I. INTRODUCTION

The pioneering experiment of R. Davis has started the era of neutrino astronomy. Because they only have weak interactions with matter, neutrinos are precious messengers of what happens in the interior of stars, like our sun, or in explosive phenomena, such as Supernova type II explosions. Such astronomical neutrinos therefore provide an important source of information for our understanding of the life and death of stars. Nuclei are commonly used as detectors in neutrino observatories as well as in various experiments aiming at studying intrinsic neutrino properties, such as their masses and mixings. A precise knowledge of neutrino-nucleus cross-sections is needed for the interpretation of these measurements and/or to study the feasibility of new projects. The understanding of neutrino-nucleus interactions is also of crucial importance for various astrophysical processes. Timely examples include neutrino nucleosynthesis, or the nucleosynthesis of heavy elements during the so-called r-process. If the latter takes place during the explosion of Supernovae type II, where a gigantic amount of energy is emitted as neutrinos of all flavors, final abundances depend on several nuclear properties, among which the interactions with neutrinos.

According to existing simulations, the average energy of neutrinos emitted from core-collapse Supernovae is about 10 MeV for electron neutrinos and about 20 MeV for muon and tau neutrinos. Notice however that, due to oscillations, electron neutrinos can become hotter while traversing the star. The predicted spectra cover the 50 MeV region and present a tail up to about 100 MeV. Reactor and solar neutrinos have typical energies in the 10 MeV energy range, while accelerator and atmospheric neutrinos cover the GeV and multi-GeV range. The various theoretical approaches employed to describe neutrino-nucleus interactions therefore involve nuclear as well as nucleonic degrees of freedom (for a review, see [2, 12]). There are a number of open issues in this context. The A=2 system is the simplest case, for which the reaction cross sections can be estimated with high accuracy [15]. However, there is still an important quantity, namely L_{1,A}, related to the axial two-body current, which dominates the theoretical uncertainty in neutrino-deuteron interactions. For heavier nuclei, in the tens of MeV energy range, the reaction cross sections are dominated by collective modes, like the Gamow-Teller resonance or the Isobaric Analog State, which have been extensively studied in the past [14]. As the neutrino impinging energy increases, transitions to states of higher multipolarity (such as the spin-dipole or higher forbidden transitions) become important [17]. The latter also play an important role in the context of core-collapse Supernova physics [2, 14, 15, 13]. Although some information on these states can be gathered through other probes, such as charge-exchange reactions, muon capture, or inelastic electron scattering, the experimental information is rather scarce. Note that the understanding of neutrino-carbon reactions with neutrinos produced from the decay in flight of pions is still an open issue, for most of the theoretical calculations over-estimate the experimental value [22]. So far, measurements with low-energy neutrinos have been performed in a few cases only, namely deuteron [23], carbon [24], and iron [25]. Systematic studies would be of great importance both for what concerns the interpolation from the MeV to the GeV neutrino energy range and the extrapolation to neutron-rich nuclei, as required in the astrophysical context.

Neutrino-nucleus interaction studies were one of the main physics issues of the proposed ORLAND underground neutrino facility, which was based on a conventional neutrino source (pion and muon decays) [14, 26]. A smaller version of the ORLAND project is now under study [27]. At present, the MINERνA project [28] includes the study of neutrino-nucleus interactions for neutrino energies in the GeV range. Here, we study the potential of a low-energy neutrino facility based on beta-beams, a novel method to produce neutrino beams [29]. This consists in boosting exotic ions which decay through beta-decay and produce pure, collimated and well-understood electron neutrino fluxes. Such a method

---

†Electronic address: volpe@ipno.in2p3.fr
could be exploited for a future facility at CERN\cite{24,30}. High energy beta-beams would be fired to a gigantic Cherenkov detector like UNO\cite{31}, located in an (upgraded) Fréjus underground laboratory to study, in particular, the possible existence of CP violation in the leptonic sector\cite{29,30,32}. The discovery potential with a very high $\gamma$ and a longer baseline is discussed in \cite{32}\cite{33}.

It has recently been proposed to use the beta-beam concept for the production of low-energy neutrinos\cite{35}. Several laboratories will produce intense exotic beams in the near future and could, therefore, be possible sites for a low-energy beta-beam facility. These include GANIL, CERN, GSI, as well as the EURISOL project. Low-energy neutrino beams would offer an interesting opportunity to study various neutrino properties, such as e.g. the neutrino magnetic moment\cite{36}, as well as neutrino-nucleus interactions, of interest for nuclear physics, particle physics and astrophysics. In the former case, one would exploit the ions at rest as an intense neutrino source, whereas, in the latter case, one would use boosted ions, which would be collected in a storage ring\cite{35}, as in the original high energy proposal. An important feature of such beta-beams is that the boost factor of the accelerated ions can be varied, allowing one to explore various neutrino energy ranges.

In this paper, we present for the first time charged-current neutrino-nucleus interaction rates achievable at a low-energy beta-beam facility. We consider two possible cases for the dimensions of the storage ring, for which we inspire ourselves of the one planned in the future GSI facility\cite{37}, and the one thought in the CERN baseline scenario\cite{24,30}. We consider various target nuclei as neutrino detectors, namely deuteron, oxygen, iron and lead, which are commonly used in existing or planned experiments\cite{24}. Related work in the case of lead can be found in\cite{38}.

II. FORMALISM

A. Neutrino fluxes and interaction rates

The decay rate of a nucleus in the rest (cm) frame can be written as:

$$\frac{dW}{dt}\bigg|_{cm} = \Phi_{cm}(E_\nu) dE_\nu \frac{d^2\Omega}{4\pi},$$

(1)

where $E_\nu$ and $\Omega$ denote respectively the energy and the solid angle of the emitted (anti-)neutrino, and where the neutrino flux $\Phi_{cm}(E_\nu)$ is given by the well-known formula\cite{39}:

$$\Phi_{cm}(E_\nu) = b E^2_\nu E_e \sqrt{E^2_e - m^2_e} F(\pm Z, E_e) \Theta(E_e - m_e),$$

(2)

where the constant $b = \ln 2/m^5_e f t_{1/2}$, with $m_e$ the electron mass and $f t_{1/2}$ the $t$-value. The quantities appearing in the above expression are the energy $E_e = Q - E_\nu$ of the emitted lepton (electron or positron), $Q$ being the $Q$-value of the reaction, and the Fermi function $F(\pm Z, E_e)$, which accounts for the Coulomb modification of the spectrum.

In the laboratory frame, where the boosted nucleus has a velocity $v = \beta c$, the decay rate reads:

$$\frac{dW}{dt}\bigg|_{lab} = \frac{1}{\gamma} \Phi_{lab}(E_\nu, \theta) dE_\nu \frac{d^2\Omega}{4\pi},$$

(3)

where $\gamma = (1 - \beta^2)^{-1/2}$ is the time dilation factor and where $E_\nu$ and $\Omega \equiv (\theta, \varphi)$ now denote the energy and solid angle of the emitted (anti-)neutrino in the laboratory (lab) frame, $\theta$ being the angle of emission with respect to the beam axis. The boosted flux $\Phi_{lab}(E_\nu, \theta)$ is given by:

$$\Phi_{lab}(E_\nu, \theta) = \frac{\Phi_{cm}(E_\nu \gamma |1 - \beta \cos \theta|)}{\gamma |1 - \beta \cos \theta|}.$$  

(4)

We consider a storage ring of total length $L$ with a straight sections of length $D$. In the stationary regime the mean number of ions in the storage ring is $\gamma \tau g$, where $\tau = t_{1/2}/\ln 2$ is the lifetime of the parent nuclei and $g$ is the number of injected ions per unit time. The total number of neutrinos emitted per unit time from a portion $dl$ of the decay ring is:

$$\frac{dN_\nu}{dt} = \gamma \tau g \times \frac{dW}{dt}\bigg|_{lab} \times \frac{dl}{L}.$$ 

(5)

For simplicity, we consider a cylindrical detector of radius $R$ and depth $h$, aligned with one the straight sections of the storage ring, and placed at a distance $d$ from the latter. After integration over the useful decay path and over the volume of the detector, the total number of events per unit time is:

$$\frac{dN_{\nu e}}{dt} = g \tau n h \int_0^\infty dE_\nu \Phi_{tot}(E_\nu) \sigma(E_\nu),$$

(6)

where $n$ is the number of target nuclei per unit volume, $\sigma(E_\nu)$ is the relevant neutrino-nucleus interaction cross-section, and where

$$\Phi_{tot}(E_\nu) = \int_0^D \frac{dl}{L} \int_0^h \frac{dz}{h} \int_0^{\tilde{\theta}(l,z)} \sin \theta \theta \frac{d\theta}{2} \Phi_{lab}(E_\nu, \theta),$$

(7)

with

$$\tan \tilde{\theta}(l,z) = \frac{R}{d + l + z}.$$ 

(8)

B. Large versus Small Ring configurations

The storage ring geometry is characterized by the length of the straight sections $D$ and by its total length $L$. Below, we consider the cases of a small (SR) and a large (LR) ring configurations, characterized by $(D_{SR}, L_{SR})$
and \((D_{\text{LR}}, L_{\text{LR}})\) respectively. The results in both configurations can easily be related to one another by splitting the integral over the useful decay path \(I_{0}^{D_{\text{LR}}} = I_{0}^{D_{\text{SR}}} + I_{0}^{D_{\text{SR}}}\) in Eq. (7). Up to trivial \(1/L\) factors, the LHS corresponds to the \(LR\) configuration and the first term on the RHS to the \(SR\) configuration. The remaining integral can be given a simple analytical estimate if one can neglect the angular dependence of the flux under the integral. This happens when the angle under which the detector is seen from the extremity of the \(SR\) decay path \(\sim R/(d + D_{\text{SR}})\) is small compared to \(1/\gamma\), i.e. to the typical opening angle of the boosted flux. In that case, we obtain, for the total flux \((1):\)

\[
\Phi_{\text{tot}}^{\text{LR}}(E_{\nu}) \simeq \left\{ \Phi_{\text{tot}}^{\text{SR}}(E_{\nu}) + G \Phi_{\text{tot}}^{\text{SR}}(E_{\nu}, \theta = 0) \right\}, \tag{9}
\]

where the geometrical factor \(G\) is given by:

\[
G = \frac{R^{2}}{4L_{\text{SR}}(d + D_{\text{SR}})} \left( 1 - \frac{d + D_{\text{SR}}}{d + D_{\text{LR}}} \right). \tag{10}
\]

The overall factor \(L_{\text{SR}}/L_{\text{LR}}\) in \((1)\) simply accounts for the fact that the number of decaying ions per unit length is smaller in a larger storage ring, and the second term in brackets on the RHS represents the contribution from the longer useful straight section. Figure \(\text{II}\) shows a comparison between the exact flux obtained with Eqs. \((7)-(8)\) in both the \(SR\) and the \(LR\) configurations, and the analytic estimate Eq. \((9)\), for the two possible detector sizes considered in the following. We see that the analytical formula \((1)\) works very well in the cases considered here. Besides, Figure \(\text{III}\) shows that the contribution from the longer decay path only brings a \(\sim 10\%\) difference for the small detector and contributes a factor \(\sim 2\) for the larger detector. This already shows that the main difference between the \(LR\) and \(SR\) fluxes comes from the geometrical factor \(L_{\text{SR}}/L_{\text{LR}} \simeq 1/15\).

Using the approximate formula for the total fluxes, we obtain an approximate relation between the total number of events in the \(LR\) and \(SR\) configurations:

\[
\left. \frac{dN_{\text{ev}}}{dt} \right|_{LR} \simeq \frac{L_{\text{SR}}}{L_{\text{LR}}} \times \left\{ \left. \frac{dN_{\text{ev}}}{dt} \right|_{SR} + \gamma^{2}(1 + \beta)^{2}G \gamma \langle \sigma \rangle \right\}, \tag{11}
\]

where \(\langle \sigma \rangle\) denotes the flux-averaged cross section in the forward direction \(\theta = 0:\)

\[
\langle \sigma \rangle \gamma = \frac{\int_{0}^{\infty} dE_{\nu} \Phi_{\text{lab}}(E_{\nu}, \theta = 0) \sigma(E_{\nu})}{\int_{0}^{\infty} dE_{\nu} \Phi_{\text{lab}}(E_{\nu}, \theta = 0)}. \tag{12}
\]

Using Eq. \((11)\), the latter can be re-written as:

\[
\langle \sigma \rangle \gamma = \frac{\int_{0}^{\infty} dE_{\nu} \Phi_{\text{em}}(E_{\nu}) \sigma(1 + \beta)E_{\nu})}{\int_{0}^{\infty} dE_{\nu} \Phi_{\text{em}}(E_{\nu})}. \tag{13}
\]

It is to be noted that, when the detector is placed close to the storage ring, as it is the case here, the total rate \((11)\) depends non-trivially on the geometry of the latter. For instance, as discussed above, we observe an approximate \(1/L\) scaling at fixed \(D/L\) in the small detector case. This is in contrast with the case of a far detector considered in the high energy beta-beam scenarios \([29, 32, 33, 34]\), where the rate is simply proportional to the ratio \(D/L\) of the straight section over the total length of the ring \([44]\).

### III. RESULTS

Here, we present charged-current neutrino interaction rates with various target nuclei as obtained from Eqs.
Four possible nuclei are taken as typical examples, namely deuterium, oxygen, iron, and lead. A detailed study for the case of lead is also done in [53]. The “small ring” we consider has 150 meter straight sections and 450 meter total length, while the “large ring” has 2.5 km straight sections and 7 km total length. The detectors are located at a distance 10 meters from the storage ring, to allow a maximum shielding of the induced background in the ring [40]. Figure 2 shows the total rate for the reaction $\nu + D$ as a function of the boost factor $\gamma$. This corresponds to the small ring and small detector configuration.

Let us discuss the number of events shown in Tables I and II. The differences between the $\nu$-induced versus $\bar{\nu}$-induced reactions is a combined effect of the relative intensities $g_\nu/g_{\bar{\nu}} = 1/20$ and of the different interaction cross-sections: the ratio $\sigma(\nu+D)/\sigma(\bar{\nu}+D)$ is roughly 2 in the whole energy range considered here [13]; from [41], one can see that $\sigma(\nu+^{18}\text{O})/\sigma(\bar{\nu}+^{18}\text{O})$ is about 0.5 on average in the energy range relevant to the case $\gamma = 7$, namely $20 \text{ MeV} \lesssim E_\nu \lesssim 40 \text{ MeV}$, and about 1.5 on average in the range $40 \text{ MeV} \lesssim E_\nu \lesssim 80 \text{ MeV}$, relevant for the case $\gamma = 14$. The very low rates obtained for oxygen with $\gamma = 7$ despite the large detector size are due to the 15 MeV threshold in the interaction cross-section. Next, we observe that the suppression of the rates in the LR configuration as compared to the SR case for a given $\gamma$ roughly corresponds to the geometrical factor $L_{\text{SR}}/L_{\text{LR}}$, as expected from the previous discussion. In fact, the difference between the LR and SR rates can be fully understood by means of the approximate relation Eq. (11). This formula can be used to rescale our results for other possible dimensions of the storage ring. To this aim, we give the relevant values of $\langle \sigma \rangle_\gamma$ in each case. When going from $\gamma = 7$ to $\gamma = 14$, the neutrino fluxes become more collimated and the typical energy of the neutrinos increases. This, together with the fact that the neutrino-nucleus interaction cross sections rapidly rise with the impinging neutrino energy, increases the number of events by more than an order of magnitude. Figure 3 illustrates the rapid rise of the total rates with increasing $\gamma$. Note that, in the present case, where the detector is relatively close to the storage ring, the total rates do not have a simple scaling with the detector size, due to the non-trivial angular dependence of the impinging neutrino flux.

It is important to emphasize the complementarity between low-energy beta-beams and conventional neutrino facilities. The latter provide intense sources of electron and muon neutrinos and cover the very low energy region, similar to the case $\gamma = 7$ for the beta-beam. Let us mention that for comparable neutrino intensities, the rates presented in Table I are comparable to those obtained with conventional schemes with detectors located at about 50 meters from the source. Low-energy beta-beams would produce pure electron neutrino beams and,
by varying the boost factor $\gamma$, would offer a unique opportunity to study neutrino-nucleus interactions over a wide range of energies.

To conclude, the present study demonstrates that, with typical parameters available from existing studies, significant interaction rates can be achieved at a low-energy beta-beam facility. A small ring – with as long as possible straight sections – is the preferred configuration in the case of a close detector. The rates raise rapidly with increasing $\gamma$. We think our results are encouraging and we hope they will trigger further investigations, including, in particular, detailed simulations of the detectors.

We thank J. Bouchez and M. Magistris for useful discussions, R. Lombard and M. Mezzetto for careful reading of the manuscript.

[44] For a distant detector \((d \gg L, D, h)\), one has simply: 

\[
\Phi_{\text{tot}}(E_\nu) = \Phi_{\text{lab}}(E_\nu, \theta = 0) \frac{D}{L} \frac{N_{\text{target}}}{4\pi d^2} \gamma^2 (1 + \beta)^2 \langle \sigma \rangle, \]

where \(N_{\text{target}} = n \pi R^2 h\) is the total number of target nuclei.
