An Optically Targeted Search for Gravitational Waves emitted by Core-Collapse Supernovae during the First and Second Observing Runs of Advanced LIGO and Advanced Virgo

LIGO Scientific Collaboration, Virgo Collaboration, ASAS-SN Collaboration, DLT40 Collaboration, and F. Salemi
(Dated: 22 August 2019)

We present the results from a search for gravitational-wave transients associated with core-collapse supernovae observed within a source distance of approximately 20 Mpc during the first and second observing runs of Advanced LIGO and Advanced Virgo. No significant gravitational-wave candidate was detected. We report the detection efficiencies as a function of the distance for waveforms derived from multidimensional numerical simulations and phenomenological extreme emission models. For neutrino-driven explosions the distance at which we reach 50% detection efficiency is approaching 5 kpc, and for magnetorotationally-driven explosions is up to 54 kpc. However, waveforms for extreme emission models are detectable up to 28 Mpc. For the first time, the gravitational-wave data enabled us to exclude part of the parameter spaces of two extreme emission models with confidence up to 83%, limited by coincident data coverage. Besides, using ad hoc harmonic signals windowed with Gaussian envelopes we constrained the gravitational-wave energy emitted during core-collapse at the levels of $4.27 \times 10^{-2} M_{\odot} c^2$ and $1.28 \times 10^{-1} M_{\odot} c^2$ for emissions at 235 Hz and 1304 Hz respectively. These constraints are two orders of magnitude more stringent than previously derived in the corresponding analysis using initial LIGO, initial Virgo and GEO 600 data.

I. INTRODUCTION

The direct detection in September 2015 of a binary black hole merger [1] initiated the field of gravitational-wave astronomy. During the first and second observing runs (O1 and O2) of Advanced LIGO and Advanced Virgo several more mergers were reported [2–7] and in August 2017 a binary neutron star merger [8] was observed in the gravitational-wave (GW) and electromagnetic spectra. This event gave birth to multimessenger astronomy with gravitational waves [9–13].

Core-collapse supernovae (CCSNe) are another important target of multimessenger astronomy with GWs, as all recorded supernovae were observed in the electromagnetic spectrum and low energy neutrinos were observed from SN 1987A [14–16]. GWs and neutrinos provide unique information about the dynamics of the collapse and the onset of the explosion, as opposed to electromagnetic emission which is delayed and originates in regions thousands of kilometers away from the central engine. Their observation could provide hints to the shock revival mechanism [17–23]. The most promising opportunity for multimessenger GW astronomy with CCSNe would be a Galactic CCSN, although the rate of such events is expected to be just one or two per century [24–30].

In contrast to all-sky, all-time unmodelled GW transient searches [31–34], targeted searches for CCSNe impose the sky location, the source distance, and a time window for the arrival time of the GW signal. In the previous CCSN targeted search with first-generation GW detector data [35] we developed the methodology, derived distance ranges for various GW emission processes, provided null model exclusion statements, and established GW energy constraints.

This paper describes a targeted search focusing on CCSNe recorded by astronomical observations at distances up to approximately 20 Mpc during O1 and O2. We selected five CCSNe, four of which are type-II supernovae (SN 2015as, SN 2016B, SN 2016X, SN 2017eaw) and one is type-Ib/c (SN 2017gax). We have not found any evidence for a GW signal associated with them. Similarly to [35], we obtain distance ranges for a selection of waveforms which were computed from numerical simulations and that are representative of different emission mechanisms and progenitors. We also use phenomenological waveforms representing possible but extreme emission models and we derive standard candle model exclusion statements for them. Finally, we adopt ad hoc sine-Gaussian waveforms to simulate GW emission in specific time-frequency regions allowing us to derive upper limits on the emitted GWs from a specific CCSN.

This paper is organized as follows: In Sec. II we list the CCSNe that we study in this search. We also describe

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{sky_location.png}
\caption{Sky locations of core-collapse CCSNe analyzed in this search. All were recorded within 20 Mpc during the O1 and O2 observing runs.}
\end{figure}
methods for calculating the time period when we expect the moment of collapse. In Sec. III we describe the data used in the search. Sec. IV describes the methodology, the pipeline, simulated GW signals, and systematic uncertainties. The results in Sec. V include distance reaches for several models of emission, GW energy constraints, and model exclusion statements. We draw conclusions in Sec. VI.

II. TARGETED CORE-COLLAPSE SUPERNOVAE

From all core-collapse supernovae recorded during the O1 and O2 periods, we have selected those that contribute to model exclusion statements and meet the following criteria: (i) the distance is less than approximately 20 Mpc, (ii) the period where we expect to find the GW transient, the on-source window, (see Sec. II A) is sufficiently well identified (order of days maximum), and (iii) there is sufficient GW detector data within the supernova on-source window to allow us to accumulate at least a few years of background data (see Sec. IV B).

During O1 and O2, astronomers found and followed-up numerous CCSNe in the nearby universe. Based on the information from Astronomical Telegrams [36] and supernova catalogs (ASAS-SN [37–40], DLT40 [41], Gaia [42, 43], ASRAS [44], TNS [45], OSC [46], CBAT [47]), we found 9 supernovae of interest.

Only five CCSNe meet the selection criteria and are used for the astrophysical statements in this paper. They are: SN 2015as, SN 2016B, SN 2016X, SN 2017eaw, and SN 2017gax. They are reported in Table I and Figure 1 presents their sky locations. The majority of these are type-II supernovae originating from red supergiant progenitor stars and the host galaxy was identified for each. The distance to each CCSNe is determined using the estimated distance to its host galaxy. The on-source window calculation methods are described Sec. II A.

SN 2015as, a type-Ib supernova, was discovered on 2015 November 15.78 UTC [48] during O1. The host galaxy is UGC 5460 at a distance of 19.2 Mpc [49]. Although the spectrum transitions to a type-Ib supernova around 75 days after explosion, the spectrum evolution closely relates to that of SN 2008ax, suggesting type-Ib [49]. The progenitor star is either a main sequence star or 20 $M_\odot$ Wolf-Rayet star [50]. CCSN ejecta is estimated to be $1.1 - 2.2 M_\odot$.

SN 2016B (ASASSN-16ab), a type-IIP supernova, was discovered by ASAS-SN on 2016 January 03.62 UTC [51] during O1. The host galaxy is PGC 037392 at a distance of 18.6 Mpc [51]. The progenitor star is estimated to be a red supergiant [52].

SN 2016X (ASASSN-16at), a type-IIP supernova, was discovered by ASAS-SN on 2016 January 20.59 UTC [53]. It exploded in the spiral galaxy UGC 08041 at a distance of 15.2 Mpc [54]. Optical observations in [54] indicate that the progenitor star is a massive red supergiant with an initial mass larger than $19 - 20 M_\odot$ and a radius larger than $930 \pm 70 R_\odot$.

SN 2017eaw (Gaia17bmy), a type-IIP supernova, was discovered by Gaia on 2017 May 14.24 UTC [55]. The CCSN exploded in galaxy NGC 6946, the estimated distance to be $6.72 \pm 0.15$ Mpc away [56]. This is the closest CCSN considered in the search. The analyses in [57–59] provide indication that the progenitor was a red supergiant with an estimated initial mass of $13 M_\odot$ and radius of 4000 $R_\odot$.

SN 2017gax (DLT17ch), a type-Ib/c supernova, was discovered by the DLT40 on 2017 August 14.71 UTC [41]. This CCSN was found in NGC 1672, 19.7 Mpc away [60]. Unfortunately, little is known about the progenitor star.
FIG. 2. Visual representation of the on-source windows (see Sec. II A), the data coverage for each detector, and the detector duty factors (percentage of available data inside on-source window). Dates in brackets are CCSN discovery times in UTC and \( t_2 \) is the end time of the on-source window for each CCSN. The plotted interferometers (IFO) are LIGO Hanford (H1), LIGO Livingston (L1) and Virgo (V1).

TABLE II. Overview of GW interferometers for the O1 and O2 observing runs from which we draw data for our search. The O1 observing run lasted four months and was followed by a half year maintenance period. The observing runs were preceded by engineering runs which we do not report here. O2 lasted around nine months, however the run was interrupted twice, between 2016.12.22–2017.01.04 and 2017.05.08–2017.06.26. The numbers in the table were calculated after periods of poor data quality were removed.

| Run | Detectors | Run Period | Duty Factors | Coin. Duty Factor |
|-----|-----------|------------|--------------|------------------|
| O1  | H1,L1     | 2015.09.12–2016.01.19 | 49.5% (H1), 42.4% (L1) | 31.4% (H1L1) |
| O2  | H1,L1     | 2016.11.30–2017.08.25  | 65.4% (H1), 63.6% (L1) | 49.0% (H1L1) |
| O2  | H1,L1,V1  | 2017.08.01–2017.08.25  | 77.7% (H1), 79.2% (L1), 85.1% (V1) | 62.0% (H1L1V1) |

A. On-source window calculation

The collapse of a star’s iron core forms a proto-neutron star and initiates a hydrodynamical shock wave propagating outward. Depending on the size of the progenitor star, the ensuing shock propagates for a period of seconds to days [69]. When it reaches the surface, i.e. shock breakout, a CCSN emits observable light. Because of weather conditions, limited sky coverage, and many other limitations, astronomical surveys typically record CCSNe hours to months after light first reaches Earth. The ability to extrapolate backwards in time to the moment of core-collapse, depends primarily on how quickly a CCSN is detected, its last non-detection, and the properties of its progenitor star.

The on-source window (OSW) is defined as the time interval \([t_1, t_2]\), where \( t_1 \) and \( t_2 \) are the beginning and end times respectively. An upper bound to this interval is \( t_{\text{disc}} \), the time at which the CCSN was first observed electromagnetically. We define \( t_{\text{Null}} \) as the time of the last observation of a host galaxy without a supernova present. To estimate the OSW we consider two methods. The choice between the early observation method (Early) and the expanding photosphere method (EPM) is based on the quality of the multi-band photometry, the determination of the host galaxy and the type of CCSN. We apply the early observation method when \( t_{\text{disc}} - t_{\text{Null}} \) is of order a few days, the supernova type is known, and the progenitor star is inferred [70–73]. In all other cases, we consider the EPM.

In the early observation method, \( t_2 \) is the time when the CCSN is discovered, i.e. \( t_2 = t_{\text{disc}} \). To determine \( t_1 \), we need to take into account \( t_{\text{Null}} \), and the shock propagation travel time between the moment of explosion and shock breakout, \( \Delta t_{\text{SB}} \). We get that \( t_1 = t_{\text{Null}} - \Delta t_{\text{SB}} \). \( \Delta t_{\text{SB}} \) depends mainly on the type of the progenitor star. Wolf-Rayet stars are stripped of helium and hydrogen and they lead to type-Ib/c supernovae. Their radii are on the order of a few \( R_\odot \) with typical shock breakout times ranging from a few seconds up to a minute [74]. Red supergiant stars have radii of 500-1000 \( R_\odot \) [75] and typical \( \Delta t_{\text{SB}} \) ranges from more than ten hours up to a...
The L1 and H1 detectors were observing jointly during November 30, 2016 and August 25, 2017 [2].

The expanding photosphere method is used in astronomy primarily to estimate distances to CCONSNe, but we employ it to estimate the time of core-collapse [79]. We briefly describe the method, but a detailed explanation can be found in [80–85]. When the shock breaks through a star’s surface, it heats up the outer layers and pushes them outwards. The expanding photosphere grows with time and its speed can be measured using Doppler shifts in its spectrum. As a consequence, we can extrapolate backward in time from the moment when explosion was caught in the optical bands in order to estimate $t_1$ and $t_2$. Since the interval between $t_{\text{disc}} - t_{\text{Null}}$ for SN 2017eaw was greater than a week and because SN 2017eaw follow-up observations allow it [57, 58], we used the EPM to calculate the OSW.

The data are affected by instrumental and environmental sources of noise that prevent some of the data from being analyzed [86]. Periods of poor data quality are excluded using the information from many probes monitoring the environment of the detectors and probes controlling the different optical elements [87, 88]. For all CCSNe, we applied the same criteria for excluding times of poor data quality that were used in the all-sky short-duration unmodelled transient GW searches [33, 34].

Table II specifies the data taking periods along with the availability of each detector, which is referred to as the duty factor. The duty factor for each detector in O2 was higher than in O1 and was growing towards the end of the period. Figure 2 shows the OSWs for each CCSN together with the periods when detector data was available. The analysis is performed on data that is coincident between two or more detectors. OSW for SN 2016X extends past the end of O1.

Figure 3 shows the noise spectral density for all available detectors at the times of SN 2016B and SN 2017gax. For comparison, we plot the sensitivities of the two detectors for SN 2007gr [35] observed during LIGO Science Run 5 (S5). When comparing the data for SN 2007gr to the O1-O2 sensitivity, the detectors are 3 to 5 times more sensitive in the most sensitive detector band between 100 and 300 Hz [33] and around 10 times more sensitive around 1 kHz. Moreover, the low frequency part of the spectrum (below 100 Hz) improved during O2, especially in the L1 detector.

SN 2017gax happened in August 2017 when the LIGO and Virgo detectors were acquiring data. We have considered not only the H1L1 coincident time but also the H1L1V1 coincident time. Because of the sensitivity difference between Virgo and the two LIGO detectors, we found that the H1L1V1 network is less sensitive. We thus report results using the H1L1 network.

### III. DETECTOR NETWORKS AND COVERAGE

Data from O1 and O2 were used for this search. This includes data from the Advanced LIGO detectors in Hanford (H1) and Livingston (L1) and the Advanced Virgo (V1) detector. O1 started on September 12, 2015 and ended on January 19, 2016, while O2 spanned the period between November 30, 2016 and August 25, 2017 [2]. The L1 and H1 detectors were observing jointly during O1 and O2, and Virgo joined the LIGO detectors on August 1, 2017 [2].

In this paper we search for GW signals in a large frequency band, 16-2048 Hz, without specific assumptions about the signal morphology. This frequency band allows us to cover most of the main emission processes inside a CCSN. We employ coherent WaveBurst (cWB) [96] as the search algorithm, which we describe in the following section.

#### A. Coherent Waveburst

Coherent WaveBurst is an excess power pipeline that is based on the constrained maximum likelihood ratio method [96]. For each event, the pipeline calculates correlation coefficients $cc = E_c/(E_c + E_n)$ which measures the degree of similarity of the waveforms between

![Noise Amplitude Spectral Densities of the GW interferometers](image-url)
the detectors. $E_c$ is the normalized coherent energy obtained by cross-correlating the reconstructed waveforms in each detector and $E_n$ is the normalized per detector residual noise energy after the reconstructed waveform is subtracted from the data. For a real GW, $cc \approx 1$, and we accept events that have $cc > 0.8$. Each event is ranked according to a coherent network signal-to-noise ratio, $\rho \propto \sqrt{E_c}$. A more detailed explanation of these statistics is given in Refs. [87, 96].

The events are divided into two mutually exclusive classes based on their morphologies, similarly to [33]. Class $C1$ contains transients of a few cycles. This class is primarily polluted by blip glitches which are very short duration transients, $O(10)$ ms, with large bandwidth, $O(100)$ Hz [86, 97]. These noise transients are currently of unknown origin. To separate blip glitches from the bulk of the trigger population in class $C2$ we use the selection criteria described in [87].

### B. Background estimation

As mentioned earlier, each GW detector is constantly monitored with various sensors that allow us to exclude poor data quality periods from the analysis. However, it is not possible to remove all sources of noise. To estimate how often the pipeline produces events that are falsely identified as GWs, we perform a background analysis where cWB artificially shifts the data in one detector with respect to the other. The typical time shift is a multiple of one second, which is much longer than the GW travel time between different detectors (e.g., 10 ms between H1 and L1). This allows us to estimate the false alarm rate (FAR) of the background events. We use a few years of background data for each CCSN.

GW events obtained when no shift is applied to the data may contain genuine GW signals. The events from the search classes are combined and ranked with their FAR. We assume that the event with the smallest FAR between the two search classes is a potential GW candidate and we refer to it as the loudest event. The FAR is calculated from the noise transient distribution of the class to which the loudest event belongs. Since the classes are independent, we apply a trial factor 2 to the FAR (see also [1, 33]) of the loudest event. The significance of an event with given FAR is assessed by calculating its False Alarm Probability (FAP), which is the probability of obtaining one or more noise events that are less than or equally ranked:

$$FAP = 1 - \exp \left(-\frac{T_{\text{coinc}} \times \text{FAR}}{T_{\text{coinc}}} \right)$$

where $T_{\text{coinc}}$ is the coincident data duration of the appropriate OSW.

### C. Search sensitivity

We determine how sensitive the pipeline is to particular waveform families. cWB adds (injects) supernova waveforms to the detector data inside the OSW with the right time delay in each detector such that the GW signal comes from the accurately known CCSN sky location. The fraction of the injected signals that can be detected and pass the selection criteria is the detection efficiency. The injection procedure is repeated with waveform amplitudes corresponding to different source distances. We select any event that passes the selection criteria of the search and whose rank is smaller than the loudest event FAR.

We consider two sets of multidimensional supernova explosion models, extreme emission models, and ad hoc waveforms as listed in Tables III and IV. For all of the waveforms we provide the peak frequency, number of polarizations, and other quantities. For the waveforms from

| Waveform Family | Waveform Identifier | $h_{\text{rss}}$ \text{[$10^{-22}\sqrt{\text{s}} \cdot \text{Hz}^{-3/2} \cdot \text{m}^{-1/2}$]} | $f_{\text{peak}}$ \text{[Hz]} | $E_{\text{GW}}$ \text{[$10^{-5} M_\odot c^2$]} | Polarizations |
|-----------------|-------------------|-----------------|-----------------|-----------------|-----------------|

TABLE III. Waveforms from detailed multidimensional CCSN simulations described in the text. For each waveform, we give the emission type, reference, waveform identifier, angle-averaged root-sum-squared strain $h_{\text{rss}}$, the frequency $f_{\text{peak}}$ at which the GW energy spectrum peaks, the emitted GW energy $E_{\text{GW}}$, and available polarizations. See Refs. [89, 90] for details.
multidimensional CCSN simulations and extreme emission models, we provide the GW energy, $E_{\text{GW}}$, emitted during the explosion and the source angle-averaged root-sum-squared GW strain,

$$h_{\text{rss}} = \sqrt{\langle h_+^2(t) + h_\times^2(t) \rangle_{\Omega} dt}.$$  \hfill (2)

Our efficiency estimates are subject to a number of uncertainties. The most important of these are calibration uncertainties in the strain data recorded at each detector, and Poisson uncertainties due to the use of a finite number of injections (Monte Carlo uncertainties). We use the same methodology explained in [35], to account for each of these uncertainties. For detection efficiencies, the dominant effect comes from the uncertainties in the strain amplitude calibration, as in [35]. These vary from a few percent at lower frequencies to 10% at higher frequencies in both L1 and H1. For this paper, these uncertainties are conservatively set to 10% for H1 and L1 at the times of the five CCSNe studied [98, 99]. The error analysis leads to decreasing the detection efficiencies by 9.1%.

For the waveforms coming from 2D simulations, marginalizing over all unknown angles the waveform amplitude is reduced by a factor $\sqrt{5/18}$ that we apply to the efficiencies. For optimally oriented CCSNe, the distance ranges for these models will be $\sqrt{18/5}$ times larger.

1. Waveforms from multidimensional CCSN simulations

The main mechanism behind a CCSN explosion is not yet fully understood and a complete review of the current state can be found in [21, 102–104] and in references therein. We divide the waveforms from multidimensional CCSN simulations into two sets according to their explosion mechanisms. In the first set, we consider a neutrino-driven explosion mechanism for non- or slowly-rotating progenitor stars. We employ three waveform families: Müller [91], Ott [92] and Yakunin [93]. In this scenario, neutrino heating plays a crucial role in creating the explosion. During the prompt convection, in the initial stages post bounce, GWs are emitted in the frequency range from 100–300 Hz, while at later times, GWs up to around 2 kHz can be expected [105, 106]. A typical duration for a GW transient is 0.5–1 s [21, 107, 108]. The second set of waveforms, with simulations from the Scheidegger [94] and Dimmelmeier [95] groups, utilizes the magnetohydrodynamically-driven (MHD-driven) explosion mechanism for rapidly rotating progenitor stars. The magnetic effects related to the rapid rotation may play a dominant role in creating the MHD-driven explosions. Note, however, almost all (99%) [21, 109] of explosions are believed to come from slowly rotating progenitor stars.

Müller et al [91] performed 3D simulations with a zero age main sequence (ZAMS) progenitor star of mass $15 M_\odot$ (L15-3 and W15-4), and a $20 M_\odot$ (N20-2), which we refer to as mu1, mu2 and mu3 respectively. The simulations are three-dimensional and thus result in two polarizations. The convective movement of infalling matter and its interaction with the outer layers of the proto-neutron star result in GW emission in the frequency range 100–500 Hz.

Ott et al [92] produced a 3D simulation with a $27 M_\odot$ ZAMS progenitor star (ott1). The explosion becomes aspherical due to strong convection while the SASI visibility is weak. This model is rotating and a strong burst of GWs appears at the beginning of the explosion.

Yakunin et al [93] delivers waveforms from four 2D simulations (providing only one polarization state) corresponding to $12 M_\odot$, $15 M_\odot$, $20 M_\odot$, $25 M_\odot$ ZAMS progenitor stars. We denote them as yak1, yak2, yak3 and yak4 respectively. These waveforms capture several stages of the explosion. They show both low (SASI/convection) and high (g-mode) frequency components in their signals. Due to axisymmetry, the strain grows artificially over time, resulting in higher GW amplitudes than the 3D neutrino driven models.

Scheidegger et al [94] considers effects on the GW signature due to the equation of state, the initial rotation rate, and the magnetic fields. From an extensive set of waveforms, we extract three models, R1E1CA$_L$, R3E1AC$_L$, and R4E1FC$_L$, which we refer to as sch1, sch2, and sch3, respectively. All of these models are derived from the explosion of a $15 M_\odot$ ZAMS progenitor star. The models are three dimensional and produce two GW polarization states. The degree of rotation varies between the models; model R1E1CA$_L$ has no rotation, which results in much lower GW energy in comparison to the rotating R3E1AC$_L$ and R4E1FC$_L$ models.

Dimmelmeier et al [95] performed 2D simulations (providing linearly polarized waveforms) with a $15 M_\odot$ ZAMS progenitor star. The waveforms contain very strong GW emission at the initial core-collapse and bounce that lasts less than 20 ms. We employ three waveforms with various degrees of rotation from moderate to rapid (dim1-dim3).

2. Extreme emission models

Along with the more realistic simulated CCSN explosions, we also consider two extreme scenarios: the Long-Lasting Bar Mode [100], and the Torus Fragmentation Instability [101]. The same models were used in [35], because even if they are unlikely to occur, they are not excluded [110].

In the first scenario, a very rapidly rotating progenitor star induces a bar mode instability in the proto-neutron star [94, 111–116]. This leads to large amplitude GWs that depend on the properties of the deformed proto-neutron star. We use the simple phenomenological bar model described in [100]. In this model, we use the following parameterization: the mass involved in the long-lasting bar mode of the proto-neutron star $M =$
TABLE IV. Waveforms from phenomenological and ad hoc emission models described in the text. For each waveform, we give the emission type, journal reference, waveform identifier, angle-averaged root-sum-squared strain $h_{\text{rss}}$, the frequency $f_{\text{peak}}$ at which the GW energy spectrum peaks, the emitted GW energy $E_{\text{GW}}$, and available polarizations. See [89, 90] for details. As sine-Gaussian waveforms are ad hoc, they can be rescaled arbitrarily and do not have a defined physical distance or $E_{\text{GW}}$ value.

| Emission Type | Waveform Identifier | $h_{\text{rss}}$ | $f_{\text{peak}}$ | $E_{\text{GW}}$ | Polarizations |
|---------------|---------------------|-----------------|-----------------|----------------|--------------|
|               | lb1-M0.2L60R10f4000t100 | 1.480           | 800             | $2.984 \times 10^{-4}$ | +, x         |

|               | sg3-235HzQ8d9elliptical | 235           | —               | —               | +, x         |
|               | sg4-1304HzQ8d9elliptical | 1304       | —               | —               | +, x         |

$\{0.2,1.0\} M_{\odot}$, the radius $R = 10$ km and length $L = 60$ km of the bar, the spin frequency $f = \{400,800\}$ Hz along the direction perpendicular to the bar, and the duration $t = \{25,100,1000\}$ ms of the deformation. We consider six waveforms, denoted as lb1-lb6, see Table IV for more details. Since the waveform amplitude is proportional to $M(L^2 - 3R^2)$ (see [100]), any combination of $M$, $L$ and $R$ giving the same value for $M(L^2 - 3R^2)$ as the six waveforms, will produce waveforms identical to the lb1-lb6 waveforms. Therefore results for lb1-lb6 waveforms are a good representation of the broader sections of parameter space.

In the second scenario, Piro and Pfahl [101] propose that, if a black hole and an accretion disk are formed during the collapse, the disk could fragment and large self-gravitating clumps of matter falling into the black hole would produce large amplitude GWs under the appropriate conditions. To model this signal we employ a simplified model [117] that depends on the mass of the central black hole $M_{\text{BH}} = \{5,10\} M_{\odot}$ and the properties of the disk, namely the thickness of the torus $\eta = \{0.3,0.6\}$ and the alpha viscosity parameter $\alpha = 0.1$. The torus thickness is defined as $\eta = H/r$, where $H$ is the disk scale-height and $r$ the local radius. For the disk model considered in [101], the mass of the fragmented clump is $M_f = 0.53\eta^3 M_{\text{BH}}$. The GW amplitude is proportional to the reduced mass of the BH-clump system, $\mu = M_{\text{BH}} M_f/(M_{\text{BH}} + M_f)$, which for the parameter space considered here ($M_f \ll M_{\text{BH}}$) is $\mu \approx M_f$.

3. Ad-hoc waveforms

We employ ad hoc waveforms to estimate the search sensitivity to short duration monochromatic signals that model GW emission in different frequency bands. We use sine-Gaussian signals with a fixed central frequency $f_0 = \{235,1304\}$ Hz and duration $\tau = Q/(\sqrt{2\pi} f_0)$ where $Q = 8.9$ is the quality factor. In our analysis, we use four ad hoc waveforms denoted as sg1-sg4 that are linearly and elliptically polarized, see Table IV.

FIG. 4. The False Alarm Probability (FAP) of background events together with the loudest events for each CCSN. The non-negligible values of the FAP indicate that all the loudest events appear compatible with the noise background. The shaded region is the 1σ error. The numbers in the parentheses are durations of the on-source windows and the class where the loudest events belong.

V. SEARCH RESULTS

Figure 4 presents the background as a function of $\rho$ the coherent network signal-to-noise ratio for all CCSNe. We
TABLE V. List of the loudest events for each CCSN. False alarm rate (FAR) and False Alarm Probability (FAP) for each of them indicate that they are consistent with background noise.

| Supernova | Class | \( \rho \) (kpc) | FAR [Hz] | FAP |
|-----------|-------|-------------------|---------|-----|
| SN 2015as | C2    | 5.8               | 2.9 \times 10^{-6} | 0.716 |
| SN 2016B  | C1    | 5.6               | 1.1 \times 10^{-5} | 0.732 |
| SN 2016X  | C1    | 6.2               | 1.4 \times 10^{-5} | 0.398 |
| SN 2017eaw| C1    | 6.6               | 1.3 \times 10^{-6} | 0.076 |
| SN 2017gax| C2    | 5.5               | 9.7 \times 10^{-5} | 1.000 |

The non-negligible values of the false alarm probabilities indicate that all the results appear compatible with the noise background. For each CCSN source, we estimate the search efficiency using the waveforms described in Sec. IV C considering events with a rank value smaller than the loudest event FAR.

### A. Detection efficiency vs. distance

We provide detection efficiencies for waveforms listed in Table III and Table IV. Figure 5 presents the detection efficiencies for SN 2017eaw, the closest CCSN in this search. For reference, the plots show the distances to the Galactic center (8.5 kpc), the Large Magellanic Cloud (49.6 kpc [118]) that hosted SN 1987A, and the distance to the host galaxy of SN 2017eaw, NGC 6946. For each model, we determine the distance corresponding to a 50% detection efficiency. Distance reaches for each CCSN for neutrino-driven explosions and MHD-driven explosions are summarized in Table VI and extreme emission models in Table VII. For each model the distances are consistent across CCSNe and these distances are around 3-5 times further than in [35]. The largest distances are obtained for SN 2017gax. This can be explained by the fact that the loudest event for this CCSN has the lowest \( \rho \) value and the network sensitivity at the time of the CCSN was better over the duration of the OSW.

For the neutrino-driven explosions summarized in Table VI and the upper left panel of Figure 5, the detection distance reached less than 5 kpc. None of these models reach the Galactic center, however a few of the waveforms have non-zero detection probabilities at that distance. The least detectable models are the Müller waveforms because they are the least energetic. The most detectable models are the Yakunin waveforms and the reach increases with progenitor mass. The Ott model has a smaller detection reach compared to the Yakunin waveforms, but also has higher detection efficiency at small distances.

Table VI and the upper right panel of Figure 5 also present a summary of distance reaches for MHD-driven explosions. The distance reaches for most of these models are an order of magnitude larger than for the neutrino-driven explosions. Some MHD-driven explosion models reach to the distance of Large Magellanic Cloud. If a MHD-driven supernova were to explode at the distance of SN 1987A, around 50 kpc away, we have a non-zero chance of detecting it. The detectable range for sch1 is two orders of magnitude shorter compared to those of sch2 and sch3. This Scheidegger model has a lower amplitude due to its slower rotation.

Distance reaches for the extreme emission models are given in Table VII and depicted in the bottom left panel of Figure 5. The ranges are on the order of several Mpc up to nearly 28 Mpc for the most extreme model. The reaches of a few waveforms exceed the distance of SN 2017eaw. Given the null detections, this means we can begin to exclude these models as discussed in Sec. V C.

The detection efficiencies for the linearly polarized waveforms (Dimmelmeier and Yakunin) do not reach unity even at small distances because the network of detectors is not sensitive to both polarizations for any sky position at a given time. There are sky positions where the detectors are insensitive to one of the polarizations and even a large amplitude signal with only one polarization will not be detectable. Waveforms with two polarizations are more efficiently detected than linearly polarized signals.

### B. Constraints on GW energy emission

Similarly to [35] we provide constraints on the GW energy emission from CCSNe. This is the minimum energy emitted in GWs needed to be detectable with 50% probability. We calculate these constraints individually for each CCSN. We probe low- and high-frequency GW emission using sine-Gaussian \textit{ad hoc} waveforms with central frequencies of 235 Hz and 1304 Hz (see Table IV). These waveforms do not have physical meaning, so we plot detection efficiency as a function of \( h_{\text{rss}} \) (eqn. (2)) instead of distance. We assume isotropic emission with a total energy of

\[
E_{\text{GW}} = \frac{\pi^2 c^3}{G} D^2 f_0^2 h_{\text{rss}}^2 ,
\]

where \( f_0 \) is the peak GW frequency of the sine-Gaussian, and \( D \) is the distance to the source [119].

The bottom right panel of Figure 5 shows the detection efficiency versus \( h_{\text{rss}} \) for the four \textit{ad hoc} waveforms. The quoted \( h_{\text{rss}} \) for each sine-Gaussian corresponds to the strain with a 50% detection efficiency. The best sensitivity is achieved for the sine-Gaussians around 235 Hz (sg1 and sg3), which is a result of the lower noise level of the detectors at this frequency. The efficiency curves of the elliptically polarized waveforms (sg3 and sg4) flatten at higher detection efficiencies compared to the efficiencies for linearly polarized waveforms (sg1 and sg2) for the reason discussed in Sec. V A.
FIG. 5. Panels (a), (b), and (c) show the efficiency as a function of distance using 3 families of waveforms for a source located at the position and time of SN 2017eaw. Panel (d) provides the detection efficiency for ad hoc sine-Gaussian waveforms as a function of \( h_{\text{rss}} \), which we use to constrain GW energy and discuss in Sec. VB. The numbers in parentheses for the models plotted in (a), (b), and (c) are the distances at which the detection efficiency equals 50%. For (d), the numbers in parentheses are the \( h_{\text{rss}} \) values resulting in 50% detection efficiencies. The detection reach for neutrino-driven explosions is limited to a few kpc while for magnetorotationally-driven (MHD-driven) explosions it covers the Milky Way and the detection efficiency at the distance of the Large Magellanic Cloud (LMC), that hosted SN 1987A, is non-zero. Further discussion can be found in Sec. VA. The distance reaches for extreme emission models in (c) exceed the distance of SN 2017eaw. Given that there was no GW detection, we are able to exclude some of the parameter spaces for these models, which we discuss in Sec. VC. The dashed lines show 50% and 90% detection efficiencies.

In Table VIII, we report GW energy constraints for each CCSN. For the ad hoc waveforms with peak frequency at 235 Hz (sg1 and sg3), the GW energy constraints are consistently on the order of \( 10^{-23} M_\odot c^2 \) or less. The lowest achieved energy constraints are obtained for SN 2017eaw at low frequency, \( 4.27 \times 10^{-4} M_\odot c^2 \) \( (7.63 \times 10^{50} \text{erg}) \), and high frequency, \( 1.28 \times 10^{-1} M_\odot c^2 \) \( (2.30 \times 10^{53} \text{erg}) \). For both low and high frequency emission, the energy constraints are two orders of magnitude stronger than in the search with the initial interferometer data [35]. This improvement is due to the improved sensitivity of the detectors and the closer distance of SN 2017eaw (6.72 Mpc) in comparison to SN 2007gr (10.55 Mpc). However, these energy constraints are still a few orders of magnitude larger than the energies predicted from multidimensional simulations (Table III), that lie between around \( 10^{-11} M_\odot c^2 \) and \( 10^{-7} M_\odot c^2 \).

The GW energy constraints obtained in this search can be compared to the energy budget of a CCSN. The energy available during collapse is approximately the gravitational binding energy of the final neutron star remnant, which is typically \( 1.5 \times 10^{-1} M_\odot c^2 \) \( (3 \times 10^{54} \text{erg}) \) [120–122]. Around 99% of that energy is radiated via neutrinos during the cooling of the proto-neutron star [123] and the remaining \( \sim 1% \) is mainly transferred into kinetic energy. In a realistic scenario, only a small fraction of the explosion’s energy is radiated in the GW spectrum (Sec. IV C).

In Sec. IV C we describe several processes emitting GWs. Some of them (e.g., SASI and convection) are
TABLE VI. Distance reaches (in kpc), defined as the distance with a 50% detection efficiency, for neutrino-driven explosions from Müller (mul1-mul3), Ott (ott1) and Yakunin (yak1-yak4), as well as MHD-driven explosions from Scheidegger (sch1-sch3) and Dimmelmeier (dim1-dim3).

related to the movement of matter that is ejected during an explosion. Again, according to the multidimensional simulations, only a small portion of this energy is converted into GWs. The kinetic energy of CCSN ejecta is typically on the order of $5.5 \times 10^{-4} M_\odot c^2$ ($10^{51}$ erg) [124–126]. Specifically, estimates of the kinetic energy in the ejecta of SN 2015as and SN 2017eaw are $2.5 \times 10^{-3} M_\odot c^2$ (4.4 × 10^{51} \text{ erg}) [49] and $1.1 \times 10^{-3} M_\odot c^2$ (2.0 × 10^{51} \text{ erg}) [58], respectively. The current GW constraints at low frequencies are comparable with these values. Specifically, the low frequency (235 Hz) constraints for SN 2017eaw are roughly an order of magnitude below the kinetic energy of CCSN ejecta.

For extreme emission models, the GW energies are orders of magnitude larger than those predicted for multidimensional simulations, as seen in Table IV. The energies of these extreme emission processes range from $2.98 \times 10^{-4} M_\odot c^2$ up to even $1.18 \times 10^{-1} M_\odot c^2$. Our energy constraints are comparable with these values, but the comparison would not be correct as the ad hoc signals and the extreme emission model waveforms frequency content are different.

C. Model exclusion statements for extreme emission models

Along with constraining the GW energy emitted by CCSNe, we also constrain two models of extreme GW emission. As described in Sec. VA, for a few waveforms of the extreme emission models, the distance reaches exceed the distances of the CCSNe analyzed in this search. Given no GW detection, these models most likely do not describe correctly the CCSN explosion phenomena. Similarly to Ref. [35], we consider a standard candle approach, that is we assume that each CCSN emits an identical GW signal. To characterize the models, we use waveforms that probe sample regions of the parameter spaces of these models (see Table IV and Sec. IV C 2).

The method for excluding models from multiple astrophysical sources is described in detail in [127]. In this method we use the detection efficiency, $\mathcal{E}(d)$, which is a function of the distance, $d$. If a GW transient is strong and detectable but arrives at the detectors when coincident data is not available, then the model that predicts such a transient cannot be excluded. Therefore, we need to take into account the coincident duty factor, $a \in [0, 1]$. We define the reduced detection efficiency as

$$\epsilon(d) = a \times \mathcal{E}(d).$$

Given no GW detection, the reduced detection efficiency can also be understood as a model exclusion probability. For example, the detection efficiency for the piro4 waveform reaches 96.7% (see Figure 5) at the distance of SN 2017eaw (6.72 Mpc). When we take into account the effect of the 48.8% coincident duty factor for this CCSN (see Table I) the reduced detection efficiency is 47.2%. Hence we are confident with 47% probability that the piro4 model does not correctly describe the nature of a CCSN engine.

We then combine model exclusion probabilities obtained for each CCSN by multiplying the probabilities of not detecting a signal. The overall model exclusion
### TABLE VIII. Gravitational-wave energy emission constraints at 50% detection efficiency. We assumed isotropic GW emission for the four *ad hoc* waveforms. The most stringent constraints (in bold) are achieved for the closest event, SN 2017eaw (6.72 Mpc). They are two orders of magnitude smaller than the results obtained in Ref. [35]. The energies obtained for 235 Hz emission are comparable to the typical explosion energy (~10^{51} erg) and a typical kinetic energy of CCSN ejecta (~10^{51} erg).

| Supernova | Quantity | sg1 - 235 Hz lin | sg2 - 1304 Hz lin | sg3 - 235 Hz ell | sg4 - 1304 Hz ell |

The probability

$$P_{\text{excl}} = 1 - \prod_{i=1}^{N} (1 - \epsilon_i(d_i)),$$

where $N$ is the number of CCSNe.

The results for the ten waveforms described in Sec. IV C 2 are shown in Table IX. The greatest $P_{\text{excl}} = 83.2\%$ is obtained for the piro4 waveform and the largest contributions come from SN 2017eaw and SN 2017gax because the detection ranges for these CCSNe are larger than their distances. Although SN 2017eaw makes the most important contribution to the model exclusion statements, the most energetic models, piro4 and lb5, are constrained by all CCSNe.

For the Torus Fragmentation Instability model, the waveforms are characterized by the mass of a central black hole and the thickness of a torus around it. The clump masses $M_f$ for the piro4-piro4 waveforms are 0.072 $M_\odot$, 0.576 $M_\odot$, 0.144 $M_\odot$, 1.152 $M_\odot$ respectively. There is a correlation between the mass of the fragment and $P_{\text{excl}}$ because the amplitude of the waveform scales approximately with $M_f$. We conclude that if central black holes are created in type-II and type-Ib/c supernovae after core-collapse, then any clumps formed by fragmentation are preferably small ($M_f \lesssim 1 M_\odot$). Moreover, if the torii are created around black holes, they are either non-fragmented or rather thin, for the disk model considered in Ref. [101].

For the Long-Lasting Bar Mode model, the parameter space is larger than for the Torus Fragmentation Instability model. Three models have non-zero $P_{\text{excl}}$ values, lb4, lb5, and lb6. All three models have large values of $M(L^2 - 3R^2) = 3300 M_\odot$km$^2$, which corresponds either to $R \leq 10$ km proto-neutron stars with large asymmetries ($L/2R > 2.5$) or large proto-neutron stars ($R \approx 20$km) with moderate asymmetries ($L/2R \approx 1.5 - 3.5$). If bars are created generically in type-II and type-Ib/c supernovae, the deformations are preferably small. The largest $P_{\text{excl}}$ among these models is obtained for lb5. This waveform lasts 1 s, while lb4 and lb6 are 100 ms and 25 ms respectively. It seems that, for a proto-neutron star with $R \leq 10$ km, if bars with strong deviations from axisymmetry are created ($L/2R > 3$) in CCSNe, then they are rather short lived. Larger proto-neutron stars ($R \approx 20$km) could still have large deformations and be unobservable.

The constraint for lb5 limits the possible maximum deformations in type-II and type-Ib/c supernovae. If bars are created they are probably small. In case deformations are large the proto-neutron star is either very compact ($R \approx 5$km) or the bar is short lived (< 1000 ms). These results are consistent with the current theoretical understanding of bar-mode instabilities, which are expected to appear early after bounce when the proto-neutron star mass is relatively low ($M < 1 M_\odot$) and its radius large ($R \geq 20$ km). The amplitude and duration are also expected to be severely limited by the presence of strong magnetic fields, magneto-rotational turbulence, and shear instabilities.

### VI. SUMMARY AND DISCUSSION

We present the results of a search for GWs from CCSNe with the Advanced LIGO and Advanced Virgo de-
TABLE IX. Model Exclusion Probabilities ($P_{\text{excl}}$) for extreme emission models with a standard candle approach (see Sec. V C for details of the method). We infer that if bars are created generically in type-II and type-Ib/c supernovae, then the deformations are preferably small. If central black holes are created in CCSN, then the accretion tori around them are either non-fragmented or rather thin.

| Supernova | piro1 | piro2 | piro3 | piro4 | lb1 | lb2 | lb3 | lb4 | lb5 | lb6 |

Variables during the first and second observing runs (2015-2017). Five CCSNe within 20 Mpc are used for the astrophysical statements: SN 2015as, SN 2016B, SN 2016X, SN 2017eaw, and SN 2017gax. We have not found any significant GW candidate. All the loudest events are consistent with background events.

We provide the distance reaches at 50% detection efficiencies for both realistic and extreme GW emission models. For the neutrino driven explosions the distances do not exceed 5 kpc, while the distance ranges for the magnetorotationally driven explosions reach 54 kpc. The distance reaches for extreme emission models can be as large as 28 Mpc, which exceed the distances of CCSNe analyzed in this search. Given no GW detection, this gives us an opportunity to estimate the exclusion probabilities for the most extreme models.

We derive GW energy constraints for generic low and high frequency GW emissions at 235 Hz and 1304 Hz respectively using linearly and elliptically polarized ad-hoc sine-Gaussian waveforms. The constraints are around $10^{-3} M_{\odot} c^2$ and $10^{-4} M_{\odot} c^2$ for low and high frequency GW emission, respectively. The best GW emission constraints we obtained are for SN 2017eaw of $4.27 \times 10^{-4} M_{\odot} c^2$ (7.63 $\times 10^{50}$ erg) for low frequency emission and $1.28 \times 10^{-1} M_{\odot} c^2$ (2.30 $\times 10^{50}$ erg) for high frequency emission. These are two orders of magnitude more stringent than in [35], but still a few orders of magnitude larger than predicted from multidimensional simulations. The low frequency emission constraints are comparable to the typical kinetic energy of CCSN ejecta.

We provide the first supernova model constraints based on O1 and O2 data with a standard candle approach. The most extreme emission models, piro4 and lb5, are constrained at the level of 83.2% and 63.8% respectively. Out of ten waveforms, we place limits on six of them with 5% to 83% exclusion probabilities. Based on our results, we conclude that if central black holes are created in type-II and type-Ib/c supernovae, the sizes of the fragments are preferably small. Moreover, if disks around central black holes are created, they are either non-fragmented or rather thin. If bars are created, they are probably small. In cases where deformations of the proto-neutron star are large, they are either very compact ($R \sim 5$ km) or they shortly lived ($< 1000$ ms).

These model exclusion statements are the first constraints on CCSN engines based on GW data. In the future, with targeted searches and upgraded detectors (third observing run and beyond) it will be possible to further exclude the extreme emission models and better constrain the GW energy emitted by CCSN engines, making both more astrophysically meaningful.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the support of the United States National Science Foundation (NSF) for the construction and operation of the LIGO Laboratory and Advanced LIGO as well as the Science and Technology Facilities Council (STFC) of the United Kingdom, the Max-Planck-Society (MPS), and the State of Niedersachsen/Germany for support of the construction of Advanced LIGO and construction and operation of the GEO600 detector. Additional support for Advanced LIGO was provided by the Australian Research Council. The authors gratefully acknowledge the Italian Istituto Nazionale di Fisica Nucleare (INFN), the French Centre National de la Recherche Scientifique (CNRS) and the Foundation for Fundamental Research on Matter and the Foundation for Fundamental Research on Matter supported by the Netherlands Organisation for Scientific Research, for the construction and operation of the Virgo detector and the creation and support of the EGO consortium.
