\rho}_{tot}(t) \). As the total system is always quantum, its density matrix evolves unitarily
according to the Hamiltonian \( H_{tot} \) of the total system:

\[
\hat{\rho}_{tot}(t) = e^{-iH_{tot}(t-t_i)} \hat{\rho}_{tot}(t_i) e^{iH_{tot}(t-t_i)}
\]

(1)

where \( \hat{\rho}_{tot}(t_i) \) is the initial density matrix of the total system at \( t = t_i \) and we set \( \hbar = 1 \)
throughout the paper. We assume the factorized initial condition, i.e. at \( t = t_i \) the ‘system’
and the ‘environment’ are unentangled:

\[
\hat{\rho}_{tot}(t_i) = \hat{\rho}_{sys}(t_i) \otimes \hat{\rho}_{env}(t_i)
\]

(2)

Once \( \hat{\rho}_{tot}(t) \) is known, the reduced density matrix of the ‘system’ of interest is given by
tracing out the degrees of freedom of the ‘environment’:

\[
\hat{\rho}_{sys}(t) = Tr_{env} \hat{\rho}_{tot}(t).
\]

(3)
Then we can prepare the initial ‘system’ to be in a pure state, and the quantum decoh-
erence process of the ‘system’ is encoded in the way the reduced density matrix $\hat{\rho}_{\text{sys}}(t)$ evolves from that of a pure state into a classical one. Formally, the dynamics of the reduced density matrix can be encoded in a Schrödinger-like equation, i.e.,

$$i \frac{d\hat{\rho}_{\text{sys}}(t)}{dt} = [H_{\text{sys}}, \hat{\rho}_{\text{sys}}(t)] + \cdots$$

(4)

where $H_{\text{sys}}$ is the renormalized Hamiltonian of the ‘system’. The $\cdots$ terms characterize the non-unitarity of the influence from the ‘environment’ and is responsible for the quantum decoherence. In a general lab experiment, the transition of the ‘system’ from quantum to classical happens very fast. (Indeed, in general it appears to happen instantaneously.) Now, in the framework of environment-induced decoherence, we can actually compute this decoherence time-scale by a direct study of the time-evolution of $\hat{\rho}_{\text{sys}}(t)$. In particular we can verify that when the ‘environment’ is macroscopic as in a lab experiment, and the transition is indeed very fast.

Most of the computation in this paper is carried out in the path-integral formalism, therefore let us now look at the Lagrangian description. The Lagrangian for the total system (‘system’ plus ‘environment’) consists of three parts:

$$\mathcal{L}[\phi, \chi] = \mathcal{L}_{\text{sys}}[\phi] + \mathcal{L}_{\text{env}}[\chi] + \mathcal{L}_{\text{int}}[\phi, \chi].$$

(5)

The first two terms $\mathcal{L}_{\text{sys}}[\phi]$ and $\mathcal{L}_{\text{env}}[\chi]$ define the ‘system’ and ‘environment’, respectively. We use $\phi$ to denote collectively the degrees of freedom of the ‘system’, and $\chi$ those in the ‘environment’. The interaction between the two is given by $\mathcal{L}_{\text{int}}$. In this paper, we consider the simple case of linear coupling:

$$\mathcal{L}_{\text{int}}[\phi, \chi] = g \phi \mathcal{O}[\chi]$$

(6)

where $g$ is the coupling constant and $\mathcal{O}[\chi]$ is a given function of $\chi$.

We also assume that the number of degrees of freedom of the ‘system’ is much smaller than that of the ‘environment’, such that the back-reaction of the ‘system’ to the ‘environment’ can be ignored during the time scale of quantum decoherence of the ‘system’. This is a realistic assumption and have been adopted in the past study of quantum decoherence (see e.g. [6, 8, 15])

The main difference of the present paper from earlier study is the following. Previous studies of quantum decoherence usually consider the case in which ‘system’ $\phi$ is a simple
harmonic oscillator (SHO) and the ‘environment’ $\chi$ consists of a collection of independent SHOs at thermal equilibrium with temperature $T = 1/\beta$. The (linear) interaction between the two is dictated by the spectral weight $C_i$ of the SHOs in the ‘environment’:

$$L_{\text{int}}^{(\text{SHO})} = g \phi \sum_i C_i \chi_i . \quad (7)$$

This model is quadratic therefore the influence functional and evolution dynamics of $\hat{\rho}_{\text{sys}}$ can be obtained exactly in this case. Indeed, this is the simplest model to study non-equilibrial process in the presence of environmental influence: the Feynman-Vernon formalism was developed using this model \cite{5}; and later it was used to study the quantum Brownian motion in \cite{6} (which derived its Langevin equation after making a suitable choice of the spectral weight $C_i$); finally it was also used to study the quantum decoherence in \cite{8,16}. See also \cite{17–20} for the similar consideration of the fermionic version.

However, interesting physics happens when we go beyond the models with simple harmonics oscillators — this is what we will do in this paper. Both the ‘system’ and the ‘environment’ have two different aspects: the theory itself (given by the Lagrangians) and its physical state (given by its time-dependent density matrix). Since the ‘environment’ is assumed to be in a thermostatic state throughout the decoherence process (i.e. $\hat{\rho}_{\text{env}} = e^{-\beta H_{\text{env}}}$), we will allow the ‘environment’ Lagrangian to be arbitrary, although later in the actual computation we focus on theories with a dual gravity description so that we can use the holographic machinery to obtain results that would have been hard to compute directly in the fired theory side. And we are interested in the difference between different environment Lagrangians. On the other hand, we consider the ‘system’ as a probe to study the decoherence effects of different ‘environments’; therefore we will choose a simple ‘system’: a canonical scalar with Lagrangian

$$L_{\text{sys}}[\phi] = -\frac{1}{2} (\partial_{\mu} \phi)^2 - \frac{1}{2} \Omega^2 \phi^2 . \quad (8)$$

The influence functional can be regarded as the probe’s effective action, which is obtained after the “environment” degrees of freedom $\chi$ are integrating out.

B. Feynman-Vernon and Schwinger-Keldysh

In the coupled total system given by the Lagrangian \cite{5}, we are only interested in the evolution dynamics of the ‘system’, but not in the detailed dynamics of the ‘environment’.

Therefore the degrees of freedom of the ‘environment’ should be integrated out and its whole influence on the ‘system’ packaged into one or a few quantities. For the generic time-dependent problem at hand, this task requires the path-integral formalism devised by Feynman and Vernon in [5].

In this subsection, we review the Feynman-Vernon (FV) formalism. The main point of FV formalism is in rewriting the evolution (1) in the path-integral representation, and thereby integrating out the ‘environmental’ degrees of freedom \( \chi \) to produce an ‘influence functional’ that contains all the ‘environmental’ effect on the ‘system’. As the evolution of density matrix involves both forward \( (e^{-iH_{\text{tot}}t}) \) and backward \( (e^{iH_{\text{tot}}t}) \) propagators, the path integral should be formulated on an ordered closed-time path (Keldysh contour \( K \)), i.e., from \( t = t_i \) to \( t_f \) and then back [21, 22]. The ordinary causal Green function is replaced by a 2 \( \times \) 2 matrix of Green functions (a.k.a. Schwinger-Keldysh propagators) to account for the two branches in the Keldysh contour. The influence functional is precisely the generating function of these Schwinger-Keldysh propagator [23].

This formalism, including the connection between Feynman-Vernon and Schwinger-Keldysh, is valid for any initial density matrix \( \hat{\rho}_{\text{env}} \) of the ‘environment’. For our present case of thermostatic environment with \( \hat{\rho}_{\text{env}} = e^{-\beta H_{\text{env}}} \), the effect of the thermo-average can also be represented as a path-integral, but along the imaginary time direction from \( t_i \) to \( t_i - i\beta \). The thermo-Keldysh contour \( C \) is along the path

\[
C : \quad t_i \xrightarrow{1} t_f \xrightarrow{2} t_f - i\sigma \xrightarrow{3} t_i - i\sigma \xrightarrow{4} t_i - i\beta.
\]

In the original thermo-Keldysh contour, \( \sigma \) is chosen to be 0. Later it was shown in [24] that \( \sigma \) can actually be chosen arbitrarily since the ‘environment’ is thermostatic. To compare with the bulk computation, the symmetric choice \( \sigma = \frac{\beta}{2} \) is the most convenient one [25]. Therefore in this paper we will use the thermo-Keldysh contour \( C \) with \( \sigma = \frac{\beta}{2} \), as shown in Fig. 1.

Now let us use the method of Feynman-Vernon to compute the reduced density matrix \( \hat{\rho}_{\text{sys}} \) at the final time \( t_f \). Take an arbitrary element \( \langle \bar{\phi}_+ | \hat{\rho}_{\text{sys}}(t_f) | \bar{\phi}_- \rangle \). It is given by the total density matrix \( \hat{\rho}_{\text{tot}}(t_f) \) via (3):

\[
\langle \bar{\phi}_+ | \hat{\rho}_{\text{sys}}(t_f) | \bar{\phi}_- \rangle = \int d\tilde{\chi} \langle \bar{\phi}_+ , \tilde{\chi} | \hat{\rho}_{\text{tot}}(t_f) | \bar{\phi}_- , \tilde{\chi} \rangle
\]

where we use the bar to label the final values (at \( t = t_f \) of fields. Since we know that the total density matrix \( \hat{\rho}_{\text{tot}} \) evolves by (1), after inserting complete sets of fields at \( t = t_i \) we
can expand (10) into

$$
\langle \bar{\phi}^+|\hat{\rho}_{\text{sys}}(t_f)|\bar{\phi}^-\rangle = \int d\bar{\phi}^+ d\bar{\phi}^- d\bar{\chi}^+ d\bar{\chi}^- d\bar{\phi}^+ d\bar{\phi}^- \\
\langle \tilde{\phi}^+|e^{-iH_{\text{tot}}(t_f-t_i)}|\bar{\phi}^+,\bar{\chi}^+\rangle \cdot \langle \tilde{\phi}^+|\hat{\rho}_{\text{sys}}(t_i) \otimes \hat{\rho}_{\text{env}}(t_i)|\tilde{\phi}^+,\bar{\chi}^+\rangle \cdot \langle \tilde{\phi}^-|e^{iH_{\text{tot}}(t_f-t_i)}|\tilde{\phi}^-,\bar{\chi}^-\rangle
$$

(11)

where we used tilde to label the initial values (at $t = t_i$) of fields.

The integrand of (11) consists of three terms. The first and third are forward and backward propagators, respectively, which can be rewritten in the path-integral representation as

$$
\langle \tilde{\phi}^+|e^{-iH_{\text{tot}}(t_f-t_i)}|\tilde{\phi}^+,\bar{\chi}^+\rangle = \int_{\tilde{\phi}^+}^{\bar{\phi}^+} D\tilde{\phi}^+ \int_{\bar{\chi}^+}^{\tilde{\chi}^+} D\bar{\chi}^+ e^{i \int_{t_i}^{t_f} dt L[\phi^+,\chi^+]} , \\
\langle \tilde{\phi}^-|e^{iH_{\text{tot}}(t_f-t_i)}|\tilde{\phi}^-,\bar{\chi}^-\rangle = \int_{\tilde{\phi}^-}^{\bar{\phi}^-} D\tilde{\phi}^- \int_{\bar{\chi}^-}^{\tilde{\chi}^-} D\bar{\chi}^- e^{-i \int_{t_i}^{t_f} dt L[\phi^-,\chi^-]} 
$$

(12)

where $\tilde{\chi}^+ = \tilde{\chi}^- = \tilde{\chi}$ and we have used the subscript $+/-$ to denote fields living on forward/backward time path.

Now let us extract all the information of the ‘environment’ field $\chi$ from the r.h.s of (11). Plugging (12) back into (11) and recalling that the Lagrangian in (12) is given by (5), we
can package all the information of the ‘environment’ field $\chi$ into an influence functional $F$ defined as:

$$F[\phi_+, \phi_-] \equiv \int d\chi_+ d\chi_- \langle \chi_+ | \hat{\rho}_{\text{env}}(t_f) | \chi_- \rangle$$

$$\cdot \int_{\chi_+}^{\chi} \mathcal{D}\chi_+ \int_{\chi_-}^{\chi} \mathcal{D}\chi_- e^{-i \int_{t_i}^{t_f} dt (L_{\text{env}}[\chi_+] - L_{\text{env}}[\chi_-] + L_{\text{int}}[\phi_+ \chi_+] - L_{\text{int}}[\phi_- \chi_-])} .$$  (13)

Once the influence functional is known, (11) is given by

$$\langle \tilde{\phi}_+ | \hat{\rho}_{\text{sys}}(t_f) | \tilde{\phi}_- \rangle = \int d\tilde{\phi}_+ d\tilde{\phi}_- J[\tilde{\phi}_+, \tilde{\phi}_-; t_f | \tilde{\phi}_+, \tilde{\phi}_-; t_i] \langle \tilde{\phi}_+ | \hat{\rho}_{\text{sys}}(t_f) | \tilde{\phi}_- \rangle$$  (14)

where $J$ is the propagating function that dictates the evolution of $\hat{\rho}_{\text{sys}}$ from $t = t_i$ to $t_f$, and it depends on the ‘system’ Lagrangian and ‘environmental’ influence functional via:

$$J[\tilde{\phi}_+, \tilde{\phi}_-; t_f | \tilde{\phi}_+, \tilde{\phi}_-; t_i] \equiv \int_{\tilde{\phi}_+}^{\phi_+} \mathcal{D}\phi_+ \int_{\tilde{\phi}_-}^{\phi_-} \mathcal{D}\phi_- e^{i \int_{t_i}^{t_f} dt (L_{\text{sys}}[\phi_+] - L_{\text{sys}}[\phi_-])} F[\phi_+, \phi_-].$$  (15)

Therefore the most crucial task is to compute the influence functional $F$.

First, (13) can be written concisely as

$$F[\phi_+, \phi_-] = \langle \mathcal{T}_K e^{i \int_K L_{\text{int}}[\phi, \chi]} \rangle_{\text{env}}$$  (16)

where the correlator is averaged w.r.t. the initial density matrix of the ‘environment’:

$$\langle \cdots \rangle_{\text{env}} \equiv \text{Tr}_{\text{env}} [\hat{\rho}_{\text{env}} \cdots]$$  (17)

and $K$ denotes the closed-time path (i.e. the contour $\mathcal{C}$ of Fig. 1 if the ‘environment’ is thermostatic.), $\mathcal{T}_K$ is the path-ordering operator. For a generic interaction $L_{\text{int}}$, the influence functional $F$ is difficult to compute. However, when the interaction $L_{\text{int}}$ is linear in $\phi$ as given in (6), (16) becomes

$$F[\phi_+, \phi_-] = \langle \mathcal{T}_K e^{i g \int_K O[\chi]} \rangle_{\text{env}} .$$  (18)

If we consider the ‘system’ field $\phi$ regarded as the source of the ‘environment’ field $\chi$ (or more precisely of $O[\chi]$), the influence functional $F$ with the linear coupling (18) is precisely the generating function of the real-time Green function at finite temperature (a.k.a. Schwinger-Keldysh propagators), which are defined as

$$G_{ss'}(1, 2) \equiv -i \langle \mathcal{T}_K O_s(1) O_{s'}(2) \rangle_{\text{env}}$$  (19)
where $T_K$ is the path-ordering operator along the closed-time path $K$, $s, s' = \pm$, and $O_s(1) \equiv O[\chi_s(t_1, x_1)]$. Namely
\begin{equation}
G_{ss'}(1, 2) = -i \frac{\delta \ln F[\phi_+, \phi_-]}{\delta \phi_s(1) \delta \phi_{s'}(2)} \Big|_{\phi = 0}. \tag{20}
\end{equation}

Given the influence functional, the Schwinger-Keldysh Green functions can be obtained via (20). However, for the decoherence problem at hand, the question is the inverse: How to compute the influence functional $F$ once we know the Schwinger-Keldysh Green function $G_{ss'}(1, 2)$ of the ‘environment’? To answer this question, additional assumption on the coupling between ‘system’ and ‘environment’ is needed. In the case of weak coupling $g \ll 1$, we can approximate by keeping only the quadratic coupling term (in the exponent of $F$) and dropping all higher order terms:
\begin{equation}
-i \ln F[\phi_+, \phi_-] \approx -\frac{g^2}{2} \int d^{d+1}x \int d^{d+1}x' \sum_{s, s'} \text{sgn}(ss') \phi_s(x) G_{ss'}(x - x') \phi_{s'}(x'). \tag{21}
\end{equation}

In fact, when the ‘environment’ is composed of collection of simple harmonic oscillators, the coupling is necessarily quadratic (in $\phi$), and (21) is actually the exact answer.

To summarize, the strategy of studying the decoherence (in the FV formalism) is to first solve the Schwinger-Keldysh Green function of the ‘environment’, then using (21) we can immediately obtain the influence functional $F$, which in turn gives the propagating function $J$ via (15), and then it is straightforward to study the evolution of $\hat{\rho}_{\text{sys}}$ using (14).

Before we proceed, let us first simplify (21) further. First of all, out of the four Green functions $G_{ss'}$ only three are independent, since by definition
\begin{equation}
G_{++} + G_{--} = G_{-+} + G_{+-}. \tag{22}
\end{equation}

The remaining three linear combinations of $G_{ss'}$ contains two types of information on the ‘environment’. The advanced and retarded Green function $\{G_A, G_R\}$ encode the dispersion relations of the ‘environment’, whereas the symmetric Green function $G_{\text{sym}}$ describes the actual state of the ‘environment’. Therefore it is more convenient to switch to a basis for the matrix Green function such that its four components are manifestly $\{G_R, G_A, G_{\text{sym}}, 0\}$. Accordingly, instead of $\{\phi_+, \phi_-\}$, we should switch to the basis $\{\Sigma, \Delta\}$ in ‘system’:
\begin{equation}
\Sigma = \frac{\phi_+ + \phi_-}{2}, \quad \Delta = \phi_+ - \phi_- \tag{23}
\end{equation}

$^4$ It was explicitly shown in [26] that the leading term of the influence functional yields the generating function for the Schwinger-Keldysh Green functions of $O[\chi]$ in a thermal reservoir.
The field $\Delta$ is the difference (i.e. relative) between the two fields $\phi_+$ and $\phi_-$ (from the two branches of the contour), and $\Sigma$ is the average — therefore this is $\{\Sigma, \Delta\}$ is called the ‘ra’ basis, in which the influence functional can be written as

\[ -i \ln \mathcal{F} = -g^2 \int_{t_i}^{t_f} dt \int_{t_i}^{t_f} dt' \int d^4x \, d^4x' \left[ \Delta(x) G_R(x - x') \Sigma(x') - \frac{i}{2} \Delta(x) G_{\rm sym}(x - x') \Delta(x') \right] \]

(27)

where we have used the relation

\[ G_A(1, 2) = G_R(2, 1) \, . \]

(28)

So far, the derivation applies to generic $\hat{\rho}_{\text{env}}(t_i)$. Indeed, as long as we can obtain the ‘environment’$^{5}$’s Green function, we can study the decoherence in this ‘environment’ using no matter how exotic the ‘environment’ is — even if the ‘environment’ itself is in non-equilibrium (with interesting examples being de Sitter space and non-thermal ‘environment’).

Now let’s restrict to the most realistic and simply situation when the ‘environment’ is in a thermo-equilibrium with temperature $\frac{1}{\beta}$ when $\hat{\rho}_{\text{env}} = e^{-\beta H_{\text{env}}}$. As explained earlier, the effect of the thermo-average can be accounted for by the vertical segments in the contour $\mathcal{C}$, and the fields that appear in the definition of Schwinger-Keldysh propagators become $O_{\pm}(1) \equiv O[\chi_{\pm}(t_1, \vec{x}_1)]$ with

\[ \chi_+(t) = e^{iH_{\text{env}}t} \chi e^{-iH_{\text{env}}t} \, , \quad \chi_-(t) = e^{iH_{\text{env}}(t-i\sigma)} \chi e^{-iH_{\text{env}}(t-i\sigma)} \, . \]

(29)

When the ‘environment’ is in a thermo-equilibrium its Green’s functions satisfies another constraint, namely the Kubo-Martin-Schwinger (KMS) condition $^{27}$:

\[ G_{++}(t - i\beta, \vec{x}) = G_{--}(t, \vec{x}) \]

(30)

which gives rise to the condition

\[ G_{\text{sym}}(\omega) = -[1 + 2n(\omega)] \text{Im} G_R(\omega) \]

(31)

Accordingly, the Green functions in the ‘ra’ basis are related to the Schwinger-Keldysh ones as follows:

\[ G_{\text{sym}} = \frac{i}{4}(G_{++} + G_{--} + G_{+-} + G_{-+}) \, , \]

(24)

\[ G_R = \frac{1}{2}(G_{++} - G_{--} - G_{+-} + G_{-+}) \, , \]

(25)

\[ G_A = \frac{1}{2}(G_{++} - G_{--} + G_{+-} - G_{-+}) \, . \]

(26)

If not, the condition (30) and (31) are not valid. However, in this paper we will restrict to the thermostatic environment at all time as the probe is small and local compared to the environment. For discussions of quantum decoherence in the non-thermostatic environment, see $^{17, 18, 20}$.
in the frequency domain, where \( n(\omega) = \frac{1}{e^{\omega T} - 1} \) is the thermal distribution of the ‘environment’. Eq. (31) relates the symmetric Green function to the imaginary part of the retarded Green function, which is the spectral function for the \( \mathcal{O}[\chi] \) excitations.

To summarize, when the ‘environment’ is thermostatic, all its dynamical information can be encoded in the retarded Green function \( G_R \). Note that there is no quadratic term for \( \Sigma \) in (27) due to the condition (28). Moreover, the quadratic form of (27) ensures that one can further solve the propagating function for \( \hat{\rho}_{\text{sys}} \), i.e. (15) in a closed form as long as \( S_{\text{sys}}[\phi] \) is also quadratic. This implies that the dynamics of \( \hat{\rho}_{\text{sys}} \) can be accurately determined once \( G_R \) is known.

We consider the relation (27) (or together with its higher order term) the most essential element in study of quantum decoherence as it connects the Feynman-Vernon (the theoretical framework of environment-induced decoherence) to Schwinger-Keldysh (the machinery that allows us to capture and compute the influence from the ‘environment’). Its interpretation is the following. Once the ‘system’ starts to interact with the ‘environment’, it is under the influence of the ‘environmental noise’. The basic properties of this noise, such as its energy and lifetime, is characterized by the ‘environment’\’s retarded Green function \( G_R \) (in terms of its poles and zeros), from which one can extract the corresponding transport coefficients of the thermal reservoir by, for instance, the Kubo formula. (This step is the standard application of Schwinger-Keldysh formalism.) Then from the viewpoint the ‘system’, the transport phenomena carries away its quantum information and causes its (gradual) decoherence.

At this point, one might wonder why this natural connection hasn’t been very visible in the literatures of quantum decoherence. There are two reasons. In the usual discussion of quantum decoherence, the ‘environment’ is modeled by a collection of SHOs for simplicity, and its spectral function (i.e. the spectral weight \( C_i \) in (7)) can then be chosen at will and put in by hand (instead of being determined from first principle QFT computation). Furthermore, the simplicity of the SHO model makes the machinery like (27) unnecessary since in this case the influence functional can be easily obtained in closed-form. It is this simplicity that has delayed the application of Feynman-Vernon formalism to more general ‘environments’ and therefore the study of quantum decoherence in more physical and interesting situations.
C. Holographic influence functional

The relation \( (27) \) is central to Environment-induced decoherence and applies to any ‘environment’; now let us apply it to cases beyond the toy model with SHO ‘environment’. A crucial step is to evaluate the retarded Green function \( G_R \) of \( O[\chi] \) (the operator in the ‘environment’ that couples to the ‘system’ field \( \phi \)). After obtaining the retarded Green function, we can plug it into \( (27) \) to calculate the influence functional from which one can explore the behaviors of quantum decoherence. The retarded Green function is in general difficult to evaluate except for the free theory. This is part of the reason that the quantum decoherence for the interacting ‘environment’ is much less studied.

However, besides the free theory, there exists a class of strongly-coupled theories whose retarded Green functions can be obtained in practice. These are the theories with dual gravity descriptions. The most developed class of Gauge/Gravity duality is the AdS/CFT correspondence, in which the (non-gravitational) field theory is a \( d \)-dimensional conformal field theory and its gravity dual lives in a \((d+1)\)-dimensional asymptotically AdS space. The zero-temperature (Euclidean) two-point functions of these CFTs have power-law behaviors; whereas the finite-temperature real-time Green functions cannot be determined by the conformal symmetry alone, but can be evaluated through its gravity dual.

In the present context, our probe field \( \phi \) plays the role of the external source coupled to the operator \( O[\chi] \). In the gravity dual, \( \phi \) is the boundary value of a massive elementary field in the asymptotically AdS space, with its mass determined by the conformal dimension of operator \( O[\chi] \). Then, the generating function for the correlation functions of operator \( O[\chi] \), i.e., the influence functional, is determined by the on-shell action of the corresponding massive field \( [28] \):

\[
F^{(h)}[\phi] := \langle e^{ig \int_C d^{d+1}x \phi \cdot \partial^2 \chi} \rangle_{\chi} = e^{iS_{\text{bulk}}[\Phi]}[\phi]
\]

where \( \Phi|\phi \) is the on-shell bulk scalar with \( \phi \) being its value at AdS boundary, and \( S_{\text{bulk}} \) is the bulk action of \( \Phi \). The superscript \( h \) denotes the “holographic”.

The prescription of calculating the on-shell bulk action to derive the Euclidean two-point functions was proposed in \( [28] \): one imposes Dirichlet boundary condition at the AdS boundary and needs to choose appropriate boundary action when evaluating the on-shell action. For evaluating the Lorentzian correlation functions such as the retarded Green function, especially at finite temperature (corresponding to a black hole in asymptotically AdS space),
the choice of the boundary condition at the black hole horizon and the corresponding boundary action are more subtle. The subtlety arises because there is a coordinate singularity at the horizon, thus one should choose the appropriate boundary condition for \( \Phi \rvert_\phi \) at horizon to have a smooth solution. This choice corresponds to the thermal vacuum for the dual CFT. To compute the retarded Green function, one should choose the in-falling condition for the on-shell \( \Phi \rvert_\phi \) at the black hole horizon, and the result is [29, 30]:

\[
G^{(h)}_R(x) = -\lim_{r \to \infty} \frac{\Pi(x, r)\rvert_{\Phi \rvert_\phi}}{\Phi \rvert_{\phi}(x, r)}
\]

where \( x \) is the transverse coordinate of the AdS space and \( r \) is the radial one with the AdS boundary at \( r \to \infty \). Here \( \Pi\rvert_{\Phi \rvert_\phi} \) is the conjugate momentum of \( \Phi \) with respect to the on-shell bulk action.

In fact, the denominator of (33) is the leading term in the large \( r \) expansion of \( \Phi\rvert_\phi \), and the numerator is the sub-leading one. After scaling away the \( r \) factors in both the numerator and denominator of (33), it can be seen as a linear response theory for the dual CFT: \( G^{(h)}_R = \langle \mathcal{O} \rangle_{\phi} \) if one identifies \( \Pi\rvert_{\Phi \rvert_\phi} \) as \( \langle \mathcal{O} \rangle_{\phi} \) after some appropriate rescaling.

It was shown in [25] that the on-shell action for a bulk scalar in the AdS black hole background yields the same form as the r.h.s. of (21). The forward and backward paths in the Schwinger-Keldysh formalism correspond to the time path in a causal patch and the one in its mirror image of the Penrose diagram for an eternal AdS black hole. Combining this result with (32), we summarize that the holographic influence functional is given as follows:

\[
-i \ln F^{(h)} = -g^2 \int_{t_1}^{t_f} d\tau \int_{t_1}^{t_f} d\tau' \int d^d x \int d^d x' \left[ \Delta(x) G^{(h)}_R(x-x') \Sigma(x') - i \Delta(x) G^{(h)}_{sym}(x-x') \Delta(x') \right]
\]

where \( G^{(h)}_R \) is evaluated as in (33), and \( G^{(h)}_{sym} \) is related to \( G^{(h)}_R \) by KMS condition (31). This is the holographic version of (27). Again, the quadratic form of (34) is guaranteed by the weak coupling \( g \) so that the higher order correlation terms are suppressed.

Here, two remarks are in order:

1. Although one can obtain the holographic influence functional by treating the ‘environment’ as a holographic CFT, one cannot naturally incorporate the kinetic term for the probe field in this context as it is treated as an external source. Thus, we need to

---

7 For a massive canonical bulk scalar \( \Phi \) in a \((d+1)\)-dimensional AdS space, \( \phi(x) = \lim_{r \to \infty} \Phi \rvert_{\phi}(x, r) \) and \( \langle \mathcal{O} \rangle_{\phi} = \lim_{r \to \infty} r^{d-\Delta} \Pi(x, r) \rvert_{\Phi \rvert_\phi} \) with \( \Delta \) the conformal dimension of \( \mathcal{O} \).

8 This kind of identification was first proposed in [31] for Schwarzschild black hole, and later generalized to AdS one in [32].
put in probe’s kinetic term such as $[8]$ by hand. It would be more satisfactory if the dynamics of the probe field can also be embedded in the bulk holographically.

2. The holographic CFTs are usually gauge theories therefore the operator $O[\chi]$ should be a gauge invariant observable. Hence the probe can only decohere through a particular channel of physical observable to which it couples. The probe and its decoherence behavior are characterized by the spectral density of $O[\chi]$ encoded in the retarded Green function. This is in contrast to the case of SHO ‘environment’ in which the probe SHO couples directly to all the ‘environmental’ degrees of freedom and the probe and its decoherence behavior are characterized by the spectral weight $C_\ell$ in $[7]$. This difference is illustrated in Fig. 2.

![FIG. 2. Different decoherence mechanisms for the probe $\phi$. Left: $\phi$ in thermal reservoir of simple harmonic oscillators. Right: $\phi$ in holographic thermal reservoir.](image)

**III. PROPAGATING FUNCTION**

As shown in the previous section, the evolution of the ‘system”s reduced density matrix $\hat{\rho}_{\text{sys}}$ is given by an integral transform $[14]$, whose kernel is the propagating function $J$ given by $[15]$. The propagating function $J$ is determined by two inputs via the path-integral $[15]$: (1) the data of the ‘system’ (i.e. its Lagrangian and its initial and final states $\{\tilde{\phi}_\pm, \bar{\phi}_\pm\}$); (2) the effect from the ‘environment’ (i.e. the influence functional $\mathcal{F}$, which can be expressed in terms of Schwinger-Keldysh propagators of the ‘environment’). In this section, we first combine the two inputs to rewrite the propagating function directly in terms of the ‘environment”s Green function plus the ‘system”s data. This then allows us to derive the master equation of $\hat{\rho}_{\text{sys}}$. 

18
A. Langevin equation from propagating function

The propagating function $J$ given in (15) can also be interpreted as the path-integral of the ‘system’ on the Keldysh contour $\mathcal{K}$:

$$
J\left[\phi_+^\ast, \phi_-^\ast; t_f | \phi_+^\ast, \phi_-^\ast; t_i\right] = \int_{\phi_+^\ast}^{\phi_-^\ast} \mathcal{D}\phi_+ \int_{\phi_-^\ast}^{\phi_+^\ast} \mathcal{D}\phi_- e^{iS_{\text{eff}}[\phi_+, \phi_-]} 
$$

(35)
in which the action of the ‘system’ is modified into $S_{\text{eff}}$ due to the influence of the ‘environment’:

$$
S_{\text{eff}}[\phi_+, \phi_-] \equiv \int_{t_i}^{t_f} dt \left( \mathcal{L}_{\text{sys}}[\phi_+] - \mathcal{L}_{\text{sys}}[\phi_-] \right) - i \ln \mathcal{F}[\phi_+, \phi_-]. 
$$

(36)

Now we switch to the ‘ra’ basis which is more suitable when studying the non-equilibrium process in terms of ‘environment’’s Green functions, and set $t_i = 0$ and $t_f = t$, with which $J$ becomes a partition function of $\{\Sigma, \Delta\}$:

$$
J\left[\Sigma, \Delta; t | \Sigma, \Delta; 0\right] = \int_{\Sigma}^{\Sigma} \mathcal{D}\Sigma \int_{\Delta}^{\Delta} \mathcal{D}\Delta e^{iS_{\text{eff}}[\Sigma, \Delta]} 
$$

(37)

with action

$$
S_{\text{eff}}[\Sigma, \Delta] = \int_{0}^{t} d\tau [\dot{\Sigma}(\tau)\dot{\Delta}(\tau) - \Omega^2 \Sigma(\tau)\Delta(\tau)]
$$

$$
- g^2 \int_{0}^{t} d\tau \int_{0}^{t} d\tau' [\Delta(\tau)G_R(\tau - \tau')\Sigma(\tau') - \frac{i}{2} \Delta(\tau)G_{\text{sym}}(\tau - \tau')\Delta(\tau')]. 
$$

(38)

where have used the ‘system’ Lagrangian (8) and the expression of $\mathcal{F}$ in terms of Schwinger-Keldysh propagators (27), and $\dot{\Sigma} \equiv \frac{\partial \Sigma}{\partial t}$, and we suppress the spatial dependence for simplicity.

Before we proceed to evaluate the propagating function $J$ using (37) and (38), let’s first check that it has the correct semi-classical limit. In the semi-classical approximation, $J$ should give the Langevin equation for the quantum Brownian motion as shown earlier in [6, 33, 34]. Now we review the derivation. Viewing $J$ as the partition function of $\{\Sigma, \Delta\}$, and recall that the ‘average’ field $\Sigma$ is slow and heavy whereas the ‘relative’ field $\Delta$ is fast and light, we can integrate out the light field $\Delta$ and obtain the classical trajectory of the heavy field $\Sigma$.

First, via a Legendre transform, the $\Delta^2$ term in the r.h.s. of (38) can be rewritten as

$$
e^{-\frac{1}{2}g^2 \int_{0}^{t} d\tau \int_{0}^{t} d\tau' \Delta(\tau)G_{\text{sym}}(\tau - \tau')\Delta(\tau')} = \int \mathcal{D}\xi e^{i \int_{0}^{t} d\tau \xi(\tau)\Delta(\tau)-\frac{1}{2g^2} \int_{0}^{t} d\tau \int_{0}^{t} d\tau' \xi(\tau)G_{\text{sym}}^{-1}(\tau - \tau')\xi(\tau')}.
$$

(39)
Namely the fast field $\Delta$ can be considered as the response field of a Gaussian random force $\xi$ which has the correlation

$$
\langle \xi(\tau)\xi(\tau') \rangle_{\text{env}} = g^2 G_{\text{sym}}(\tau - \tau') .
$$

Intuitively, integrating out the light ‘relative’ (light and fast) mode $\Delta$ should provide random kicks to the ‘center-of-mass’ (heavy and slow) mode $\Sigma$. Therefore we plug (39) into (37) and (38) and integrate out $\Delta$ to obtain

$$
J = \int \mathcal{D}\xi e^{-\frac{1}{2} \int_0^t dt \int_0^t dt' \xi(\tau)G_{\text{sym}}^{-1}(\tau-\tau')\xi(\tau')} \int D\Sigma \delta \left[ \dddot{\Sigma}(\tau) + \Omega^2 \Sigma(\tau) + g^2 \int_0^\tau d\tau' G_R(\tau-\tau')\Sigma(\tau') - \xi(\tau) \right].
$$

(41)

The argument of the delta-function gives the classical equation obeyed by the center-of-mass field $\Sigma$:

$$
\dddot{\Sigma}(\tau) + \Omega^2 \Sigma(\tau) + g^2 \int_0^\tau d\tau' G_R(\tau-\tau')\Sigma(\tau') = \xi(\tau)
$$

(42)

which is precisely the Langevin equation, where $\Sigma$ is the slow field and $\xi(\tau)$ the noise that satisfies (40). The fluctuation-dissipation theorem for this quantum Brownian motion is nothing but the KMS condition (31).

**B. Evaluating the propagating function and master equation**

Unlike the discussion in the previous subsection, to fully characterize the dynamics of $\hat{\rho}_{\text{sys}}$ and examine the quantum decoherence of the probe, one should carry out explicitly the Gaussian path integral of (37). Though the calculation was done, for example in [8], we review it in Appendix A for completeness and fixing the notation. Besides, there are some issue about the normalization of $\hat{\rho}_{\text{sys}}$ which was not considered explicitly in [8], thus we carry out the explicit calculation in Appendix C.

Since in the decoherence process, we are mainly interested in the time-dependence of $\hat{\rho}_{\text{sys}}$, from now on we will focus on the case in which the ‘system’ field has no spatial dependence. For example, this is the case when the ‘system’ is a particle and the $\phi$ field its coordinate, or if we only consider one particular momentum mode of $\phi$. The result of $J$ is then summarized here:

$$
J[\Sigma, \Delta, t|\bar{\Sigma}, \bar{\Delta}, 0] = \frac{1}{2\pi|h(t)|} e^{iW_{\text{eff}}[\Sigma, \Delta, \bar{\Sigma}, \bar{\Delta}; t]}
$$

(43)
where

\[
\mathcal{W}_{\text{eff}} \equiv \left( \dot{f}_0(t) \bar{\Sigma} + \dot{f}_1(t) \Sigma \right) \Delta - \left( \dot{f}_0(0) \bar{\Sigma} + \dot{f}_1(0) \Sigma \right) \Delta - \frac{1}{2} \left( a_{00} \Delta^2 + (a_{01} + a_{10}) \Delta \Delta + a_{11} \Delta^2 \right)
\]  

(44)

and

\[
a_{ij}(t) \equiv g^2 \int_0^t d\tau \int_0^t d\tau' g_i(\tau) G_{\text{sym}}(\tau - \tau') g_j(\tau').
\]  

(45)

For simplicity, we set \( t_i = 0 \) and \( t_f = t \) from now on. The functions \( \{h, f_0, f_1, g_0, g_1\} \) are defined as follows. First, \( h(\tau) \) is the central one based on which all others are defined; and it is the solution of the initial value problem:

\[
\ddot{h}(\tau) + \Omega^2 h(\tau) + g^2 \int_0^\tau d\tau' G_R(\tau - \tau') h(\tau') = 0 \quad \text{with} \quad h(0) = 0, \quad \dot{h}(0) = 1
\]  

(46)

which can be solved via Laplace transform:

\[
h(\tau) = \mathcal{L}^{-1} \left[ \hat{h}(s) \right]
\]

with

\[
\hat{h}(s) = \frac{1}{s^2 + \Omega^2 + g^2 \hat{G}_R(s)}.
\]  

(47)

Then \( \{f_0, f_1, g_0, g_1\} \) are defined in terms of \( h \) via:

\[
f_0(\tau) = -\frac{\dot{h}(t)}{h(t)} h(\tau) + \dot{h}(\tau) \quad f_1(\tau) = \frac{1}{h(t)} h(\tau)
\]  

(48)

and

\[
g_0(\tau) = f_1(t - \tau), \quad g_1(\tau) = f_0(t - \tau).
\]  

(49)

Note that \( \{f_0, f_1, g_0, g_1\} \) are actually functions of both \( \tau \) and \( t \), with \( t \) entering as the boundary point. For details of the derivation above see Appendix \[A\].

With the above explicit form of the propagating function, we can now derive \( \dot{\rho}_{\text{sys}} \)'s master equation (the evolution equation of a density matrix) starting from (14). In the ‘ra’ basis, the l.h.s. of (14) is a function of \( \{\Sigma, \Delta\} \), and we compute its time-derivation. Since the derivation is rather long, we leave the details is Appendix \[B\] and here only write down the final result:

\[
i \frac{\partial \rho_{\text{sys}}(\Sigma, \Delta, t)}{\partial t} = \left[ -\frac{\partial^2}{\partial \Sigma \partial \Delta} + \Omega^2 \delta_{\text{ren}}(t) \Sigma \Delta \right] \rho_{\text{sys}}(\Sigma, \Delta, t)
\]

\[
+ \left[ i \gamma_1(t) \frac{\partial}{\partial \Delta} + \gamma_2(t) \Delta \frac{\partial}{\partial \Sigma} + i \gamma_3(t) \Delta^2 \right] \rho_{\text{sys}}(\Sigma, \Delta, t)
\]

\[
+ i \gamma_4(t) \frac{\partial^2}{\partial \Sigma^2} \rho_{\text{sys}}(\Sigma, \Delta, t)
\]  

(50)

\[\text{---}
\]

\[\text{---}
\]
(for detailed expression of $\Omega_{ren}$ and $\gamma_i$ please refer to Appendix B).

Let us now explain the master equation (50). In the first line, $\Omega_{ren}(t)$ is the renormalized frequency, and this line is the renormalized Liouville term which preserves the unitarity. The terms in the second line are responsible for the quantum decoherence. $\gamma_i(t)$ with $i = 1, \ldots, 4$ are functions of time in generic situations; in the special case where all $\gamma$’s are time-independent, the evolution dynamics is Markovian. Note that the last term is absent in [8], however it can be re-absorbed into the kinetic term of the Hamiltonian via a renormalization of the mass. The difference could be due to the different routes in the derivation of (50): We obtained (50) by directly taking time derivative on (43), whereas in [8] the counterpart of (50) was derived via a perturbation analysis of the path integral expression of (15).

IV. CHARACTERIZATION OF QUANTUM DECOHERENCE

After deriving the explicit form of the master equation (50), we could now solve it to obtain the density matrix $\hat{\rho}_{sys}(t)$ for a given initial state. Alternatively, since we have the explicit form of the propagating function given by (43), we can also directly compute $\hat{\rho}_{sys}(t)$ via (14). Once we obtain $\hat{\rho}_{sys}(t)$, how can we use it to characterize a decoherence process?

Recall that the ‘environment’ is not only responsible for destroying the coherence in the ‘system’: first and foremost it selects from the Hilbert space of the ‘system’ a subspace of states that are most stable against the ‘environmental’ disturbance; these states are called pointer states, and become classical states at the classical limit $\hbar \to 0$ [1].

In the basis of these pointer states, the quantum coherence is encoded in the off-diagonal elements of the density matrix of the ‘system’, and the Environment-Induced decoherence is then the process of the gradual decrease (to zero) of these off-diagonal elements.

However, for our present ‘system’ of a scalar $\phi$, it is not feasible to directly look at the explicit elements of $\hat{\rho}_{sys}$, for the following two reasons. First, since $\phi$ takes continuous values, $\hat{\rho}_{sys}$ is an infinite-dimensional matrix. Second, “decoherence is the disappearance of $\hat{\rho}_{sys}$’s off-diagonal elements” is a basis-dependent statement; however, the pointer states are not exactly stable under the ‘environmental’ disturbance (since we do not take $\hbar \to 0$ limit) therefore the pointer basis of the density matrix is not invariant during the decoherence process.

To solve the first problem, we can coarse-grain the ‘system’ — i.e. to prepare its ini-
tial state to resemble a simple finite-dimensional system, even a qubit (the quintessence of Schrödinger’s cat). In this section, we will first explain how to prepare (an approximation of) Schrödinger’s cat with the scalar $\phi$ in our ‘system’.

The second problem can be solved in two ways. The first basis-independent information on the degree of ‘coherence’ can be found in the Wigner function $W(\Sigma, p, t)$ (the Fourier transform w.r.t. the fast variable $\Delta = \phi_+ - \phi_-\) of a density matrix $\rho(\Sigma, \Delta, t)$. $W(x, p, t)$ is the quantum version of the distribution function $f(x, p, t)$ in the phase space $\{x, p\}$; and unlike $f(x, p, t)$, $W(x, p, t)$ is not always positive-definite, but will become so once the system completely decoheres and becomes classical. Therefore, we can unambiguously use the disappearance of $W(r, p, t)$’s negative parts to characterize the decoherence.

Another way to solve the basis-dependence problem is to look at the entanglement entropy or the Rényi entropy since they are scalars therefore are independent of the basis choice. In this paper, we will choose the second order Rényi entropy (also called ‘purity’). As we will see, the Wigner function and the purity are both very effective in characterizing decoherence.

Finally, we will show in this section that our setup to study the quantum decoherence is almost parallel with the one for the local quantum quench [35]. Thus, it is interesting to establish the connection (if there exists any) between the quantum decoherence and the local quantum quench.

A. Preparation of initial state

A prototype for the study of quantum decoherence is Schrödinger’s cat. The initial pure state of the cat is in a superposition of the two pointer states $|\text{Dead}\rangle$ and $|\text{Alive}\rangle$: $|\text{Cat}\rangle = \frac{1}{\sqrt{2}} (|\text{Dead}\rangle + |\text{Alive}\rangle)$. After decoherence, the cat has a classical probability of being 50% $|\text{Dead}\rangle$ and 50%$|\text{Alive}\rangle$ (after she comes into contact with the environment for long enough but before we open the window to peek). The initial and final states of the density matrix in the $|\text{Dead}\rangle/|\text{Alive}\rangle$ basis is:

$$\hat{\rho}_{\text{sys}}(0) = \begin{pmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{2} \end{pmatrix} \rightarrow \hat{\rho}_{\text{sys}}(t_f) = \begin{pmatrix} \frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{pmatrix}.$$  

(51)

The simplest lab realization of Schrödinger’s cat is a qubit: $|\text{Dead}\rangle \equiv |\uparrow\rangle$ and $|\text{Alive}\rangle \equiv$

\[^{10}\text{For the cat, the states }|\text{Dead}\rangle\text{ and }|\text{Alive}\rangle\text{ are stable against further ‘environmental’ disturbance: once the cat becomes dead/alive, it remains dead/alive. In addition, }\langle\text{Dead}|\text{Alive}\rangle = 0 \text{ since we take } \hbar \rightarrow 0 \text{ limit for the cat.}\]
| ↓⟩. However, our ‘system’ is a canonical scalar \( \phi \) defined by (8), how do we prepare a |Dead Cat⟩ and an |Alive Cat⟩ with \( \phi \)? First of all, we need to use pointer states from the Hilbert space of \( \phi \), namely states that are least perturbed by the ‘environment’ and therefore resemble classical states. There are various definitions for pointer states; and for a generic ‘environment’, locating the pointer states is a non-trivial problem [1, 36]. Intuitively, the pointer states in the present case should be Gaussian wave-packets in \( \phi \) because they are closest to the classical point since \( \Delta \phi \Delta p_\phi = \frac{\hbar}{2} \) — the minimal value for a quantum state.

Therefore we describe the two states |Dead⟩ and |Alive⟩ by two Gaussian wave-packets wavefunctions of width \( \sigma \) that are centered at \( \phi = \pm \phi_0 \):

\[
|\text{Dead}\rangle \equiv \Psi_1(\phi) = \frac{1}{\sqrt{N/2}} e^{-\frac{(\phi_+ - \phi_0)^2}{2\sigma^2}}, \\
|\text{Alive}\rangle \equiv \Psi_2(\phi) = \frac{1}{\sqrt{N/2}} e^{-\frac{(\phi_+ + \phi_0)^2}{2\sigma^2}}. \tag{52}
\]

The initial state and the density matrix of the cat is then

\[
|\text{Cat}\rangle \equiv \Psi(\phi) = \frac{1}{\sqrt{2}} \left( \Psi_1(\phi) + \Psi_2(\phi) \right), \\
\hat{\rho}_\text{sys}(0) = |\Psi(\phi)\rangle \langle \Psi(\phi)|. \tag{53}
\]

Note that in this representation \( \langle \text{Dead}|\text{Alive} \rangle = 0 \) only when \( \phi_0 \gg \sigma \), therefore we define the normalization factor by \( \text{Tr} \hat{\rho}_\text{sys} = 1 \) and get \( N = \sqrt{2\pi\sigma(1 + e^{-\frac{\phi_0^2}{2\sigma^2}})} \). The elements of \( \hat{\rho}_\text{sys}(0) \) is shown in the left panel of Fig. [3] The two ‘diagonal’ peaks represent the two wave-packets centered at \( \phi = \pm \phi_0 \) (i.e. the high probability of the scalar \( \phi \) being near \( \pm \phi_0 \)):

\[
\phi_+ = \phi_- = \pm \phi_0 \quad \Rightarrow \quad (\Sigma, \Delta) = (\pm \phi_0, 0) \tag{54}
\]

which corresponds to the |Dead⟩⟨Dead| and |Alive⟩⟨Alive| elements. The two ‘off-diagonal’ peaks signify the interference of these two wave-packets:

\[
\phi_+ = -\phi_- = \pm \phi_0 \quad \Rightarrow \quad (\Sigma, \Delta) = (0, \pm 2\phi_0) \tag{55}
\]

which correspond to the |Dead⟩⟨Alive| and |Alive⟩⟨Dead| elements.

**B. Wigner function: quantum distribution function of phase-space**

One effective way to study the quantum decoherence is to go to \( \rho_{\text{sys}} \)’s phase-space description furnished by the Wigner function. So far we have been working with the density matrix \( \hat{\rho}_{\text{sys}} \) in the position space: the element \( \rho(\bar{\Sigma}, \bar{\Delta}, t) \) characterizes the overlap between two points (in position space) that are centered in \( \bar{\Sigma} = \bar{\phi}_+ + \bar{\phi}_- \) and separated by \( \bar{\Delta} = \bar{\phi}_+ - \bar{\phi}_- \). Intuitively, when \( \rho(\bar{\Sigma}, \bar{\Delta} \neq 0, t) \neq 0 \), the nonzero \( \bar{\Delta} \) signifies the uncertainty in position space,
therefore should be conjugate to the momentum of the (average) position $\Sigma$. This intuition is borne out by the Wigner function which is defined as the Fourier transform (w.r.t. the fast variable $\Delta$) of $\rho_{\text{sys}}(\Sigma, \Delta, t)$:

$$W(\Sigma, p, t) \equiv \frac{1}{2\pi} \int_{-\infty}^{\infty} d\Delta \ e^{-ip\Delta} \rho_{\text{sys}}(\Sigma, \Delta, t).$$ (56)

The Wigner function $W(\Sigma, p, t)$ is the quantum version of the distribution function $f(\Sigma, p, t)$ in the phase space $\{\Sigma, p\}$ and reduces to $f(\Sigma, p, t)$ in the classical limit. However, unlike its classical counterpart $f(\Sigma, p, t)$, $W(\Sigma, p, t)$ is not always positive-definite — a consequence of the quantum uncertainty. Thus, in terms of the Wigner function, the signature of the quantum-to-classical transition is the disappearance of its negative part. After this process is complete, the Wigner function becomes the probability distribution function of the classical states.

Let us now compute the Wigner function for the cat made of our scalar $\phi$ — the superposition of two Gaussian wave-packets defined in (53). In the right panel of Fig. 3 we plot the Wigner function of the cat at the initial time. This should be compared with $\hat{\rho}_{\text{sys}}(0)$ in the left panel. The two diagonal peaks of $\hat{\rho}_{\text{sys}}(0)$ defined in (54) represent the two wave-packets, therefore in the Wigner function they correspond to the two ridges that are centered in $\Sigma = \pm \phi_0$ and extend along $p$. The two off-diagonal peaks of $\hat{\rho}_{\text{sys}}(0)$ defined in (55) correspond to the interference of the two wave-packets, therefore in the Wigner function they give rise to the interference pattern along the $\Sigma = 0$ line (note its negative parts).

The cat starts to interact with the ‘environment’ and decohere after $t \geq 0$. To see this,
we first compute \( \hat{\rho}_{\text{sys}}(t) \) starting with \( \hat{\rho}_{\text{sys}}(0) \) given in (53), using the convolution (14) and the propagating function (43). Then we Fourier transform to obtain its Wigner function. The result has three terms:

\[
W(\Sigma, p, t) = W_1 + W_2 + W_c
\]

where

\[
W_1(\Sigma, p, t) = \frac{\sigma L_{\Delta}}{4N|\hbar(t)|\sqrt{\pi C}} \left[ e^{\frac{\phi_0^2}{8\sigma^2} (\frac{1}{\Delta^2} + \frac{1}{\Delta^2} \hbar_0^2)} - \frac{l_{\Delta}^2}{\Delta^2} \left( \frac{1}{\Delta^2} \Sigma + \frac{l_{\Delta}^2}{2\Delta^2} p \right) \right] e^{-\frac{\phi_0^2}{2\sigma^2}} (58a)
\]

\[
W_2(\Sigma, p, t) = \frac{\sigma L_{\Delta}}{4N|\hbar(t)|\sqrt{\pi C}} \left[ e^{\frac{\phi_0^2}{8\sigma^2} (\frac{1}{\Delta^2} + \frac{1}{\Delta^2} \hbar_0^2)} - \frac{l_{\Delta}^2}{\Delta^2} \left( \frac{1}{\Delta^2} \Sigma + \frac{l_{\Delta}^2}{2\Delta^2} p \right) \right] e^{-\frac{\phi_0^2}{2\sigma^2}} (58b)
\]

correspond to the two individual Gaussian wave-packets and

\[
W_c(\Sigma, p, t) = \mathcal{A}_w(t) \cos \left[ \left( \frac{L_{\Delta}^2}{2L_{\Delta}^2 l_1^2} + \frac{1}{l_3} \right) \Sigma + \frac{L_{\Delta}^2}{2l_4^2} p \right] \left( \frac{L_{\Delta}^2}{4l_4^2} \Sigma \right) e^{-\frac{\phi_0^2}{2\sigma^2}} (59)
\]

with

\[
\mathcal{A}_w(t) \equiv \frac{\sigma L_{\Delta}}{4N|\hbar(t)|\sqrt{\pi C}} e^{\frac{\phi_0^2}{8\sigma^2} + \frac{l_{\Delta}^2}{4\sigma^2} - \frac{\phi_0^2}{2\sigma^2}} . (60)
\]

giving the interference between the two wave-packets. The parameters in (58) and (59) are defined as follows:

\[
C = \frac{\sigma^2}{4} \dot{f}_0(0)^2 + \frac{1}{4\sigma^2} + \frac{1}{2} a_0(t) , \quad (61a)
\]

\[
L_{\Sigma}^{-2} = \frac{1}{4C} \dot{f}_1(0)^2 , \quad (61b)
\]

\[
L_c^{-2} = \frac{1}{4C} \left( \sigma^2 \dot{f}_0(t) \dot{f}_0(0) \dot{f}_1(0) - \dot{f}_1(t)(a_{10} + a_{01}) - 4C \dot{f}_1(t) \right) , \quad (61c)
\]

\[
L_{\Delta}^{-2} = \frac{1}{4C} \left( \sigma^2 C \dot{f}_0(t)^2 - \frac{\sigma^4}{4} \dot{f}_0(t)^2 \dot{f}_0(0)^2 - \left( \frac{a_{10} + a_{01}}{2} \right)^2 + \frac{\sigma^2}{2} \dot{f}_0(t) \dot{f}_0(0)(a_{10} + a_{01}) \right) + \frac{1}{2} a_{11} , \quad (61d)
\]

and

\[
l_1^{-1} = \frac{\phi_0}{2C} \left( \dot{f}_0(0) a_{10} + a_{01} + \frac{\phi_0}{2C} \dot{f}_0(t) \left( \frac{1}{2\sigma^2} + a_{00} \right) \right) , \quad (61e)
\]

\[
l_2^{-1} = \frac{\phi_0}{2C} \dot{f}_0(0) \dot{f}_1(0) , \quad (61f)
\]

\[
l_3^{-1} = \frac{\phi_0}{2C \sigma^2} \dot{f}_1(0) , \quad (61g)
\]

\[
l_4^{-1} = -\frac{\phi_0}{4C \sigma^2} \left( a_{10} + a_{01} - \sigma^2 \dot{f}_0(t) \dot{f}_0(0) \right) . \quad (61h)
\]
Let us focus on the $W_c$ term which characterizes the interference between the two wave-packets. It has three factors: an enveloping amplitude $A_w(t)$ that decreases over time to zero, a cosine factor that produces the oscillation both in $\Sigma$ and in $p$ and therefore is responsible for the non-positive-definiteness of the Wigner function, and finally an exponential factor that encode the shapes and positions of the two wave-packets. To study the decoherence process, we only need to watch how the amplitude $A_w(t)$ evolves with time.

C. Purity/Rényi entropy

One way to characterize the purity of a quantum state is to examine its entanglement entropy. The entanglement entropy is zero for the pure state and reaches the maximum for the completely mixed state. As the quantum decoherence is a process from a pure state to a mixed state, we may use the purity to characterize it. Then, one may wonder how the purity/entanglement entropy behaves when the decoherence happens.

One hint to answer this question is the analogue with the thermalization, for which the thermal entropy saturates when reaching the thermal equilibrium. In a thermal environment, the quantum decoherence could be closely related to the thermalization, and part of the entanglement entropy could be related to the thermal one. Thus, the entanglement entropy might saturate when the pure state decoheres in a similar way to the saturation of the thermal entropy when reaching the thermal equilibrium.

There are many possible quantities qualified for the entanglement entropy: positive-definite and concave. They can all be derived from the reduced density matrix. The most commonly used one is the von Neumann entropy: $S_{vN} = -\text{Tr} \, \hat{\rho}_{sys} \log \hat{\rho}_{sys}$. The other ones are called the Rényi entropy of order $\alpha$:

$$S_\alpha = \frac{1}{1 - \alpha} \log \text{Tr} \, \hat{\rho}_{sys}^\alpha \quad (62)$$

where $\alpha$ is a positive real number. It can be shown that $S_{vN} = \lim_{\alpha \to 1} S_\alpha$.

For simplicity, we will only calculate the Rényi entropy of second order, which is related to $\mathcal{P} := \text{Tr} \, \hat{\rho}_{sys}^2$, named as “purity” in the community of quantum information sciences. To compare with the results from the phase-space viewpoint discussed in the previous subsection, here we also consider the two Gaussian wave-packets for the initial state, i.e.,
Using the explicit form (43) of $\rho_{\text{sys}}(t)$, after lengthy calculations we arrive

$$
P = A(t)^2 \pi^2 \sigma^2 L^2 \Sigma e^{\frac{\sigma^2}{2C\phi^2}} e^{\frac{1}{2C\sigma^2}} \left( e^{-\frac{L^2}{2\sigma^2} + e^{-\frac{L^2}{2\sigma^2}}} + e^{-\frac{L^2}{2\sigma^2} + e^{-\frac{L^2}{2\sigma^2}}} + e^{\frac{1}{2C\sigma^2}} \right)
$$

$$+ 8A(t)^2 \pi^2 \sigma^2 L^2 \Sigma e^{\frac{1}{8}} \left( e^{\frac{1}{8}} + e^{\frac{1}{8}} + e^{\frac{1}{8}} + e^{\frac{1}{8}} \right) \cos \left[ \frac{1}{4} \left( \frac{L^2}{l_1 l_4} - \frac{L^2}{l_2 l_3} \right) \right] \tag{63}
$$

where the parameters used here are already defined in (61).

D. Relation to local quantum quench

The entanglement entropy has been used to characterize the quantum quench process \[37, 38\]. The setup for the quantum quench is to bring the total system to a highly excited state and let it evolve. There are different ways of create such a setup. The simplest one is to tune a parameter of the Hamiltonian homogeneously so that the original ground state turns into non-eigenstate of the new Hamiltonian suddenly. This is the so-called global quantum quench.

The other is the local quantum quench: Excite the total system locally by either tuning a parameter of the Hamiltonian in-homogeneously or simply creating local excitation such as quasi-particles or qubits. This setup is the same as ours for quantum decoherence if we treat the local excitations (unentangled with the ‘environment’ when created) as the ‘system’ and the rest of the unperturbed region as the ‘environment’, see Fig. 4. More specifically, the initial state of two Gaussian wave-packets given in (53) can be thought as the local excitations of some effective linear size \(L\) which should be determined by the profile of the wave-packets, i.e., by $\phi_0$ and $\sigma$. We will try to determine $L$ later.

One way to characterize the quantum quench is to study the time evolution of the entanglement entropy for a region of size $L$ enclosing the initial local excitations or the ‘system’.

FIG. 4. Our setup for quantum decoherence can be also thought as the one for local quantum quench in (1 + 1) dimensions.
By the casual motions of the entangled quasi-particle one will expect a cross-over to a saturated or mildly growing regime for the growth of the entanglement entropy. The detailed time evolution behaviors of the (holographic) entanglement entropy for the local quantum quench have been studied extensively \[35, 37, 40\]; the initial growing rate is quadratic in \(t\), and then turns to the so-called linear \(t\) “Tsunami” regime \[38\] before dropping suddenly to the mildly growing regime. For the case of local quantum quench in \((1 + 1)\)-dimensional CFT, the entanglement entropy for the a region of size \(L\) \[35, 38\],

\[
S_L(t) \sim \begin{cases} 
t^2, & t \approx 0 \\
t, & t < L \\
\text{const. or } \ln t, & t > L.
\end{cases}
\]

For \(t > L\), \(S_L\) either saturates (for global quantum quench) or mildly grows as \(\ln t\) (for local quantum quench). Thus, \(t_Q \approx L\) here can be thought as the relaxation time scale (for the probe to relax to its classical state).

As we can calculate the reduced density matrix for the ‘system’, from it we can then evaluate the entanglement entropy for our setup and compare the relaxation time scale \(t_Q\) with the decoherence time scale \(t_D\). For simplicity, we will consider the Rényi entropy of 2nd order, i.e., \(S_2 = -\log \mathcal{P}\) see \[62\] to extract \(t_Q\) for our decoherence setup. If these two time scale are comparable in order of magnitude, then the quantum decoherence is closely related to the quantum quench. Though this could be naively expected, it still deserves to check this connection directly, especially there are other environmental influences such as temperature which are usually turned off in the consideration of quantum quench. We will find that indeed these two time scales are of the same order. Moreover, our approach yields the similar behaviors to \[64\].

V. Holographic Quantum Decoherence: Case Studies

To recapitulate, our ‘system’ is a scalar \(\phi\) whose initial state is a superposition of two Gaussian wave-packets (simulating Schrödinger’s cat); the ‘environment’ is a thermal CFT with a gravity dual. The decoherence process is captured by the time-evolution of the enveloping function \(A_w(t)\) of Wigner function’s interference term and the purity \(S_2(t)\). The effect from the environment is encoded in the influence functional which are given by ‘environment”s Green’s function. On the one hand, the ‘environment’ is non-trivial (in fact
strongly interacting), on the other hand, having a gravity dual allows its Green’s function to be computed holographically. Once we obtain the Green’s function, we can compute $A_w(t)$ via (60) and the purity $S_2(t)$ via (63), and then use them to quantify the decoherence process.

We will use two examples to illustrate the above. Since the problem is technically rather demanding, we present here only simple cases for which analytical computation can be carried out as much as possible (in fact up to the point of computing $h(\tau)$) and the rest are done numerically. Then, to study generic holographic ‘environment’, we also composed a python program [41] which can compute numerically $h(\tau)$ and then $A_w(t)$ and $S_2(t)$ for any holographic ‘environment’ once its Green’s functions are given.

A. Two Cases

The two cases we choose are: (1) a static particle coupled to the ‘environment’ of a (1+1)-dimensional holographic CFT at finite temperature; (2) a scalar zero mode coupled to a (3+1)-dimensional holographic CFT at zero temperature. Their retarded Green functions were computed holographically and have closed forms, which allow the function $h(t)$ to be obtained analytically as well.

1. Straight string in BTZ black hole

Let us first look at a static particle in a (1 + 1)-dimensional CFT at finite temperature. The finite temperature CFT is holographically dual to the ((2 + 1)-dimensional) BTZ black hole, and the point particle is dual to a straight string connecting the black hole horizon and the AdS$_3$ boundary.\footnote{This setup was also used in [33, 34] to study the holographic quantum Brownian motion (which has been briefly reviewed in Sec. [11A]). The horizon-end of the string receives random kicks from the Hawking radiation near the horizon, and these random kicks then propagate along the string and cause the Brownian motion of the boundary-end of the string.} Now we summary the procedure to compute the retarded Green function holographically.

The metric of the BTZ black hole is

$$ds^2 = \frac{r^2 - r_H^2}{\ell^2} dt^2 + \frac{r^2}{\ell^2} dX^2 + \frac{\ell^2}{r^2 - r_H^2} dr^2 \tag{65}$$

with $\ell$ the AdS radius and $r_H$ the radius of the horizon. Its Hawking temperature is

$$T = \frac{r_H}{2\pi \ell^2}. \tag{66}$$
Let us consider a static string configuration connecting the black hole horizon and the AdS$_3$ boundary. In the static gauge this configuration is given by $X(t,r) = 0$. Now consider the perturbation of $X$ along this static string, the equation of motion of this perturbation $\delta X(t,r)$ can be obtained from the Nambu-Goto action of the probe string [33]:

$$
\left[-\partial_t^2 + \frac{r^2 - r^2_H}{r^2 \ell^4} \partial_r \left( r^2 (r^2 - r^2_H) \partial_r \right)\right] \delta X(t,r) = 0 \quad . \tag{67}
$$

The solution with in-falling boundary condition at the black hole horizon is

$$
\delta X(t,r) = e^{-i\omega t} X_\omega(r) , \quad \text{with} \quad X_\omega(r) \propto \frac{r - i\omega \ell^2}{r} \left( \frac{r - r_H}{r + r_H} \right)^{-\frac{i\omega \ell^2}{2r_H}} . \tag{68}
$$

The conjugate momentum of $X_\omega(r)$ is

$$
\Pi_\omega(r) = -T_s \frac{r^2 (r^2 - r^2_H)}{\ell^4} \partial_r X_\omega(r) \tag{69}
$$

where $T_s = \frac{1}{\ell^2}$ is the string tension. Then using the prescription given by [33], we obtain the retarded Green’s function:

$$
G_R(\omega, r_c) = -\lim_{r \to r_c} \frac{\Pi_\omega(r)}{X_\omega(r)} = -T_s \frac{\omega^2 r_c^2 \ell^2 + i \omega r_c r_H^2}{r_c \ell^2 - i \omega \ell^4}
$$

$$
\approx T_s r_c \left( -1 + \frac{r^2_H}{r_c^2} \right) \omega^2 - iT_s \left( \frac{\ell^2 \omega^3 + r^2_H}{\ell^2 \omega} \right) \tag{70}
$$

with $r_c (\approx \infty)$ the UV-cutoff.

The real part of (70) is UV-divergent but can be considered as the renormalization of the probe’s mass, and only the imaginary part of (70) drives the quantum decoherence. However, its form has unreasonable high frequency behaviors and we need to regularize by introducing some windowed function, which we choose to be commonly used Lorentzian function (with width $\Gamma_w$). With the real part is dropped and after the regularization, the retarded Green function (70) becomes:

$$
G_R(\omega) = -i N_{st}^2 \left( \omega^3 + 4\pi^2 T^2 \omega \right) \frac{\Gamma_w^2}{\Gamma_w^2 + \omega^2} \tag{71}
$$

where $N_{st} \equiv \ell \sqrt{T_s} = \ell / \ell_s$ is the number of degrees of freedom of the dual CFT. Then the symmetric Green’s function $G_{sym}$ can be obtained from (71) via (31).

---

12 These unreasonable UV behaviors are termed ohmic ($\sim \omega$) or super-ohmic ($\sim \omega^\delta$ with $\delta > 1$) in the literature, see e.g. [5] which also used the windowed function to regularize the UV-behavior.
With the closed form of $G_R$ given by (71) we can solve for $h(\tau)$ via the inverse Laplace transform (47). First, the Laplace transform of $G_R(\tau)$ is

$$\hat{G}_R(s) = \pi N^2_{st} \frac{\Gamma^2_w (4\pi^2 T^2 - \Gamma^2_w)}{\Gamma w + s} .$$

(72)

We then compute $h(\tau)$ using (47). (Recall that once $h(\tau)$ is known, all other functions can be immediately expressed in terms of simple functions of $h(\tau)$ and its derivatives.) Let us consider the case for which $\hat{h}(s)$ given in has two complex poles at $s = s_1 \pm is_2$ and one real pole at $s = s_3$, where $s_i$'s are real functions of $T$ and $\Gamma$. However, their detailed expressions are not very illuminating and will be omitted. Then the inverse Laplace transform of $\hat{h}(s)$ gives $h(\tau)$:

$$h(\tau) = \frac{s_2(s_3 + \Gamma_w)(e^{s_1 \tau} - e^{s_1 \tau} \cos s_2 \tau) + (s_1^2 + s_2^2 - s_3 \Gamma_w + s_1(\Gamma_w - s_3)) e^{s_1 \tau} \sin s_2 \tau}{s_2(s_1^2 + s_2^2 - 2s_1 s_3 + s_3^2)} .$$

(73)

Knowing $h(\tau)$, we can then first compute $f_i$'s and $g_i$'s by (48), and then use them to calculate the Wigner function and purity.

2. **Scalar probe in AdS$_5$ spacetime**

Most of the earlier studies of quantum decoherence assumed the ‘environment’ is a thermal reservoir. This might cause the misconception that the thermal fluctuation of the ‘environment’ is necessary for the quantum decoherence of the ‘system’. However, as we are about to see, decoherence can happen even in zero temperature.

To show this, we choose the ‘environment’ to be $(3 + 1)$-dimensional CFT at zero temperature and the ‘system’ a scalar operator. The total setup is holographic dual to a scalar in AdS$_5$ spacetime. Following the procedure described in Sec. II C, one can compute holographically the retarded Green functions $G_R$ of an operator $O$ with conformal dimension $\Delta_O$. This was done in [29], and we summarize the results here:

$$G_R(\omega) = \begin{cases} 
\frac{N^2_{sc} \Gamma(3-\Delta_O)e^{2(\Delta_O-4)}}{8\pi^2 T(\Delta_O-2)^22^{\Delta_O-3}}} (q^2)^{\Delta_O-2} ~[\cos \pi \Delta_O - i \text{ sgn}(\omega) \sin \pi \Delta_O] & 2 < \Delta_O \notin \mathbb{N} \\
\frac{N^2_{sc} e^{2(\Delta_O-4)}}{8\pi^2 (\Delta_O-3)^22^{\Delta_O-7}} (q^2)^{\Delta_O-2} ~[\ln q^2 - i \pi \text{ sgn}(\omega)] & 2 \leq \Delta_O \in \mathbb{N}
\end{cases}$$

(74)

where $N^2_{sc}$ is the number of degrees of freedom of the dual CFT, and $\epsilon \approx 0$ is the UV cutoff.

For simplicity, we only consider the zero-mode (with $q \equiv \sqrt{\omega^2 - \vec{k}^2} = \omega$) of $\phi$, namely we assume the ‘system’ is homogenous in space. The problem is then effectively $(1 + 1)$-dimensional, which can be compared directly with the string string case. In contrast to
the static string case, the non-zero and non-renormalizable real part of the retarded Green function is absent here.

In order to solve \( h(\tau) \) analytically by the Laplace transform (47), we only consider the integer and half-integer \( \Delta_\O \) cases. Moreover, as \( G_R \) contains the ‘super-ohmic’ factor \( (q^2)^{\Delta_\O - 2} \) we will again regularize by introducing the Lorentzian windowed function of width \( \Gamma_w \). The Laplace transform of \( G_R(\tau) \) is the following:

\[
\hat{G}_R(s) = \begin{cases} 
\frac{N_w^2 \Gamma (3-\Delta_\O) e^{2(\Delta_\O - 4)}}{8\pi \Gamma (\Delta_\O - 2) 2^{2\Delta_\O - 5}} \Gamma_w^{2n+2} \frac{1}{s + \Gamma_w} & 2 < \Delta_\O \in \mathbb{N} + \frac{1}{2} \\
\frac{N_w^2 e^{2(\Delta_\O - 4)}}{8\pi \Gamma (\Delta_\O - 3) 2^{2\Delta_\O - 5}} (-1)^\Delta_\O \Gamma_w^{2\Delta_\O - 3} \left( \pi \ln \Gamma_w \frac{1}{s + \Gamma_w} + \frac{1}{s - \Gamma_w} - \frac{1}{s + \Gamma_w} \right) & 2 \leq \Delta_\O \in \mathbb{N}
\end{cases}
\]

(75)

Then \( h(t) \) can be computed by inverse Laplace transform (47). For large \( N_{sc} \) and \( \Gamma_w \), \( \hat{h}(s) \) has two conjugated poles at \( s = s_1 \pm is_2 \) and two real poles at \( s = s_3, s_4 \), therefore \( h(t) \) takes the following form:

\[
h(t) = \left[ s_2(s_2^2 + (s_1 - s_3)^2)(s_2^2 + (s_1 - s_4)^2)(s_3 - s_4) \right]^{-1} \\
\cdot \left[ s_2(s_3 - \Gamma_w^2)(s_2^2 + (s_1 - s_4)^2)e^{s_1 t} + s_2(s_2^2 + (s_1 - s_3)^2)(\Gamma_w^2 - s_2^2)e^{s_2 t} + (s_4^2 - s_1(s_3 + s_4))(s_1^2 - s_2^2 + \Gamma_w^2) + (s_2^2 + \Gamma_w^2)(s_2^2 - s_3 s_4) + s_1^2(2s_2^2 - \Gamma_w^2 + s_3 s_4) \right] (s_3 - s_4) e^{s_3 t} \sin s_2 t \\
- \left[ s_2^2(s_3 + s_4) + (s_2^2 + \Gamma_w^2)(s_3 + s_4) - 2s_1(\Gamma_w^2 + s_3 s_4) \right] s_2(s_3 - s_4) e^{s_4 t} \cos s_2 t
\]

(76)

Again, we omit the detailed expressions for \( s_i \)'s. In the numerical calculation, we set \( N_{sc} = 10 \) and the UV-cutoff \( \epsilon \approx 1/\Gamma_w \).

B. Results and remarks

Based on the the expressions of \( h(t) \) in the previous subsection, we can now calculate the enveloping function \( A_w(t) \) via (60) and the purity \( S_2(t) = -\log \mathcal{P} \) via (63), and use them to characterize the decoherence of the superposition of two Gaussian wave-packets.

The task requires long numerical calculations. Before we present the detailed results below, let us first show (in Fig. 5) four snap shots in the time-evolution of the Wigner function. Note the decay of its negative part (which characterizes the quantumness of the Wigner function). In the scenario of the environment-induced decoherence, the coherence decay exponentially. Therefore, we first need to define precisely what mean by decoherence. Since the decay is exponential, only the order of magnitude of \( t_D \) is relevant. We will declare
that the ‘system’ has almost decohered once the enveloping function $A_w(t)$ decreases to the 1% of its initial value and define the decoherence time $t_D$ by\[\text{decoherence time} \ t_D : \ \frac{A_w(t_D)}{A_w(0)} = 0.01 \ . \] (77)

Note that the time-dependence of the Rényi entropy $S_2$ exhibits a crossover around $t \approx t_D$.

From our computation we extract two important results. First, for the decoherence time $t_D$, we obtain its dependence on the temperature $T$ of the ‘environment’ and on the conformal dimension $\Delta_O$ of field coupled to the ‘system’. Second, we obtain the growing rate of $S_2(t)$, using which we can define different stages of decoherence. We then show that these stages are nicely matched with those in the holographic quantum quench discussed recently in [38–40].

Note that in all the numerical plots presented below, we set the the width of the windowed function $\Gamma_w = 10$, the coupling $g = 1$ and the constants $N_{st} = 1$ and $N_{sc} = 10$. The width $\Gamma_w$ also serves as a reference inverse time scale.

\[\text{The decoherence time} \ t_D \text{ is roughly the same order of the half-life scale of } A_w(t) \text{ as } A_w(t) \text{ is exponentially decaying. Here defining the ‘almost decoherence’ by (77) is simply for convenience.}\]
FIG. 6. Time evolutions of the enveloping function $A_w$ and the purity $S_2$ for a string probe in BTZ background. The parameters chosen for [60], [63] and [62] are $(\phi_0, \sigma, N_{st}, \Omega, \Gamma_w) = (0.5, 0.1, 1, 1, 1, 10)$. Left: $A_w$ (thick lines) and $S_2$ (thin lines) for $T=50$ (circle), 30 (triangle) and 0.1 (square). Note we have rescaled $S_2$ by 1/2. Right: The long-term time behavior of $S_2$ for $T=20$ and 1, which will be used for the fitting in Fig. 8.

FIG. 7. Left: Decoherence time $t_D$ v.s. temperature $T$. Right: Zoom-in of high-$T$ regime ($T > 50$) with fitting function (blue line) $t = \frac{0.0078}{T}$. The ‘soft mass gap’ $\Gamma_w = 10$.

1. String probe

For the case in which the ‘system’ plus ‘environment’ are the holographic dual of a string probe in a BTZ background, we present in Fig. 6 the time-evolution of the $A_w(t)$ and $S_2(t)$ at different temperatures. We can see that $A_w$ almost decays away at $t = t_D$, and around this time scale $S_2$ goes through a crossover. As discussed, this implies that the quantum quench, which is characterized by this crossover behavior, is closely related to the quantum decoherence.

Next we study the temperature ($T$) dependence of the decoherence time $t_D$. The results are shown in Fig. 7. First, let us look at the left panel which covers the entire $0 < T < 200$
region. We see $t_D$ decreases as $T$ increases, namely, the hotter the ‘environment’ the faster
the ‘system’ decoheres — consistent with the intuitive picture of decoherence.

Next, we look at the high-$T$ and low-$T$ regimes separately. A conformal field theory has
no intrinsic scale which we can use to define high-$T$ or low-$T$ regime. However, when we
regularize the Green function with a windowed function, we introduce a length scale into
the system in term of its width $\Gamma_w$; therefore we can define high-$T$ or low-$T$ w.r.t. $\Gamma_w$.

In the low-$T$ ($T < \Gamma_w$) regime, we can see the decoherence time $t_D$ is almost independent
of $T$. The reason is the following. The windowed function of width $\Gamma_w$ has introduced a
‘soft mass gap’ into the CFT. When $T < \Gamma_w$ the excitation is suppressed by the mass gap
and the decoherence process resembles the one at zero-temperature therefore is insensitive
to the actual temperature.

For the high-$T$ regime (see right panel of Fig. 7) we discover a nice scaling behavior

$$t_D \sim \frac{1}{T},$$

by fitting the data points. This scaling behavior is the same as the one extracted directly
from the master equation (50) for the simple toy model in [1]. While not surprising, this is
the first time this scaling behavior is obtained when the ‘environment’ is a non-trivial CFT.

Finally, let us look the time-evolution of the purity $S_2$ of the ‘system’. In Fig. 6 we can
already see $S_2$ has different scaling behaviors at different regions of $t$. This suggests that
the decoherence process happens in stages. With the fitting tool ‘formulize’ [42], we fit the
data and divide the decoherence process into the following four different stages according to
the scaling behavior of $S_2(t)$:

$$S_2(t) \sim \begin{cases} 
C_0 t^2 + \mathcal{O}(t^4), & t < \frac{t_D}{10} \quad \text{(initial)}; \\
C_{b.c.} t + \mathcal{O}(1), & \frac{t_D}{10} \lesssim t \lesssim t_D \quad \text{(intermediate)}; \\
C_{a.c.} \ln t + \mathcal{O}(1), & t_D \lesssim t \lesssim 10t_D \quad \text{(late)}; \\
C_1 t, & 10t_D \ll t \quad \text{(final)}. 
\end{cases}$$

(79)

where $C_0$, $C_{b.c.}$, $C_{a.c.}$ and $C_1(< C_{a.c.})$ are all positive and increase monotonically with $T$.
The plots of the first three stages are shown in Fig. 8. We also compare the high-$T$ and
low-$T$ cases and find that the scaling behavior of $S_2(t)$ is insensitive to the temperature.
The intermediate stage is about one order of magnitude longer than the initial stage, which
agrees with the corresponding result for the quantum quench in \[38\]. After the crossover, \(S_2\) grows like \(\ln t\), in agreement with the results in \[35, 39\]. Matching (79) with (64) we conclude that the local quantum quench occurs when the local excitations decohere.
Time evolutions of the enveloping function $A_w$ and the purity $S_2$ for a scalar probe (zero-mode only) in $\text{AdS}_5$ space-time. The parameters chosen for (60), (63) and (62) are $(\phi_0, \sigma, N, \Omega, \Gamma_w) = (0.5, 0.1, 10, 1, 1, 10)$. Left: $A_w$ (thick lines) and $S_2$ (thin lines) for $\Delta_\mathcal{O} = 4.5$ (triangle), 4 (circle) and 3.5 (square). Note we have rescaled $S_2$ by 1/2. Right: The long-term behaviors of $S_2$ for $\Delta_\mathcal{O} = 3.5$ and 3, which will be used for the fitting in Fig. 11. Note that we have rescaled the time for $\Delta_\mathcal{O} = 3$ case by 1/10 in order to fit it in the same plot with $\Delta_\mathcal{O} = 3.5$ case.

$\ln t_D$ v.s. $\Delta_\mathcal{O}$ for $2.5 \leq \Delta_\mathcal{O} \leq 5$. The blue line is the fitting function: $\ln t_D = 2.26 - 3.34 \Delta_\mathcal{O}$.

2. Scalar probe

Similar to the string probe case, we first present in Fig. 9 the evolution of $A_w(t)$ and $S_2(t)$ for operator $\mathcal{O}$ with different conformal dimensions. The qualitative behavior is the same as the string probe case. Again, we find that the quench and decoherence time scales are of the same order. In fact, since now the ‘environment’ is at zero temperature, it is closer to the quantum quench setup. This provides another supporting evidence for the connection between quantum decoherence and quantum quench.
FIG. 11. Scaling behaviors of $S_2$ at different stages of the growth shown in the right panel of Fig. 9. The three rows from up to down corresponds to the three stages defined in the main text. Initial: The solid (orange) lines corresponds to $S_2 \sim t^2 + O(t^4)$ and fit better than the solid (blue) lines that have only $t^2$ term. Intermediate: $S_2 \sim t + O(1)$. Late: $S_2 \sim \ln t + O(1)$.

Next, we fit the scaling behavior of $t_D$ w.r.t. $\Delta_\Theta$ and find (as shown in Fig. 10):

$$\ln t_D \sim - C_\Delta \Delta_\Theta$$

(80)

with $C_\Delta > 0$. (This is to be compared with the scaling $t_D \sim 1/T$ in the previous case (shown in Fig. 7).) This means that the pure state of the superposition of two Gaussian wave-packets has a lifetime of order $\frac{1}{\Delta_\Theta}$. The fact that the lifetime depends on $\Delta_\Theta$ could serve as a guideline when devising the robust (against decoherence) qubits.
Finally, using the fitting tool ‘formulize’ we determine the scaling behaviors of the purity $S_2(t)$ at different stages for two different $\Delta_O$’s and the results are shown in Fig. 11. Although the total system is different from the previous case, we found the scaling behavior to be basically the same as (79). (And all the constants $C$’s in (79) increase with $\Delta_O$.) This suggests that the scaling behaviors of $S_2$ and the definition of the different stages given in (79) might be universal for different probes and environments. It is also very reassuring to see all our results agree with the studies based on the (holographic) entanglement entropy for the local quantum quench.[35, 37–40] It would be interesting to explore this connection further.

C. Initial state profile dependence of decoherence time

The decoherence time $t_D$ depends on how the ‘system’ (the scalar $\phi$) interacts with the ‘environment’ and on the properties of $\phi$ such as its mass or conformal dimension. The other relevant attribute of the ‘system’ is the profile of its initial state, e.g. in our case of two Gaussian wave-packets the relevant data is the width ($\sigma$) of each packet and the ‘distance’ ($2\phi_0$) between the two.

Further, the similarity between (79) and (64) implies a close relation between the quantum decoherence and the local quench once we identify the decoherence time $t_D$ in (79) with the effective length $L$ in (64). Then once we determine $t_D$’s dependence on the initial state profile, it immediately gives the relation between the initial state profile and the effective length. This dependence is nontrivial due to the complexity of $A_w(t)$ given in (60), and needs to be extracted by numerical methods.

In Fig. 12 we show the decoherence time $t_D$ as a function of the profile ($\{\sigma, \phi_0\}$) for the scalar probe with $\Delta_O = 3$. Fitting the data by constant $\sigma$ or $\phi_0$ slices, we find

$$t_D \sim \frac{c_1(\sigma)}{\phi_0 + c_2(\sigma)}$$

for fixed $\sigma$; 

$$t_D \sim c_3(\phi_0) + c_4(\phi_0)\sigma^3$$

for fixed $\phi_0$. \hspace{1cm} (81)

This shows that the effective length ($\approx t_D$) is not proportional to $\phi_0$ (the distance between two packets) as naively expected for uniform probe. Instead, the relevant quantum information is only encoded in the property of each individual Gaussian wave-packets, and the

\textsuperscript{14} The ln $t$ growing behavior in [64] or [79] could be a feature of 2D CFT. Although we consider the scalar probe in AdS$_5$ at very beginning, we only focus on the decoherence behavior of its zero-mode, which can be thought as an effective (1 + 1)-dimensional problem. Thus, we obtain the scaling behaviors [79] as expected.
decoherence time $t_D$ or the effective length $L$ increase with $\sigma$. Thus, for fixed $\sigma$ a larger $\phi_0$ means a bigger zero-information region therefore lower concentration of nontrivial information, which accelerate the decoherence or the quench process. These results could provide theoretical guidelines in the construction of robust physical qubits.

![FIG. 12. Dependence of decoherence time $t_D$ on the profile ($\{\sigma, \phi_0\}$) of initial state of the two Gaussian wave-packets, for scalar probe with $\Delta_\sigma = 3$. All other parameters (except for $\sigma$ and $\phi_0$) are the same as used in Fig. 9.](image)

**D. Numerical studies for discretized time systems**

All the above results are based on exact solutions of $h(\tau)$ without any (numerical) approximation. This is possible because the retarded Green function $G_R$ is simple enough to allow $h(\tau)$ to be computed analytically via Laplace transform. In general, $G_R$ is more complicated and solving (47) to obtain $h(\tau)$ requires numerical methods. In order to generalize our proposed scheme in this paper and examine the environment-induced decoherence scenario for more general situation, we compose a python code [41] to solve (47) and then evaluate $A_w(t)$ and $S_2(t)$ for a given retarded Green function.

Here we show a typical example computed by our python code [41]: the retarded Green function is given by (74) with $\Delta_\sigma = \frac{10}{3}$. Note that for this case (47) can only be solved numerically. The results for $A_w(t)$ and $S_2(t)$ are shown in Fig. 13. It again shows the decoherence behavior as expected, however, the detailed behavior depends on the discretized
FIG. 13. Evolution of $A_w$ (decreasing) and the purity $S_2$ (increasing) for the two Gaussian wave packet of scalar probe for $\Delta \mathcal{O} = 10/3$. The discretized time unit is $10^{-5}$ and $\Gamma_w = 4000$.

The python code still needs to be improved, in particular, its sensitivity to the choice of the (discretized) time unit and of the windowed function needs to be further reduced. Once this is achieved, we could used it to search for the robust systems against generic quantum decoherence — a necessary ingredient in designing real quantum computers.

VI. CONCLUSION

In this paper, based on the earlier observation [23, 26] we elucidate the connection between Feynman-Vernon and Schwinger-Keldysh formalisms: The influence functional of Feynman-Vernon is the generating function of the Schwinger-Keldysh correlation functions. We then apply this connection to study quantum decoherence when the ‘environment’ is a holographic CFT, since the Schwinger-Keldysh retarded Green function can be obtained holographically. We consider two cases for which the influence functional can be computed exactly, and derive the time evolution of the ‘system’’s reduced density matrix, from which we then evaluate its Wigner function and Rényi entropy. We use the disappearance of the negative part of Wigner function to characterize the decoherence process and define the decoherence

\[15\] Despite the efficiency of this numerical code, we still need to discretize the time (with the main bottleneck being the integral-differential equation (46)), which leads to a discretized retarded Green function. Therefore, the final results depend on the unit scale of the discretized time and would be different from the continuum time limit.
time. We consider the scaling behaviors of the decoherence time scale. Though we consider some particular systems, we expect the results to be rather universal for CFT reservoir ‘environment’. The second case also proves that the quantum decoherence happens even at zero temperature.

As we can obtain the dynamics of the reduced density matrix, we can directly calculate its Rényi entropy which was used to characterize the quantum quench. As argued, the setup for the quantum decoherence considered in this paper is very similar to that of the local quantum quench. We show that these two quantum phenomena are closely related by comparing their time scales and the scaling behaviors (with time) of the Rényi entropy. Our results imply that the local quantum quench happens as the local excitations decohere. However, the long time scaling behavior deviates from the logarithmic growth. It is interesting to explore this connection further.

Based on our scheme, one can study the quantum decoherence for very generic ‘environment’ as long as the retarded Green function can be computed holographically. Therefore, our scheme is helpful for systematically study the general behaviors of quantum decoherence and serve as the guideline when constructing robust quantum computers. However, in practical one needs to implement numerical calculations to pin down the time evolution of reduced density matrix, which involve solving the intragl-differential equations and will cause numerical artifacts. A more fundamental way to bypass this technical involvement is to find a holographic way of calculating the propagating function. This could be related to the issue of how to treat the probe also in the holographic way. We hope to explore this possibility in the near future.

Acknowledgements. We thank Sung-Po Chao, Chung-Hsien Chou, Jen-Tsung Hsiang, Bei-Lok Hu, Matisse Tu and Wei-Min Zhang for very helpful discussions. We also thank Ying-Jer Kao for providing valuable help in writing the python code. FLL and BN are supported by NSC grant: 100-2112M-003-003-MY3, 101-2811-M-003-005, 102-2811-M-003-015.

Appendix A: Evaluating propagating function: a review

In this appendix, we evaluate the propagating function \( J \) by regarding it as a partition function with action. This has been done before, e.g. in 

14. This could be related to the issue of how to treat the probe also in the holographic way. We hope to explore this possibility in the near future.
derivation to make the paper self-contained and to fix the notation.

First, we go to the momentum space, in which the effective action (38) becomes
\[
S_{\text{eff}} = \sum_{\vec{k}} \int_{0}^{t} d\tau \left[ \dot{\Sigma}_{\vec{k}} \dot{\Delta}_{\vec{k}} - (\Omega^{2} - |\vec{k}|^{2}) \Sigma_{\vec{k}} \Delta_{\vec{k}} \right]
- g^{2} \sum_{\vec{k}} \int_{0}^{t} d\tau \int_{0}^{t} d\tau' \left[ \Delta_{\vec{k}}(\tau) G_{R}^{(\vec{k})}(\tau - \tau') \Sigma_{\vec{k}}(\tau') - \frac{i}{2} \Delta_{\vec{k}}(\tau) G_{\text{sym}}^{(\vec{k})}(\tau - \tau') \right].
\]
(A1)

As explained in the main text, now we will only consider the \( \vec{k} = 0 \) mode to focus our attention on the time-dependent behavior. Then evaluating (37) only takes two steps: first we expand the action (A1) around the classical saddle points, then we integrate out the fluctuations to obtain the overall normalization factor. Expanding \( \Sigma \) and \( \Delta \) as follows:
\[
\Sigma = \Sigma + q_{1}, \quad \Delta(\tau) = \Delta + q_{2}
\]  
(A2)

where \( \Sigma \) and \( \Delta \) are the classical solutions that solve the EOMs derived from the real part of (A1):
\[
\ddot{\Sigma}(\tau) + \Omega^{2} \Sigma(\tau) + g^{2} \int_{0}^{\tau} d\tau' G_{R}(\tau - \tau') \Sigma(\tau') = 0,
\]  
(A3)
\[
\ddot{\Delta}(\tau) + \Omega^{2} \Delta(\tau) + g^{2} \int_{\tau}^{t} d\tau' G_{R}(\tau' - \tau) \Delta(\tau') = 0
\]  
(A4)

with the boundary conditions (in time)
\[
\Sigma(\tau = 0) = \Sigma_{0} \equiv \bar{\Sigma}, \quad \Sigma(\tau = t) = \Sigma_{1} \equiv \bar{\Sigma},
\]
\[
\Delta(\tau = 0) = \Delta_{0} \equiv \bar{\Delta}, \quad \Delta(\tau = t) = \Delta_{1} \equiv \bar{\Delta}.
\]  
(A5)

The time variable \( \tau \in [0, t] \). Note that for the ease of reading, in the derivation of this Appendix we use \{ \( \Sigma_{0,1}, \Delta_{0,1} \) \} but will switch to the tilde and bar notation in the main text.

Now let us solve the boundary value problem (A3)-(A5). First, note that (A3) and (A4) are related by a change of variable \( \tau \to t - \tau \), therefore we only need to solve one of them. The matching of the boundary data can be done as follows. First we separate the boundary data out of \{ \( \Sigma, \Delta \) \} by introducing \( \{ f_{0,1}, g_{0,1} \} \):
\[
\Sigma(\tau) = f_{0}(\tau) \Sigma_{0} + f_{1}(\tau) \Sigma_{1} \quad \text{and} \quad \Delta(\tau) = g_{0}(\tau) \Delta_{0} + g_{1}(\tau) \Delta_{1}
\]  
(A6)

then \( \{ f_{0,1} \} \) are two solutions of (A3) and \( \{ g_{0,1} \} \) of (A4), and with the boundary conditions
\[
f_{0}(0) = 1, \quad f_{0}(t) = 0; \quad f_{1}(0) = 0, \quad f_{1}(t) = 1,
\]  
(A7)
\[
g_{0}(0) = 0, \quad g_{0}(t) = 1; \quad g_{1}(0) = 1, \quad g_{1}(t) = 0.
\]  
(A8)
Combining (A3), (A4) with (A7) and (A8), we see

\[ g_0(\tau) = f_1(t - \tau) \quad \text{and} \quad g_1(\tau) = f_0(t - \tau) . \]  

(A9)

Therefore we only need to solve for \( f_i \)'s.

\( f_i \)'s satisfy the integral equation

\[ \ddot{f}(\tau) + \Omega^2 f(\tau) + g^2 \int_{0}^{\tau} d\tau' G_R(\tau - \tau') f(\tau') = 0 \]  

(A10)

with initial and final values given by (A7). However a solution to (A10) can be uniquely determined either by fixing the initial and final values (boundary value problem) or the initial value plus its derivative (initial value problem); since a boundary value problem usually requires the shooting method therefore is rather difficult, we recast this boundary value problem into an initial value problem (by shifting the information at \( \tau = t \) to \( \tau = 0 \)) following [7].

To convert (A10) into an initial value problem, let’s first apply the Laplace transform on it, suggested by the convolution term. The Laplace transform \( \hat{f} \equiv \mathcal{L}(f) \) of \( f \) satisfies

\[ \hat{f}(s) = \frac{1}{s^2 + \Omega^2 + g^2 \hat{G}_R(s)} \hat{f}(0) + \frac{s}{s^2 + \Omega^2 + g^2 \hat{G}_R(s)} f(0) . \]  

(A11)

The original boundary value problem is now recast into an initial value problem: for given \( f(0) \) and \( \dot{f}(0) \), \( f(\tau) \) is uniquely determined as the inverse Laplace transform of (A11). It has two fundamental solutions:

\[
\begin{aligned}
\begin{cases}
  h(0) = 0 & \dot{h}(0) = 1 \\
  H(0) = 1 & \dot{H}(0) = 0
\end{cases}
\Rightarrow
h(\tau) = \mathcal{L}^{-1} \left( \frac{1}{s^2 + \Omega^2 + g^2 \hat{G}_R(s)} \right), \\
H(\tau) = \mathcal{L}^{-1} \left( \frac{s}{s^2 + \Omega^2 + g^2 \hat{G}_R(s)} \right).
\end{aligned}
\]  

(A12)

We see \( H(\tau) = \dot{h}(\tau) \), since \( \dot{H}(s) = s \dot{h}(s) \) and \( h(0) = 0 \).

Since the integral equation (A10) is linear, all its solutions are linear combinations of \( h(\tau) \) and \( \dot{h}(\tau) \). The two solutions to the boundary value problem (A7) are therefore easily determined to be:

\[ f_0(\tau) = -\frac{\dot{h}(t)}{\dot{h}(t)} h(\tau) + \dot{h}(\tau), \quad f_1(\tau) = \frac{1}{\dot{h}(t)} h(\tau) \]  

(A13)

where \( h(\tau) \) is the solution to the initial value problem

\[ \ddot{h}(\tau) + \Omega^2 h(\tau) + g^2 \int_{0}^{\tau} d\tau' G_R(\tau - \tau') h(\tau') = 0, \quad h(0) = 0, \quad \dot{h}(0) = 1 . \]  

(A14)
For simple $G_{R}$, (A14) can be easily solved via inverse Laplace transform $h(\tau) = \mathcal{L}^{-1}\left(\frac{1}{s^2 + \Omega^2 + g^2 G_{R}(s)}\right)$.

Note that due to the boundary condition (A7), $\{f_0, f_1\}$ are actually functions of both $\tau$ and $t$, with $t$ entering as the boundary point.

Substituting (A2) into (A1) (with $\vec{k} = 0$ mode being considered) and use the equations of motion (A3) and (A4), one obtain

$$S_{\text{eff}} \equiv S_{\text{cl}}[\Sigma, \Delta] + S_{q}[q_1, q_2]$$  \hspace{1em} \text{(A15)}

with

$$S_{\text{cl}}[\Sigma, \Delta] = \dot{\Sigma}(\tau)\Delta(\tau)|^t_0 + \frac{i}{2}g^2 \int_0^t d\tau \int_0^t d\tau' \Delta(\tau)G_{\text{sym}}(\tau - \tau')\Delta(\tau')$$  \hspace{1em} \text{(A16)}

and

$$S_{q}[q_1, q_2] = \int_0^t d\tau \left[q_1(\tau)q_2(\tau) - \Omega^2 q_1(\tau)q_2(\tau)\right]$$

$$- g^2 \int_0^t d\tau \int_0^t d\tau' \left[q_2(\tau)G_{R}(\tau - \tau')q_1(\tau') - \frac{i}{2}q_2(\tau)G_{\text{sym}}(\tau - \tau')q_2(\tau')\right]$$  \hspace{1em} \text{(A17)}

Note also that one can obtain the same results by using the complex saddle point.

One can factor out the boundary data in $S_{\text{cl}}$ and obtain

$$S_{\text{cl}} = \sum_{i=0}^{1} [\dot{f}_i(t)\Sigma_i\Delta_1 - \dot{f}_i(0)\Sigma_i\Delta_0] + \frac{i}{2} \sum_{i=0}^{1} \sum_{j=0}^{1} a_{ij}(t)\Delta_i\Delta_j$$  \hspace{1em} \text{(A18)}

with

$$a_{ij}(t) \equiv g^2 \int_0^t d\tau \int_0^t d\tau' g_i(\tau)G_{\text{sym}}(\tau - \tau')g_j(\tau').$$  \hspace{1em} \text{(A19)}

On the other hand, to carry out the integration over the fluctuation, it is convenient to rewrite $S_{q}$ into the following form

$$iS_{q} = -\frac{1}{2} \int_0^t d\tau \int_0^t d\tau' Q^T(\tau)O(\tau - \tau')Q(\tau')$$  \hspace{1em} \text{(A20)}

where $Q^T(t) = \left( q_2(t), \ q_1(t) \right)$ and

$$O(t-t') = \begin{pmatrix} g^2 G_{R}(\tau - \tau') & i[(\partial_\tau^2 + \Omega^2)\delta(\tau - \tau') + g^2 G_{R}(\tau - \tau')] \\ i[(\partial_\tau^2 + \Omega^2)\delta(\tau - \tau') + g^2 G_{R}(\tau - \tau')] & 0 \end{pmatrix}.$$  \hspace{1em} \text{(A21)}

In the Appendix C, we show that the normalization factor

$$A(t) \equiv \int Dq_1 Dq_2 e^{iS_{q}[q_1, q_2]} = |\det O|^{-1/2} = \frac{1}{2\pi|h(t)|}$$  \hspace{1em} \text{(A22)}
with \( h(t) \) given in \( (A12) \).

Combining the above results, we obtain the propagating function \( J \)

\[
J[A_4, \Delta_4, t| A_0, \Delta_0, 0] = A(t) e^{i \sum_{i=0}^{1} \sum_{j=0}^{1} a_{ij}(t) \Delta_i \Delta_j} \tag{A23}
\]

with \( a_{ij}(t) \) given in \( (A19) \) and \( A(t) \) in \( (A22) \).

In summary, the propagating function \( (A23) \) can be obtained by just solving \( h(\tau) \) and \( H(\tau) \) for a given \( G_R \) using \( (A14) \). Then, the time evolution of the reduced density matrix is given by \( (A14) \).

### Appendix B: Derivation of master equation for \( \dot{\rho}_{sys}(t) \)

Now we derive the master equation of \( \dot{\rho}_{sys}(t) \). Start with the propagating function \( (A23) \) and recall that the function \( f_i(t) \) in \( (A23) \) is actually a shorthand for \( f_i(t) \equiv f_i(\tau = t, t) \) where \( \{f_0(\tau, t), f_1(\tau, t)\} \) are the function \( \{f_0, f_1\} \) given in \( (A13) \): \( f_1(\tau, t) = \frac{h(\tau)}{h(t)} \) and \( f_0(\tau, t) = h(\tau) - \frac{h(\tau)}{h(t)} h(t) \) and the dot refers to the derivative w.r.t. the variable \( \tau \). Therefore we have

\[
\dot{f}_1(t) \equiv \frac{d}{d\tau} f_1(\tau)|_{\tau=t} = \frac{\dot{h}(t)}{h(t)}, \quad \dot{f}_1(0) = \frac{1}{h(t)},
\]

\[
\dot{f}_0(t) = \dot{H}(t) - \frac{[H(t)]^2}{h(t)}, \quad \dot{f}_0(0) = -\frac{\dot{h}(t)}{h(t)} = -\dot{f}_1(t). \tag{B1}
\]

Now evaluate the \( t \)-derivative of the propagating function \( (A23) \):

\[
i \frac{d}{dt} J(t) = i A'(t) e^{i S_{eff}}
\]

\[
+ i \left( i \Delta_1 \sum_1 f_1'(t) + i \Delta_1 \sum_0 f_0'(t) - i \Delta_0 \sum_1 f_1'(0) - i \Delta_0 \sum_0 \frac{d}{dt} f_0(0) \right) J(t)
\]

\[
+ i \left( -\frac{1}{2} \Delta^2 a_{11}'(t) - \Delta_1 \Delta_0 a'_{10}(t) + a'_{01}(t) \right) J(t) \tag{B2}
\]

where the prime denotes \( t \)-derivative, with

\[
\dot{f}_1'(t) = \frac{d}{dt} \dot{f}_1(t) = \frac{d}{dt} \left[ \frac{\dot{h}(t)}{h(t)} \right] = \frac{\dot{h}(t)}{h(t)} - [\dot{f}_1(t)]^2, \quad \dot{f}_1'(0) = -\dot{f}_1(t) \dot{f}_1(0),
\]

\[
\dot{f}_0'(t) = \dot{f}_0(t) + \dot{f}_0(t) \dot{f}_0(0), \quad \dot{f}_0'(0) = -\dot{f}_0(t) \dot{f}_0(0), \tag{B3}
\]

\[
A'(t) = -\frac{\dot{h}'(t)}{h(t)^2} = -\dot{f}_1(t) A(t).
\]
Recall that $f_i(\tau, t)$ satisfy the equation of motion

\[
\frac{d^2}{d\tau^2} f(\tau) + \Omega^2 f(\tau) + g^2 \int_0^\tau ds \, G_R(\tau - s) f(s) = 0
\]  

with boundary condition $f_1(\tau = 0, t) = f_0(\tau = t, t) = 0$ and $f_1(\tau = t, t) = f_0(\tau = 0, t) = 1$.

Using this we compute the double derivatives in (B3):

\[
\begin{align*}
\ddot{f}_1(t) &\equiv \frac{d^2}{d\tau^2} f_1(\tau)|_{\tau = t} = -\Omega^2 - \int_0^t ds \, G_R(t - s) f_1(s) = -\Omega^2 - b_1(t), \\
\ddot{f}_0(t) &\equiv \frac{d^2}{d\tau^2} f_0(\tau)|_{\tau = t} = -g^2 \int_0^t ds \, G_R(t - s) f_0(s) = -b_0(t)
\end{align*}
\]

where $b_i(t) \equiv g^2 \int_0^t ds \, G_R(t - s) f_i(s)$.

Now let us derive some useful formulae:

\[
\frac{\partial}{\partial \Sigma_1} J = [i\dot{f}_1(t) \Delta_1 - i\dot{f}_1(0) \Delta_0] J, \\
\frac{\partial}{\partial \Delta_1} J = [i\dot{f}_1(t) \Sigma_1 + i\dot{f}_0(t) \Sigma_0 - a_{11} \Delta_1 - \frac{a_{10} + a_{01}}{2} \Delta_0] J, \\
\frac{\partial}{\partial \Sigma_1} \frac{\partial}{\partial \Delta_1} J = [i\dot{f}_1(t) - [\dot{f}_1(t)]^2 \Delta_1 \Sigma_1 - \dot{f}_1(t) \dot{f}_0(t) \Delta_1 \Sigma_0 + \dot{f}_1(t) \dot{f}_1(0) \Sigma_0 \Delta_0 + \dot{f}_0(t) \dot{f}_1(0) \Sigma_0 \Delta_0] J \\
+ [ia_{11} \Delta_1 (\dot{f}_1(0) \Delta_0 - \dot{f}_1(t) \Delta_1) + \frac{i}{2} (a_{10} + a_{01}) \Delta_0 (\dot{f}_1(0) \Delta_0 - \dot{f}_1(t) \Delta_1)] J \\
= [i\dot{f}_1(t) - [\dot{f}_1(t)]^2 \Delta_1 \Sigma_1 - \dot{f}_1(t) \dot{f}_0(t) \Delta_1 \Sigma_0 + \dot{f}_1(t) \dot{f}_1(0) \Sigma_0 \Delta_0 + \dot{f}_0(t) \dot{f}_1(0) \Sigma_0 \Delta_0] J \\
- \frac{i}{2} (a_{10} + a_{01}) \Delta_0 \frac{\partial}{\partial \Sigma_1} \frac{\partial}{\partial \Delta_1} J.
\]

With (B3), (B4) and (B5c), the first two lines in (B2) can be reduced into

\[
- \frac{\partial}{\partial \Sigma_1} \frac{\partial}{\partial \Delta_1} J + \Omega^2 \Delta_1 \Sigma_1 J + b_1 \Sigma_1 \Delta_1 J + b_0 \Sigma_0 \Delta_1 J - \frac{1}{2} (a_{10} + a_{01}) \Delta_0 \frac{\partial}{\partial \Sigma_1} \Delta_1 \frac{\partial}{\partial \Sigma_1} J.
\]

Then using

\[
a_{22}''(t) = g^2 \frac{d}{dt} \int_0^t \int_0^t ds ds' g_2(s) G_{\text{sym}}(s - s') g_2(s') = 2g^2 g_2(t) \int_0^t G_{\text{sym}}(t - s) g_2(s) = 0
\]

and (B5a), we can rewrite the last line in (B2) into

\[
- i \left( \frac{1}{2} a_{11} + \frac{a_{10} + a_{01}}{2} \frac{\dot{f}_1(t)}{\dot{f}_1(0)} \right) \Delta_1^2 J + \frac{a_{10} + a_{01}}{2} \dot{f}_1(0) \frac{\partial}{\partial \Sigma_1} J.
\]

48
Finally, combining (B6) and (B8) and using (B5) to replace all $\Sigma$ and $\Delta_0$, we obtain

$$
\frac{i}{\hbar} \frac{d}{dt} J = \left[ -\frac{\partial}{\partial \Sigma_1} \frac{\partial}{\partial \Delta_1} + (\Omega^2 + \delta \Omega^2) \Delta_1 \right] J + \left( -i \frac{b_0}{f_0(t)} \right) \Delta_1 \frac{\partial}{\partial \Delta_1} J 
$$

$$
+ \left[ \frac{\hat{a}_{10} + \hat{a}_{01}}{2f_1(0)} - a_{11} - \frac{2\dot{f}_1(t)}{f_1(0)(a_{10} + a_{01})} + \frac{b_0(a_{10} + a_{01})}{2f_1(0) f_0(t)} \right] \Delta_1 \frac{\partial}{\partial \Sigma_1} J 
$$

$$
+ \left[ -i \left( \frac{b_0 a_{11}}{f_0(t)} + \frac{a_{10} \dot{f}_0(t)}{f_1(t) f_0(t)} + \frac{1}{2} a_{11} + \frac{\dot{a}_{10} + \dot{a}_{01}}{2f_1(0)} \right) \right] \Delta_1^2 J 
$$

$$
- i \frac{a_{10} + a_{01}}{2f_1(0)} \frac{\partial^2}{\partial \Sigma_1^2} J 
$$

(B9)

where $\delta \Omega^2 \equiv b_1 - b_0 \frac{\dot{f}_1(t)}{f_0(t)}$. Then it is straightforward to write down the master equation for the reduced density matrix $\rho_{\text{sys}}(\Sigma, \Delta, t)$ from (B9) and (14).

Appendix C: Normalization of $\hat{\rho}_{\text{sys}}$

1. Evaluating the normalization $A(t)$ using $\text{Tr} \hat{\rho}_{\text{sys}}(t) = 1$

We now use the propagating functional given by (A23) and the condition $\text{Tr} \hat{\rho}_{\text{sys}}(t) = 1$ to evaluate the normalization factor $A(t)$. Here we assume the initial density matrix is a Gaussian wave packet.

$$
\langle \bar{\phi}_+ | \hat{\rho}_{\text{sys}}(0) | \bar{\phi}_- \rangle = \frac{1}{\sigma \sqrt{\pi}} e^{-\frac{\Delta_0^2 + \Delta_1^2}{2 \sigma^2}} = \frac{1}{\sigma \sqrt{\pi}} e^{-\frac{\Delta_0^2 + \Delta_1^2}{4 \sigma^2}} 
$$

(C1)

where the normalization factor $\sigma$ is fixed by the unitarity condition $\text{Tr} \hat{\rho}_{\text{sys}}(0) = 1$.

The reduced density matrix is

$$
\langle \bar{\phi}_+ | \rho_{\text{sys}}(t) | \bar{\phi}_- \rangle = \int d\Sigma_0 \ d\Delta_0 \ J[\Sigma_1, \Delta_1, t; \Sigma_0, \Delta_0, 0] \langle \bar{\phi}_+ | \rho_{\text{sys}}(0) | \bar{\phi}_- \rangle 
$$

(C2)

$$
= A(t) e^{-\frac{1}{2} a_{11}(t) \Delta_1^2 + i \dot{f}_1(t) \Delta_1 \Sigma_1 - \frac{a^2_0}{2} f_0(t)^2 \Delta_1^2} 
$$

$$
\cdot \int d\Delta_0 e^{-\left( \frac{a^2_0}{2} f_0(t)^2 + \frac{1}{4} \Sigma_1 + \frac{1}{4} a_{00}(t) \right) \Delta_0^2} e^{\left( \frac{a^2_0}{2} f_0(t) f_0(0) \Delta_1 - \frac{1}{2} a_{10}(t) \Delta_1 - \frac{1}{2} a_{01}(t) \Delta_1 - i \dot{f}_1(0) \Sigma_1 \right) \Delta_0} 
$$

$$
= \sqrt{\pi} C^{-1/2} A(t) e^{-\frac{1}{2} a_{11}(t) \Delta_1^2 + i \dot{f}_1(t) \Delta_1 \Sigma_1 - \frac{a^2_0}{2} f_0(t)^2 \Delta_1^2} 
$$

$$
\times \exp \left[ \left( -i \frac{\dot{f}_1(0) \Sigma_1 + \frac{a^2_0}{2} \dot{f}_0(t) \dot{f}_0(0) \Delta_1 - \frac{1}{2} (a_{10}(t) + a_{01}(t) \Delta_1) \right) \Delta_1 \right] 
$$

$$
= \sqrt{\pi} C^{-1/2} A(t) e^{-\frac{1}{4 C} \Sigma_1^2 - \frac{1}{4 C} \Sigma_1 \Delta_1 - \frac{1}{4 C} \Delta_1^2} 
$$

(C3)

where the characteristic length $L_{\Sigma}$, $L_c$, $L_\Delta$ and $C$ are defined in (61).
Now using $\text{Tr}\hat{\rho}_{\text{sys}}(t)=1$, we can derive the normalization factor $A(t)$.

\begin{equation}
1 = \text{Tr}\hat{\rho}_{\text{sys}}(t) = \int d\phi d\phi' <\phi|\hat{\rho}_{\text{sys}}(t)|\phi'> \delta(\phi - \phi') ,
\end{equation}

\begin{equation}
= \int d\Sigma_1 d\Delta_1 \delta(\Delta_1) <\hat{\rho}_{\text{sys}}(t)>,
\end{equation}

\begin{equation}
= \int d\Sigma_1 \sqrt{\pi} A(t) C^{-1/2} \exp \left[ \frac{-i\dot{f}_1(0)^2}{4C} \Sigma_1^2 \right] ,
\end{equation}

\begin{equation}
= A \cdot 2\pi \frac{1}{|\dot{f}_1(0)|} .
\end{equation}

Using (B1), we have

\begin{equation}
A(t) = \frac{1}{2\pi|h(t)|} .
\end{equation}

2. A consistency check: Evaluating the normalization through functional determinant

In this subsection, we compute the normalization factor $A(t)$ by evaluating the functional determinant in (A22) directly. We follow the formulation in [43].

Suppose we want to compute the determinant of an operator $\hat{L}$

\begin{equation}
\hat{L} = \partial_t^2 + P(t) , \quad \text{with} \quad t \in [t_0, t_f]
\end{equation}

where $P(t)$ is a real function and the boundary condition for the eigenfunction of $\hat{L}$ is $u(t_0) = u(t_f) = 0$. The prescription takes only two steps.

First we write the boundary condition as

\begin{equation}
M \begin{pmatrix} u(t_0) \\ \dot{u}(t_0) \end{pmatrix} + N \begin{pmatrix} u(t_f) \\ \dot{u}(t_f) \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix} \quad (C7a)
\end{equation}

where $M$ and $N$ are $2 \times 2$ matrices and in our case

\begin{equation}
M = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \quad \text{and} \quad N = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} . \quad (C7b)
\end{equation}

Then we define matrices $\hat{H}(t)$ and $\hat{Y}(t_f)$ as

\begin{equation}
\hat{H}(t) \equiv \begin{pmatrix} y_1(t) & y_2(t) \\ \dot{y}_1(t) & \dot{y}_2(t) \end{pmatrix} , \quad \hat{Y}(t_f) \equiv \hat{H}(t_f)\hat{H}^{-1}(t_0) \quad (C7c)
\end{equation}

50
where \( y_1(t) \) and \( y_2(t) \) are two independent solutions of the homogeneous differential equation

\[
\hat{L} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} = 0.
\]

The determinant \( \det \hat{L} \) is certainly divergent, so the only meaningful quantity is the renormalized determinant, i.e. the ratio \( \text{(C7d)} \). Usually we chose \( \hat{L} = \partial^2_t \) as in \[44\]. Finally we have the determinant ratio of \( \hat{L} \) and some other (similar type of) operator \( \bar{L} \):

\[
\frac{\det \hat{L}}{\det \bar{L}} = \frac{\det[M + N\hat{Y}(t_f)]}{\det[M + NY(t_f)]}.
\]  

(C7d)

Here the matrices \( M \) and \( N \) are given in \( \text{(C7b)} \) for our case. The determinant is

\[
\det[M + N\hat{Y}(t_f)] = \frac{y_1(t_0)y_2(t_f) - y_2(t_0)y_1(t_f)}{y_1(t_0)y_2(t_0) - y_2(t_0)y_1(t_0)}.
\]  

(C8)

If we pick \( y_1(t) \) being the solution whose initial condition is \( y_1(t_0) = 0 \), the determinant ratio \( \text{(C7d)} \) becomes

\[
\frac{\det \hat{L}}{\det \bar{L}} = \frac{1}{\det \bar{L} y_1(t_0)}.
\]  

(C9)

Now the normalization factor obtained by integrating out the quadratic action \( \text{(A20)} \) is

\[
A(t) = [\det(O)]^{-1/2} = \frac{1}{|\det[(\partial^2_\tau + \Omega^2)(\tau - \tau') + G_R(\tau - \tau')]|}
\]  

with \( O(t - t') \) defined in \( \text{(A21)} \).

It is obvious that the solution \( y(t) \) in \( \text{(C8)} \) is given by the solution \( f(t) \) in \( \text{(A13)} \). Hence the normalization factor \( \text{(C10)} \) becomes

\[
A(t)^{-1} = \frac{|f_1(t)|}{|f_1(0)|} = \left( \frac{\hat{h}(0)}{\hat{h}(t)} \right)^{-1} = \left( \frac{1}{2\pi} \frac{1}{|\hat{h}(t)|} \right)^{-1}
\]  

(C11)

which agrees with \( \text{(C5)} \).

3. Another consistency check: The behavior of \( J(t) \) and \( \hat{\rho}_{\text{sys}}(t) \) as \( t \to 0 \)

As a second consistency check, we compute the behavior of the propagating function at \( t \to 0 \) and check that it indeed recovers a Dirac delta function. Using \( \text{(B1)} \) we have

\[
\lim_{t=\epsilon \to 0} \hat{f}_1(0, t) = \frac{1}{\epsilon}, \quad \lim_{t=\epsilon \to 0} \hat{f}_1(t, t) = \frac{1}{\epsilon}, \quad \lim_{t=\epsilon \to 0} \hat{f}_0(0, t) = -\frac{1}{\epsilon}, \quad \lim_{t=\epsilon \to 0} \hat{f}_0(t, t) = -\frac{1}{\epsilon}, \quad \lim_{t=\epsilon \to 0} A(t) = \frac{1}{2\pi\epsilon}.
\]  

(C12)
and $a_{ij}(t \to 0) \to 0$. The propagating functional (A23) becomes

$$J(t \to 0) \approx \lim_{t \to 0} \frac{e^{i\frac{1}{2}(\Delta_1 - \Delta_0)(\Sigma_1 - \Sigma_0)}}{2\pi \epsilon} = \lim_{t \to 0} \frac{e^{i\frac{1}{\epsilon}(\phi_+ - \bar{\phi}_+)^2}}{\sqrt{2\pi i \epsilon}} \cdot \frac{e^{-i\frac{1}{\epsilon}(\phi_- - \bar{\phi}_-)^2}}{\sqrt{2\pi (-i) \epsilon}}$$

(C13)

(C13) again shows that our propagating functional is properly normalized.

Similarly, we expect the reduced density matrix to reduce to (C1) when $t \to 0$. Using (C12) and $a_{ij}(t \to 0) \to 0$, the exponent in (C2) is

$$- \frac{1}{L^2} \Sigma_1^2 - \frac{i}{L^2} \Sigma_1 \Delta_1 - \frac{1}{L^2} \Delta_1^2 \rightarrow \frac{1}{4C} \left( - \frac{1}{\epsilon^2} \Sigma_1^2 - i\sigma^2 \frac{1}{\epsilon^3} \Sigma_1 \Delta_1 - \frac{1}{4\epsilon^2} \Delta_1^2 + 4iC \frac{1}{\epsilon} \right)$$

$$= \frac{-1}{\sigma^2} \left( \Sigma_1^2 + \frac{1}{4} \Delta_1^2 \right)$$

(C14)

where we used $C \to \frac{\sigma^2}{4} \frac{1}{\epsilon^2}$. And the normalization factor in (C2) takes the form

$$\sqrt{\pi C^{-1/2}} A(t) \rightarrow \left( \frac{\sigma^2}{4} \frac{1}{\epsilon^2} \right)^{-1/2} \frac{1}{2\pi \epsilon} = \frac{1}{\sigma \sqrt{\pi}}.$$  

(C15)

Combining (C14) and (C15), we reproduce (C1).
