Blind source separation in the presence of weak sources

Abstract

We investigate the information processing of a linear mixture of independent sources of different magnitudes. In particular we consider the case where a number $m$ of the sources can be considered as “strong” as compared to the other ones, the “weak” sources. We find that it is preferable to perform blind source separation in the space spanned by the strong sources, and that this can be easily done by first projecting the signal onto the $m$ largest principal components. We illustrate the analytical results with numerical simulations.

Keywords: Independent component analysis, Blind source separation, Infomax
1 Introduction

During the recent years many studies have been devoted to the study of Blind Source Separation (BSS) and more generally of Independent Component Analysis (ICA) (see e.g. [7, 5, 6, 2]). Within the standard framework one assumes a multidimensional measured signal to result from a linear mixture of statistically independent components, or “sources”. In most cases one makes the optimistic hypotheses that the number of sources is equal to the dimension of the signal (the number of captors), and that the unknown mixture matrix is invertible. The goal of BSS is then to compute an estimate of the inverse of the mixture matrix in order to extract from the signal the independent components.

In the present paper we study the effect of having sources with different “strengths” when performing BSS. After giving a proper definition of the strength of a source, the main purpose of our study is to relate the strength of a source to its contribution to the information conveyed by the processing system about the signal, and to consider with more details the case where some of the sources are very weak compared to the others. We will show that in that case it is worthwhile to project the data onto the space generated by the strong sources in order to extract meaningful information and to avoid numerical problems. The contributions to the (projected) signal from the weak sources can then be considered as noise terms added to the linear mixture of strong sources. Since the sources are independent, this “noise” is thus independent of the “pure” signal (the part due to the strong sources).

The paper is organized as follows. In section 2 we introduce the model and give a precise definition to the strength of a source. In section 3 we compute Shannon information quantities from which we characterize how each source contributes to the information conveyed by the data and by the output of the processing network. We then discuss the case of a linear mixture of $N$ independent sources with $N - m$ “weak” sources and $m$ “strong” sources. The results of section 3 show that in such a case it would be preferable to be able to work in the $m$ dimensional space spanned by the strong sources. We show in section 4 that, with a good approximation, this is simply done by projecting the data onto the $m$ largest principal components. As a result one can perform BSS in the $m$-dimensional space where one is dealing with a $m$-dimensional linear mixture corrupted by a weak input noise. In section 5 we study, at first non trivial order in the noise strength, the expected performance in the estimation of the $m$ strong sources. Eventually in section 6 we present numerical simulations.

2 The Model

We consider the information processing of a signal which is a $N$-dimensional linear mixture of $N$ independent sources. At each time $t$ one observes $S(t) = \{S_j(t), j = 1, ..., N\}$ which can be written in term of the unknown sources $s(t) = \{s_\alpha(t), \alpha = 1, ..., N\}$ as:

$$S_j = \sum_{\alpha=1}^{N} M_{j\alpha} \ s_\alpha, \quad j = 1, ..., N, \quad (1)$$

where $M = \{M_{j\alpha}, j = 1, ..., N, \alpha = 1, ..., N\}$ is the mixture matrix assumed to be invertible. As it is well known, and easily seen from the above equation, it is not possible to distinguish between the mixture of $s$ with the matrix $M$ from the mixture of $s' \equiv P D s$ with the matrix $M$. **
\[
M' \equiv MD^{-1}P^{-1}
\]
where \(D\) is an arbitrary diagonal matrix with non-zero diagonal elements, and \(P\) an arbitrary permutation of \(N\) indices. If we decide to consider both normalized sources and normalized mixture matrices, we are left with a diagonal matrix \(D\) which defines the "strengths" of the sources. More precisely we write

\[
S_j = \sum_{\alpha=1}^{N} \overline{M}_{ja} \eta_{\alpha} s_{\alpha}, \quad j = 1, \ldots, N
\]

assuming zero mean and unit variance for every source:

\[
<s_{\alpha}> = 0, \quad <s_{\alpha}^2> = 1, \quad \alpha = 1, \ldots, N,
\]

where \(<.>\) denotes the average with respect to the (unknown) sources probability distributions,

\[
\rho(s) = \prod_{\alpha} \rho_{\alpha}(s_{\alpha}),
\]

and with \(\overline{M}\) the normalized mixture matrix. The normalization can be chosen in different ways, and two of them are of particular interest for what follows. The simplest one is, for each \(\alpha\),

\[
\left[\overline{M}^{-1} \overline{M}^{T}\right]_{\alpha\alpha} = \sum_{j=1}^{N} (\overline{M}_{ja})^2 = 1.
\]

The second one is a normalization on the inverse of the mixture matrix:

\[
\left[\overline{M}^{-1} \overline{M}^{T}^{-1}\right]_{\alpha\alpha} = \sum_{j=1}^{N} \left(\left[\overline{M}^{-1}\right]_{\alpha j}\right)^2 = 1.
\]

Once a particular normalization, such as (5) or (6), is chosen, the parameters \(\eta_{\alpha}\) in (2) are well defined and can be understood as the relative strengths of the sources.

### 3 Information processing in the presence of inhomogeneous sources

Since the mixture matrix is assumed to be invertible, it is in principle possible to compute an estimate of it. This can be done with any one of the known blind source separation (BSS) algorithms (see e.g. [6, 5, 3, 11]). As a result one obtains an estimate of the inverse of the mixture matrix, which in our notations can be written as

\[
\frac{1}{\eta_{\alpha}} \left[\overline{M}^{-1}\right]_{\alpha j}.
\]

This shows that it will be dominated by the smallest \(\eta\)'s, and numerical instabilities or overflows may occur if some of them are very small. In many approaches to BSS whitening of the data is first performed. The whitened data are then an orthogonal mixture of sources, so that after this preprocessing one has sources of equal strengths. But this preprocessing requires a multiplication by the inverse of the eigenvalues, and this is subject to the same numerical problems as with the computation of the inverse of the mixture matrix: as we will see in section 4, small values of \(\eta\) leads to the existence of small eigenvalues.
3.1 Information content of the data

Let us now compute the amount of information conveyed by the data, $S$, about the sources, that is the mutual information $I(S, s)$. To do so we consider

$$S_j = \sum_{\alpha=1}^{N} M_{j\alpha} \eta_\alpha s_\alpha + \nu_j, \quad j = 1, ..., N. \quad (8)$$

where $\nu = \{\nu_j, j = 1, ..., N\}$ is a vanishing additive noise, $<\nu_j> = 0$, $<\nu_j \nu_k> = b \delta_{j,k}$ with $b \to 0$. Then $I(S, s)$ is a constant (that is a quantity that depends on $b$ alone) plus the data entropy. Since the mixture matrix is invertible, we have

$$I(S, s) = \text{Const.} + \ln |\det M| + \sum_\alpha \ln \eta_\alpha - \sum_\alpha \int dh_\alpha \rho_\alpha(h_\alpha) \ln \rho_\alpha(h_\alpha). \quad (9)$$

The last term in the above expression is the sum of the source entropies. One should remember that the $s$'s are the normalized sources, $<s_\alpha^2> = 1$. This shows that each source contributes to the information by a combination of its strength and its entropy: the strength term favors strong sources, whereas the entropy term favors the sources with a probability distribution function (p.d.f.) close to Gaussian. The entropy terms, however, are bounded: the entropy of a source cannot exceeds the one of a Gaussian with same variance, that is

$$- \int dh_\alpha \rho_\alpha(h_\alpha) \ln \rho_\alpha(h_\alpha) \leq \frac{1}{2} \ln 2\pi e. \quad (10)$$

Hence the information can be easily dominated by the strength terms, which can be arbitrarily large.

It is known that for performing BSS perfect knowledge of the sources distribution is not necessary, and working on the cumulants of order 2 and 3 or 4 is sufficient (see e.g. [6, 11]). We can thus analyze the result Eq. (9) by making a close-to-Gaussian approximation [6, 11]. If we assume the sources to have non zero third order cumulants,

$$\lambda_\alpha^{(3)} \equiv <s_\alpha^3> \epsilon, \quad (11)$$

we replace the source distribution $\rho_\alpha$ by

$$\hat{\rho}_\alpha(s_\alpha) = \frac{e^{-s_\alpha^2/2}}{\sqrt{2\pi}} \left(1 + \lambda_\alpha^{(3)} s_\alpha^2(s_\alpha^2 - 3)/6\right). \quad (12)$$

The distribution $\hat{\rho}_\alpha$ has the same three first moments as the true distribution $\rho_\alpha$ [1].

In the case of a symmetric non-Gaussian distribution, the third order cumulants are zero and one has then to take into account non zero fourth order cumulants. It is a straightforward exercise to perform the same analysis as below in that case. For simplicity in this paper we will consider only the case of non symmetric distributions.

Within this approximation, Eq.(12), the mutual information (9) reads:

$$I(S, s) = \text{Const.} + \ln |\det M| + \sum_\alpha \ln \eta_\alpha + \frac{N}{2} \ln 2\pi e - \frac{1}{12} \sum_\alpha <s_\alpha^3>^2 \epsilon. \quad (13)$$
From the above expression the most important source are those for which the quantity

\[ < s^3 > \alpha \frac{2}{c} - \ln \eta \alpha \]  

(14)
is the smallest.

We consider now the information that will be conveyed by a network processing the data, and ask for the contribution to this information by each source when the network performs BSS.

### 3.2 Characterization from infomax

The infomax criterion \[8, 10\] will allow us to get some more insight onto the link between the sources strengths and the amount of information that can be extracted from the data.

We consider the information processing of the signal by a nonlinear network, and we are interested in computing the mutual information \( I(V, S) \) between the input \( S \) and the output \( V = \{V_i, i = 1, ..., N\} \) of the network. Since the signal is a linear mixture, the relevant architecture is a linear processing followed by a (possibly) nonlinear transfer function which may differ from neuron to neuron:

\[ V_i = f_i(h_i) + \nu_i \tag{15} \]

\[ h_i = \sum_j J_{ij} (S_j + \nu_0^j) \tag{16} \]

where \( \nu_0 = \{\nu_j^0, j = 1, ..., N\} \) and \( \nu = \{\nu_i, i = 1, ..., N\} \) are additive input and output noise, respectively, with \( \langle \nu_0 \rangle = 0, \langle \nu \rangle = 0, \langle \nu_j^0 \nu_j^0 \rangle = b^0 \delta_j j', \langle \nu_i \nu_i' \rangle = b \delta_i i' \). The \( J_{ij} \) can be viewed as synaptic efficacies and the \( h_i \)'s as post-synaptic potentials (PSP). As explained in the previous section, the noise has to be introduced in order to have a nontrivial mutual information, and we take the limit \( 0 \leq b^0 << b' \leq 1 \). For strictly zero input noise, \( b^0 = 0 \), in the limit \( b \to 0 \) the mutual information is up to a constant equal to the output entropy. As shown in \[10\] its maximization over the choice of both \( J \) and the transfer functions \( f_i \)'s leads to BSS. One can then derive practical algorithms for performing BSS \[3\]. In this limit of \( b^0 = 0 \) all the sources play the same role, that is the maximum of the mutual information is independent of the individual sources properties as well as of the mixture matrix. When one takes into account a non zero input noise, then at first non trivial order in \( b^0 \) one sees that the input noise introduces a scale which breaks this invariance. More precisely, at first order in \( b^0 \) the mutual information \( I(V, S) \) can be written (see \[10\] for details):

\[ I(V, S) = I_0(V, S) - \frac{b^0}{2b} \sum_{i=1}^{N} \Gamma_{ii} \int dh_i \psi_i(h_i) f_i'^2 \tag{17} \]

where \( I_0(V, S) \) is the value at \( b^0 = 0 \),

\[ I_0(V, S) = \text{Const.} - \int dh \psi(h) \ln \frac{\psi(h)}{\prod_{i=1}^{N} f_i(h_i)} \tag{18} \]

and \( \frac{b^0}{b} \Gamma_{ii} \) is the variance of the noise on the PSP \( h_i \):

\[ \Gamma_{ii} \equiv \left[ JJ^T \right]_{ii} \tag{19} \]
Finally, $\psi(h)$ is the probability distribution of $h$ induced by the sources input distribution, and $\psi_i(h_i)$ the marginal distribution of the PSP $h_i$. At a given $J$, optimizing with respect to the choice of transfer functions gives

$$f'_i(h_i) = \psi_i(h_i) \{ 1 + \frac{b^0}{b} \Gamma_{ii} [\langle \psi^2_i \rangle - \psi^2_i(h_i)] \}$$  \hspace{1cm} (20)$$

with $\langle \psi^2_i \rangle = \int dh_i \psi_i(h_i) \psi^2_i(h_i) = \int dh_i \psi_i(h_i)^3$. We now optimize over $J$. At zeroth order the optimum is reached for $J = M^{-1}$ (up to an arbitrary permutation), so that we write

$$W \equiv JM = 1_N + \frac{b^0}{b} W^1,$$  \hspace{1cm} (21)$$

where $1_N$ is the $N \times N$ identity matrix. Expanding the mutual information at first order in $\frac{b^0}{b}$ one finds that there is no contribution from $W^1$ to this order. Hence the mutual information at first order in $\frac{b^0}{b}$ is given by Eq. (17) at $J = M^{-1}$, with $f'_i$ given by (20) in which we set $\psi_i = \rho_i$. This gives

$$I(V, S) = \text{Const.} - \frac{b^0}{2b} \sum_{\alpha=1}^{N} \Gamma_{\alpha\alpha} \int ds_{\alpha} [\rho_{\alpha}(s_{\alpha})]^3$$  \hspace{1cm} (22)$$

with

$$\Gamma_{\alpha\alpha} = \left[ M^{-1} M^{-1} \right]_{\alpha\alpha}.$$  \hspace{1cm} (23)$$

One sees that the term depending on $M$ is what appears in the normalization (6) of the mixture matrix. Hence if one chooses this particular normalization (6) in order to define the strengths $\eta_{\alpha}$ of the sources, one can rewrite

$$I(V, S) = \text{Const.} - \frac{b^0}{2b} \sum_{\alpha=1}^{N} \frac{1}{\eta_{\alpha}^2} \langle \rho_{\alpha}^2 \rangle$$  \hspace{1cm} (24)$$

with $\langle \rho_{\alpha}^2 \rangle = \int ds_{\alpha} [\rho_{\alpha}(s_{\alpha})]^3$. The above expression shows how each source $\alpha$ contributes to the mutual information in term of its strength $\eta_{\alpha}$ and its pdf $\rho_{\alpha}$.

Within the close-to-Gaussian approximation (12) one gets

$$I(V, S) = \text{Const.} - \frac{b^0}{b} \sum_{\alpha=1}^{N} \frac{s_{\alpha}^3}{\eta_{\alpha}^2} > c \frac{1}{\eta_{\alpha}^2}.$$  \hspace{1cm} (25)$$

Hence the sources which contribute the most to the conveyed information are those for which the quantity

$$E_{\alpha} \equiv \langle s_{\alpha}^3 > c \frac{1}{\eta_{\alpha}^2}.$$  \hspace{1cm} (26)$$

is the smallest. One should remember that, here, $\eta_{\alpha}$ is given by

$$\frac{1}{\eta_{\alpha}^2} = \sum_{j=1}^{N} \left( [M^{-1}]_{\alpha j} \right)^2.$$  \hspace{1cm} (27)$$
3.3 Discussion

As already seen when computing the mutual information between the data and the sources, a source will contribute if it is strong and/or close to Gaussian. However the particular combination which appears here is different from the one we obtained in the previous section: here we have a multiplicative combination of strength and cumulant, whereas in (14) it was an additive combination.

An important practical remark is that, if the third order cumulants are zero, the close-to-Gaussian approximation has to take into account the fourth order cumulants. Then, instead of (14) and (26) one gets similar expressions with the fourth order cumulants in place of the third order ones.

The criterion (26) can be used in different ways, depending on the particular application considered. The quantity $\mathcal{E}_\alpha$ is zero for Gaussian sources, whatever their strengths. This is not surprising since the Shannon information is maximal for Gaussian distributions. However in many cases the Gaussian part of the signal is considered as “noise”, and the non Gaussian part is the “meaningful” part, the “true” signal. Hence mutual information can be used as a cost function in order to extract this noise, in particular when it is strong, which can then be subtracted from the input signal. In cases where one has distributions of similar shapes, (26) suggests to use the strength as defined in (27) to order the sources and select the most relevant ones.

To conclude the present section 3, we see that the intuitive idea that weak sources can be considered as noise terms and cannot be estimated, can be quantified from various point of views. From the purely numerical aspect, the mixture matrix is close to be singular; the information content of the data, the amount of information conveyed by a processing channel, are seriously diminished by the presence of weak sources. From this analysis, it appears clearly that it would be preferable to be able to project the data onto the space spanned by the strong sources, in order to work in a space of smaller dimension with sources of similar strengths. In the next section we show that this is simply done by making use of the principal component analysis.

4 Principal Component Analysis

A standard approach in data processing consists in first performing the principal component analysis (PCA), and then projecting the data onto the eigenspace associated with the largest eigenvalues. In the present context of BSS, it is reasonable to expect the space spanned by the strong sources to be essentially the same as the one associated to the largest principal components. It is the purpose of this section to give a positive and more precise answer to this question.

We consider the specific case where $m$ source are strong, while $N - m$ sources are weak. More precisely, choosing for later convenience the normalization (3), we assume

$$\eta_\alpha \sim O(1 = \epsilon^0) \text{ for } \alpha = 1, ..., m,$$

$$\eta_\alpha \sim O(\epsilon) \text{ for } \alpha = m + 1, ..., N,$$

(28)

where $\epsilon$ is a small parameter, $\epsilon << 1$. This is equivalent to state that there is a gap in the spectrum of eigenvalues at the $\lambda_m$, with $\lambda_{m+1} << \lambda_m$. 

We assume that the reduced $N \times m$ mixture matrix $M^0$, \( \{M^0_{j\alpha} = M_{j\alpha}, j = 1, ..., N; \alpha = 1, ..., m \} \) is of rank $m$, so that the $(N \times N)$ correlation matrix (the covariance of the input signal) $C^0$, which would be obtained at $\epsilon \equiv 0$, has $m$ non zero eigenvalues. It is a standard exercise in perturbation theory \cite{9} to study the behavior of the eigenvalues and eigenvectors of a symmetric matrix, here the covariance matrix $C$ of the inputs, at first non trivial order in the small parameter $\epsilon$. The eigenvalues have a smooth behavior with $\epsilon$: the $m$ largest eigenvalues of $C$ are, at first non trivial order, the $m$ non zero eigenvalues of $C^0$ shifted by quantities of order $\epsilon^2$, and the $N - m$ smallest ones are of order $\epsilon^2$. However the eigenvectors are very sensitive to small variations of $\epsilon$ - this is related to the fact that the mixture matrix $M$ is closed to be singular for small $\epsilon$. More precisely, one gets the following results.

One can write $C$ as

$$C = C^0 + \epsilon^2 C^1,$$

(29)

where $C^0$ is the correlation of the inputs that would be obtained without the weak sources ($\epsilon \equiv 0$), and $\epsilon^2 C^1$ contains all the contributions from the weak sources. We denote by $\lambda_\alpha^0$ the eigenvalues of $C^0$, with $\{\lambda_\alpha^0; \alpha = 1, ..., m\}$ non zero and $\lambda_\alpha^0 = 0$ for $\alpha = m + 1, ..., N$. The associated eigenvectors $\{v_\alpha^0; \alpha = 1, ..., N\}$ form an orthonormal basis. If all the eigenvalues of $C^0$ are different (hence in particular $N = m + 1$), then, at first order, the eigenvalues of $C$ are

$$\lambda_\alpha = \lambda_\alpha^0 + \epsilon^2 \lambda_\alpha^1,$$

$$\lambda_\alpha^1 = v_\alpha^0 C^1 v_\alpha^0 \quad (\alpha = 1, ..., N),$$

(30)

and the corresponding eigenvectors are

$$v_\alpha = v_\alpha^0 + \epsilon^2 \sum_{\beta \neq \alpha} v_\beta^0 \frac{v_\alpha^0 C^1 v_\beta^0}{\lambda_\alpha^0 - \lambda_\beta^0} \quad (\alpha = 1, ..., N).$$

(31)

If there are degenerate eigenvalues (in particular the null eigenvalue is degenerate for $N > m + 1$), this is modified as follows. Suppose $C^0$ has only $r < N$ different eigenvalues, $\mu_1 > \mu_2 > ... > \mu_r$, with degeneracies $q_a, a = 1, ..., r \quad (\sum_a q_a = N, \mu_r = 0$ if $N > m + 1$). We have

$$\lambda_\alpha^0 = \mu_a \text{ for } \sum_{b=1}^{a-1} q_b < \alpha \leq \sum_{b=1}^{a} q_b \equiv \alpha_a$$

(32)

and we set $\alpha_0 \equiv 0$. Consider an eigenvalue $\mu_a$ with degeneracy $q_a > 1$. The eigenvectors of $C^0$ associated to $\mu_a$, $\{v_\alpha^0, \alpha_{a-1} < \alpha \leq \alpha_a\}$, form an orthonormal basis of this eigenspace of dimension $q_a$, and this base is defined up to an arbitrary orthogonal transformation. This arbitrariness is removed at first non trivial order in $\epsilon$, together with the removal of the eigenvalue degeneracy: the new $q_a$ eigenvectors for $\{\alpha_{a-1} < \alpha \leq \alpha_a\}$ are given by Eq. (31), where the $v^0$'s form the particular $q_a \times q_a$ orthogonal matrix which diagonalizes $C_a^1$, the restriction of the matrix $C^1$ to the eigenspace of $\mu_a$, the $\lambda_\alpha^1$ being then the eigenvalues of $C_a^1$.

The eigenvectors $v$ are now given by an equation similar to (31), with the sum over $\beta \neq \alpha$ replaced by a sum over the $\beta$ such that $\lambda_\beta \neq \lambda_\alpha$, and a new term specific to each degenerate eigenvalue $\mu_a$:

$$v_\alpha = v_\alpha^0 + \epsilon^2 \sum_{\beta: \lambda_\beta \neq \lambda_\alpha} v_\beta^0 \frac{v_\alpha^0 C^1 v_\beta^0}{\lambda_\alpha^0 - \lambda_\beta^0}$$

where the \( \mathbf{v}^0 \) are chosen as just explained, and \( X_{\alpha,\beta} \) is an arbitrary antisymmetric matrix.

The final result is thus that the space generated by the \( m \) eigenvectors associated to the \( m \) largest eigenvalues is, to order \( \epsilon^2 \), the same space as the one which would be obtained in the absence of the weak sources. Projecting the data onto this space is then equivalent to working with the \( m \)-dimensional signal which is the mixture of the \( m \) strong sources, weakly corrupted by an additive noise.

## 5 BSS with noisy data

Let us now assume that we have pre-processed the data by projecting it onto the \( m \) largest principal components. To avoid the introduction of a new notation, in the following \( \{S_j, j = 1, \ldots, m\} \) will denote these preprocessed data (projections) instead of the data themselves. Instead of the model Eq. (33) we have thus to consider the model

\[
S_j = \sum_{\alpha=1}^{m} M_{j\alpha} s_{\alpha} + \nu_0^j, \quad j = 1, \ldots, m. \tag{34}
\]

The matrix \( \mathbf{M} \) is now a \( m \times m \) invertible mixture matrix, such that \( \mathbf{M}\mathbf{M}^T \) has \( m \) non zero, of order 1 = \( \epsilon^0 \), eigenvalues. The \( s_{\alpha} \)'s (\( \alpha = 1, \ldots, m \)) are the sources of interest, and the \( \nu_0^j \)'s are additive noises, resulting from the weak sources, as explained in the previous section. This noise \( \mathbf{\nu}_0 = \{\nu_0^j, j = 1, \ldots, m\} \) is uncorrelated with the \( m \) (strong) sources, and of arbitrary distribution \( P(\mathbf{\nu}_0) \). Since we are working in the small \( \epsilon \) regime, all we will need is to characterize this distribution by its first two cumulants:

\[
< \mathbf{\nu}_0 >= 0,
\]

\[
< \mathbf{\nu}_0 \mathbf{\nu}_0^T >= \epsilon^2 \mathbf{B}, \tag{35}
\]

where \( \mathbf{B} \) is a (possibly non diagonal) \( m \times m \) symmetric matrix. The problem we are considering now is thus strictly the same as the one of performing BSS on a linear mixture of \( m \) sources corrupted by some additive input noise, which, although small, cannot be neglected.

### 5.1 The Mutual Information

In this section we consider this noisy BSS problem within the infomax approach as formulated in [10]. The network we consider has the same architecture as the one defined in Eq. (16), but with \( m \) inputs and outputs:

\[
V_i = f_i(h_i) + \nu_i \tag{36}
\]

\[
h_i = \sum_{j=1}^{m} J_{ij} (S_j + \nu_0^j) \quad i = 1, \ldots, m, \tag{37}
\]

with \(< \nu_i \nu_{i'} > = b \delta_{i,i'}\). The limit to be considered here is the one of a vanishing output noise, \( b \to 0 \), but at a given input noise level:

\[
0 < b << \epsilon^2. \tag{38}
\]
Another important difference with the calculation done in section 3.2, is that here we are interested in computing the information conveyed about the global input, $S + \nu_0$, and not about the “pure” signal alone $S$. Indeed, in section 3.2 we considered some input noise corresponding to some noise at the level of the receptors, whereas here the actual signal is the global input, $S + \nu_0$, in which we have decided to call “(pure) signal” the part coming from the strong sources and “noise” the part due to the weak sources.

In this limit of vanishing output noise, the mutual information $I(V, S + \nu_0)$ between the output and the input of the network is up to a constant equal to the output entropy. To simplify the analysis, we assume a full adaptation of the transfer functions, which means for $J$ given,

$$f'_i(h_i) = \psi_i(h_i), i = 1, ..., m,$$

where $\psi_i(h_i)$ is the marginal probability distribution of the PSP $h_i$. As a result the mutual information is up to a constant equal to the redundancy between the PSP’s:

$$I(V, S) = \text{Const.} - \int d^m h \psi(h) \ln \frac{\psi(h)}{\prod_{i=1}^{m} \psi_i(h_i)}. \quad (40)$$

5.2 Maximization in the small $\epsilon$ limit

In term of the sources distributions, the distribution $\psi(h)$ is given by:

$$\psi(h) = \prod_{\alpha=1}^{m} ds_\alpha \rho_\alpha(s_\alpha) \int d^m \nu_0 P(\nu_0) \prod_{i=1}^{m} \delta(h_i - \sum_{\alpha} [JM]_{i\alpha} s_\alpha - \sum_j J_{ij} \nu_0^j). \quad (41)$$

Since in Eq. (41) the noises $\nu_0^j$ are $\sim O(\epsilon)$ we can perform an expansion, leading to the following expression:

$$\psi(h) = \{ 1 + \frac{\epsilon^2}{2} \sum_{i,i'} \left[ JBJ^T \right]_{ii'} \partial_i \partial_{i'} \} \psi^0(h), \quad (42)$$

where $\partial_i$ means the partial derivative with respect to $h_i$, and $\psi^0(h)$ is the p.d.f. that would be obtained at $\epsilon = 0$. Because the noise has zero mean there is no term of order $\epsilon$ in (42).

We consider now the maximization of the mutual information over the choice of $J$, taking into account that $\epsilon$ is small. If $\epsilon$ was strictly zero, we would be back to the noiseless BSS problem for which the optimum is reached for $J = M^{-1}$ (up to an arbitrary permutation). So for nonzero $\epsilon$ we write

$$W \equiv JM = 1_m + \epsilon W^1 + O(\epsilon^2), \quad (43)$$

where $1_m$ is the $m \times m$ identity matrix, and the correction is a matrix of order at least $\epsilon$. Since $W$ depends now on $\epsilon$ we can also expand $\psi^0$ in powers of $\epsilon$, and finally $\psi(h)$ can then be written as

$$\psi(h) = \left[ \prod_{\alpha} \rho_\alpha(h_\alpha) \right] \left[ 1 + \epsilon Q[h] + R[h] \right] \quad (44)$$

with

$$Q[h] \equiv - \sum_{\alpha,\beta} [\ln \rho_\alpha]' W^1_{\alpha\beta} h_\beta - Tr W^1 \quad (45)$$
and $R[h]$ contains terms of order at least $\epsilon^2$, coming from both $W$, equation (43), and $B$, equation (42). Similarly, for the marginal distributions:

$$\psi_\alpha(h_\alpha) = \rho_\alpha(h_\alpha) \left\{ 1 + \epsilon \, Q_\alpha[h_\alpha] + R_\alpha[h_\alpha] \right\},$$

(46)

with

$$Q_\alpha[h_\alpha] \equiv - [\ln \rho_\alpha]' W_{a\alpha}^1 h_\alpha - W_{a\alpha}^1.$$

(47)

The substitution of Eq.(44) and (46) in the expression (40) gives then for the mutual information, at first non trivial order:

$$I(V, S) = I_0(V, S) - \frac{\epsilon^2}{2} \int \prod_{a=1}^m dh_\alpha \, \rho_\alpha(h_\alpha) \left[ Q[h] - \sum_\alpha Q_\alpha[h_\alpha] \right]^2.$$

(48)

The term $I_0(V, S)$ corresponds to the part of the mutual information which does not take into account the weak sources. It is the same as if one computes the mutual information between the output $V$ and the signal $M_s$; $I(V, M_s)$. The fact that there is no term of order $\epsilon$ in (48) can be understood as coming from the normalization conditions $\intdh \psi_0(h) = 1$ and $\intdh \rho_\alpha(h) = 1$, which imply

$$\int \prod_{a=1}^m dh_\alpha \rho_\alpha(h_\alpha) \, Q[h] = 0$$

and

$$\int dh_\alpha \rho_\alpha(h_\alpha) \, Q_\alpha[h_\alpha] = 0$$

(these properties can be easily checked by performing the integrations using the explicit expressions (45) and (47)). One has similar properties for the quantities of order $\epsilon^2$, $R[h]$ and $R_\alpha[h_\alpha]$ defined in (44) and (46), so that they do not contribute at this order $\epsilon^2$ in the final result (48).

Now one has

$$Q[h] - \sum_\alpha Q_\alpha[h_\alpha] = - \sum_{\alpha \neq \beta} [\ln \rho_\alpha]' W_{a\alpha}^1 h_\beta.$$

(49)

The mutual information is maximized when the quadratic term in (48) is minimized, that is for $W_{a\beta}^1 = 0$ for $\alpha \neq \beta$. It follows that there is no correction to the mutual information at order $\epsilon^2$ and that corrections due to the weak sources appear at order $\epsilon^4$.

6 Numerical simulations

In this section we illustrate our analysis by numerical simulations. We test the above analysis on the following toy example. We consider the ICA of natural images performed in [3]. First we reproduce the results in [3] (not shown here). We then create a new data base with artificially increased component strengths: new images are computed as a linear mixture of the previous ICA basis function but the strength of 20 components was augmented 100 times compared to the other 124. We performed ICA in this new data base, with the same algorithm based on infomax [10, 3], but after projecting the data onto the 20 largest principal
components. The resulting basis function represented on the Figure 1 shows the efficiency of PCA preprocessing: we find the good 20 stronger components and the computational time is considerably decreased.

For such a signal, the PCA analysis is identical to a Fourier analysis, and therefore dropping the smallest eigenvalues means neglecting high frequencies. One thus expect to extract components which are smoothed versions of components extracted when working with the full space. This is indeed the case as shown on Figure 1.

7 Concluding remarks

We have discussed the task of Blind Source Separation in the case of a mixture of sources of unequal strengths.

We have presented different, but related, ways of defining the relative strengths of the sources. In particular, when non zero input noise is taken into account the contribution of a source to the conveyed information can be characterized by a criterion which combines the mixture matrix elements and the third cumulant of the source distribution. This allows to define the strength of a source once a proper normalization of the mixture matrix is assumed. Conversely, this study shows which sources will be “preferred” by the infomax criterion (which part of the signal is more likely to be well extracted by an ICA performed with infomax).

The analysis indicates also that, although arbitrary, the assumed normalization of the mixture matrix may have an important practical role in the analysis of the outcome of an ICA, whenever one wants to extract the “meaningful” sources. Which part of the signal is more important is of course an application dependent notion. Prior knowledge related to a given case should allow to define the proper normalization from which the appropriate scale of source strengths can be defined. Conversely each chosen normalization implies a particular physical interpretation which should be kept in mind when analyzing the outcome of an ICA.

We have considered with more details the particular case of the information processing of a linear mixture of independent sources when some of them are very weak as compared to the other sources. One should note that in such case the notion of strong versus weak is independent of the mixture matrix normalization. It is easily seen that the presence of weak sources leads to an almost singular mixture matrix, and this manifests itself by the existence of very small eigenvalues in the PCA analysis. We have shown that it is relevant to project the input data onto the largest principal components in order to extract the strongest independent sources. We have thus quantified the intuitive idea that the subspace, where most of the data live, is mainly spanned by the strongest independent sources. We illustrated this result on the ICA of the image data base studied in [3].

A possible situation where the PCA will not be (sufficiently) helpful is when the strong sources generate a linear space of dimension smaller than the number of sources. This space will be found by the PCA. After projection onto the largest PC’s, one has then to deal with an ICA with a number of sources larger than the number of captors. This is an interesting problem which has received considerable attention recently, and several algorithms have been proposed. Our analysis suggests then that it can be meaningfull to project onto the largest PC’s (in order to eliminate the weak sources) and yet to search for a number of (strong) IC’s
larger than the number of largest PC’s.
