ABSTRACT Multi-channel structured light with orbital angular momentum (OAM) can be applied in different applications. For example, OAM modulation and OAM multiplexing in fiber optics communications, high-dimensional quantum cryptography-based OAM states for transmitting secure information across free-space, and independent data streams through OAM beams multiplexed free-space optics links. Using a simple and efficient system consisting of a spiral phase element (SPE) and a multi-channel vortex filter (MVF), we have converted input Gaussian beams into multi-channel OAM-based vortex beams for infrared wavelengths. An SPE has been designed, which generates optical vortices with wavelength-dependent topological charge (including fractional values). The resulting complex fields are optically relayed on a binary MVF designed by modulo-2π phase addition of multiple fork gratings with topological charges 1, 2, and 3 and azimuthal orientations. In this way, the MVF generates beams with different OAM states for different carrier waves with different angles and maps them at desired locations in the detector plane. In this study, both 3×3, as well as a hexagonal configuration, were used. The presented approach opens a new pathway for developing an efficient multi-channel OAM beams generator designed for a specific wavelength and illuminated by an input beam of different wavelengths over a broad spectral range. Furthermore, the experimentally obtained OAM spectrum qualitatively agrees with the results of numerical simulations, thus verifying our approach.

INDEX TERMS Laser tuning, Optics, Optical vortices, Optical filters

I. INTRODUCTION

Vortex beams have numerous applications and have been widely reviewed [1]. Such beams with orbital angular momentum (OAM) have potential in increasing communications capacity [2-5] and revolutionize the field of free-space optical communication. However, many vortex beam generators experience limitations, such as low efficiency, complex configurations, and narrow bandwidths, particularly for transmission systems. The problems and substantial results connected to OAM beams and their concrete applications are reviewed and reported [6-9]. Specifically, vortex beams with infinite topological charge gain a new accuracy for multiplexing to enhance data capacity [2-4], and such beams induce a force for particle trapping [10]. However, single-channel vortex beams from conventional devices such as Q-plates, phase plates, and mode converters cannot overcome constraints in increasing data storage capacity and competency of optical trapping.
In such situations, multi-channel vortex beams are more desirable to achieve atomic physics, communications, and information technology requirements. The OAM optical vortex beams have unique spatial distribution, and their wavefront spirals around the optical axis during propagation. The independent structured beams with different OAM modes can be multiplexed, spatially propagated, and demultiplexed [15-17]. Usually, multi-channel OAM beams individually generated and coaxially multiplexed with multiple beam combiners lead to additional losses. A large number of optical elements, accurate alignment conditions, and intricate fabrication of optical elements together make optical schemes more complex and unsuitable for implementation in numerous applications. Therefore, we exclusively concentrated on a cost-effective optical method for easy generation and multiplexing OAM beams with minimal inherent losses. Note that in the present work, the conversion of OAM beams based on spiral phase plates strongly depends on the wavelength of an input beam, whose OAM value changes with the wavelength. The commercial and dynamic tools were discussed for OAM mode formation and detection. All those studies were based on active devices such as spatial light modulators, liquid crystals, and digital mirror devices sensitive to laser threshold damage and not suitable for high power applications. These devices are relatively expensive and responding to specific polarization states because their dimensions and combinations can control the OAM beams into different configurations and dimensions, making the approach more expensive [18-20].

In this work, we presented a robust and flexible approach for OAM mode generation, detection, and multiplexing with the combination of elements SPE and MVF are fabricated using well-established manufacturing technologies. Without using a spatial light modulator (SLM) [20] and any other digital devices, optical vortex beams of different wavelengths (visible and infra-red range) are generated with the spiral phase element printed into the fused silica substrate using a lithography process. Further, the second element, MVF of two configurations, consist of OAM generators associated with unique linear phases, which map different OAM states to different transverse locations in the sensor plane in hexagonal and 3x3 square array configurations. The MVFs are synthesized with the superposition of several rotated fork-shaped gratings. The roles of these two structures (MVF) are exciting and vital in OAM mode mapping or multiplexing in different spatial geometries. MVFs are fabricated using a well-controlled and straightforward laser writing technique.

II. THEORETICAL ANALYSIS AND NUMERICAL MODELLING

The action of SPE substantially depends on the wavelength of laser radiation \( \lambda \) and is described by the function:

\[
\hat{h}_{SPE}(\varphi, \lambda) = \frac{\varphi \lambda}{2\pi \sin(\lambda - 1)}, \quad (1)
\]

where \( \varphi \) is the azimuth angle, \( n(\lambda) \) is the refractive index of the material in which the optical element is manufactured (for radiation with the wavelength \( \lambda \)). The relief height of a SPE made for laser radiation with the wavelength \( \lambda_0 \) is described by the following formula:

\[
h_{\text{max}}(\lambda_0) = \frac{\lambda_0}{n(\lambda_0) - 1}, \quad (2)
\]

when the optical element (2) is illuminated with laser radiation with an arbitrary wavelength \( \lambda \), the field of the following type is formed [21]:

\[
\tau_{SPE}(\varphi) \propto \exp \left( i \frac{\lambda_0}{\lambda} \varphi \right) = \exp (i \mu \varphi), \quad (3)
\]

where \( \mu = \lambda_0/\lambda \) corresponds to the generated vortex beam order, which can have fractional values [22, 23]. Recently, such beams have attracted the attention of researchers in connection with their promising use in multiplexed transmission of information [5, 24-26]. The value of \( \mu \) can be measured using a multi-channel filter [27, 28] based on the correlation method [29]. We use in this work the multi-channel diffraction filter formed by a superposition of spiral phases with different topological charges and unique linear phases:

\[
\tau_F(x, y) = \sum_{p=1}^P \exp \left( -i m_y \varphi \right) \exp \left[ i(\alpha_p x + \beta_p y) \right], \quad (4)
\]

where \( P \) is the number of MVF channels (or diffractive orders) matched with angular harmonics of various orders \( m_y \) and \((\alpha_p, \beta_p)\) are the corresponding spatial carrier frequencies. Figure 1 and 2 shows the synthesis of the phase of MVF matched with optical vortices of orders \( m_y = [-3, -2, -1, 1, 2, 3] \) (hexagonal configuration) and \( m_y = [-3, -2, -1, 0, 1, 2, 3] \) (3x3 square configurations), respectively.

Let us consider a beam with a wavelength \( \lambda \) incident on the SPE designed for a topological charge \( m = 1 \) for a wavelength \( \lambda_0 \), and the phase of SPE is given as \( \Phi_{SPE} = m \varphi \). The ratio between the design wavelength and incident wavelength is given as \( \mu = \lambda_0/\lambda \). The second element, MVF, consists of OAM generators associated with unique linear phases, which map different OAM states to different transverse locations in the sensor plane.

The design wavelength is \( \lambda_0 = 1.5 \mu m \) and the optical configuration is simulated for \( \lambda = 0.5 \mu m, 0.6 \mu m, 0.75 \mu m, 1 \mu m, 1.5 \mu m, 2 \mu m \) and \( 3 \mu m \). In accordance with Equation (3), it corresponds to the generation of vortex beams with topological charges \( \mu = 3, 2.5, 2, 1.5, 1, 0.75 \) and 0.5. So, the parameter \( \mu \) need not be an integer but also fractional. It must be noted that such fractional charges have been investigated earlier, but the wavelength was constant, and the SPE phase was varied less than or greater than \( 2\pi \) [30, 31]. In this case, the wavelength is changed when the phase of SPE is maintained constant (0-2\( \pi \)) for a particular wavelength.
The resultant vortex beam with the topological charge $\mu$ incidents on the MVF. The simulation results for the MVF of the 3x3 configuration (Figure 2) are shown in Figure 3. This MVF is matched with vortices $m_p = -3, -2, -1, 0, 1, 2, 3$. Two diffraction orders have zero vortices to simplify the detection of fractional orders in the range (-1,1). The presence of correlation peaks simultaneously in two diffraction orders corresponds to the detection of an input vortex beam with a fractional topological charge [21, 26]. When a vortex beam is generated by the SPE coupled with vortices encoded in the MVF, we get a set off-axis vortex beams with the topological charges $\mu_p = \mu + m_p$. Thus, vortex beams with $\mu_p$ orders are generated simultaneously at different diffractive orders $p$ (Figure 3). A situation when $\mu_p=0$ corresponds to the generation of a non-vortex beam and a correlation peak is appeared in the focal plane, so the OAM state of the input beam can be detected. The MVF with hexagonal configuration will act analogously.

FIGURE 4. Composition of MVF with fork-gratings of different phases, and a photograph of fabricated MVF shown as a circle inset (top). Experimental arrangement for generating multi-channel vortex laser beams of different OAM orders (middle). The 2D intensity distributions generated by MVF for different wavelengths are shown in insets (bottom). The values of \( \mu \) are calculated, and the integer value of OAM spectrum for wavelengths close to multiples of the base wavelength. The correlation peaks are observed in diffraction orders for specific wavelengths, not in diffraction orders for other wavelengths. For particular wavelengths, the correlation peaks are shifted from diffraction orders corresponds to fractional OAM values.

FIGURE 6. Multiplexing OAM beams in hexagonal arrays: experimental intensity distributions of multi-channel vortex beams with different OAM states formed by the MVF over a broad spectral range.

III. EXPERIMENTAL OBSERVATIONS
An experimental arrangement for measuring the values of the orbital angular momentum at different wavelengths by spatial filtering is shown in Figure 4. The wavelength is adjusted by tuning the NT-242 laser source to the appropriate wavelength. The elliptical light beam from the NT-242 laser source was expanded by the beam expander setup. The resulting beam is limited to a converging circular beam with an initial diameter of 8 mm relayed and guided through a 4f telescope configuration. Therefore, for recording high-quality images of the emerging orders, a sufficiently large distance is necessary to focus the entire field distribution on the camera sensor. As a result, long optical track length forms large focal spots in the camera plane. Note that we employed a camera sensor (InGaAs KB-Vita-Vs-320) that is sensitive for the wavelength range of 900-1700 nm, and the selected sensor has a pixel size of 30 µm. To record the images of intensity distributions for the wavelength range of 400-1000 nm, we used a CMOS sensor (CMOSIS-CMV4000), and it has large screen dimensions with a large screen of 11.3 mm x 11.3 mm with a pixel size of 5.5 µm. The sensor matrix records the image of the focal spots and their spatial decomposition at the focal distance.

We found that while changing the wavelength, the divergence of the laser beam changes due to the dispersion of the refractive index of quartz material in lenses used in the experimental arrangement. Therefore, this effect purely depends on the incident wavelength. Consequently, it is essential to control the beam size at the outlet of the beam expander, and it is achieved by inserting the spatial filter unit before the SPE. The SPE was formed in a Fused Silica...
Substrate in a Single-stage etching process using the grey-scale mask. Grey-scale lithography enables the fabrication of the phase plate (staircases etched around 360° turn of the diffractive surface) using a single photolithography step followed by reactive ion etching (RIE). 5-micron thick positive AZ4533Photosensitive has been used. The height of the phase jump on the microrelief profile was 2200 nm. Here, both the SPE and the specially designed and manufactured multi-channel vortex filter (MVF), including the zero-order, are installed in the converging beam. The distance between the beam expander and the SPE is about 10 mm, and the light energy from the SPE is directed through a telescope and further incident on the MVF. A multi-channel vortex filter (MVF) has the same optical properties for a wide range of wavelengths. The circular laser recording method was chosen to produce the MVF pattern on the surface of 80 nm thick cerium coated quartz substrate is pre-applied by the RF-magnetron sputtering process. Subsequently, the chromium film was accurately exposed with a sharply focused laser beam in accordance with a given design topology. Under the action of high-intensity laser heating, the film was oxidized. Next, it was developed using a chemical developer based on a cerium sulfuric acid solution. The sensor array placed in the focal plane allows recording images of correlation maxima at different values of the orbital angular momentum in the corresponding diffraction orders. The intensity distributions obtained in the plane of the camera setup for different wavelengths are shown in Figure 5, 3x3 configuration. Figure 6 illustrates intensity distributions of fractional vortex laser beams over a broad wavelength range. An analyzer (MVF) was used to determine the order, and a correlation peak indicates an initial beam with an order number corresponding to a given correlation peak. As seen in experimental results, the spiral phase plate in the wavelength range 0.5µm-1.55µm forms a first-order vortex laser beam. In the wavelength range of 0.4µm-0.5µm, the vortex laser beam has two orders of magnitude. At a wavelength (λ) above 1.55µm, the vortex laser beam has a fractional orbital angular momentum.

IV CONCLUDING REMARKS

We have demonstrated robust multiplexing of OAM beams of different values into different geometrical configurations over a broad wavelength range. These results can lead to useful applications such as optical manipulation, optical tweezers, higher-order quantum entanglement, nonlinear optics, transmitting information in free-space optical communications, telecommunications, and fiber optics communications. We have experimentally demonstrated that this approach offers cost-effective OAM modes generation and multiplexing achieved with the combination of simple and effective optical elements (SPE, MVFs) that can generate efficient outputs for input laser beams over a broad wavelength range. We consider that our approach is simple and easy to handle relatively in comparison to existing techniques. The OAM multiplexing demonstrated in the present work is similar to current practices like wavelength-division multiplexing. Furthermore, adaptive optics can be used to correct wavefront distortions and scattering losses caused by atmospheric turbulence. However, optical vortex beams with OAM are resilient to atmospheric turbulence effects, and the selected infrared wavelengths match the transmission window of space. Our approach paves a way to reduce the cost of the commercial OAM modes-based communication systems and projected a simple method for increasing the number of channels in the communication system over free-space or fiber link with minimal intermodal crosstalk. With the latest advancements in fabrication technologies, we believe that high-performance diffractive elements are possible [32].

ANDRA NAresh KUMAR REDDY completed his Ph.D. at the Osmania University, Hyderabad, India in 2014. Prior to this, he obtained an M.Phil. in Optics and Thin-film Technology from the Bharathidasan University, India. He obtained M.Sc. and B.Sc. in Physics from the Department of Physics, University College of Science, Hyderabad, Osmania University. He is currently working as a postdoctoral fellow under SEDA postdoc research-aid programme, Latvia. He held a postdoctoral position at Weizmann Institute of Science, Israel between 2018-2021. He held senior scientist position at Samara National Research University, Russian Federation between 2016-2018. His current research interests include diffractive optics, coupled lasers, structured lights, laser beam shaping, free-space optics, metalenses and nanofabrication.

VIJAYAKUMAR ANAND completed his Ph.D. at the Indian Institute of Technology Madras, India in 2015. Prior to this, he obtained an M.Tech. in Laser Technology from the College of Engineering, Anna University, India. He obtained M.Sc. and B.Sc. in Physics from the American College, Madurai. He is currently a research fellow at the Center for Microphotonics at Swinburne University. He held a postdoctoral position at Ben Gurion University, Israel between 2015-2018 as a recipient of the Planning and Budgeting Committee outstanding postdoctoral fellowship of the Israel government (2015). He is a recipient of several academic prizes, namely, the Einstein prize (2004), the Manual Thanguraj prize (2004), and the Richard Riez prize (2007) for proficiency in Physics from The American College, Madurai, India. In addition, he was awarded the Monbukagakusho fellowship by the Japanese government (2010), to visit Osaka University, Japan for a duration of 18 months. He is a member of the Optical Society of America. He has more than 80 peer-reviewed international journals, book chapters, and conference proceedings. He has published a tutorial textbook on ‘Design and fabrication of diffractive optical elements with MATLAB’ which was one of the best sellers of the year 2017 in Society of Photo-Optical Instrumentation Engineers (SPIE) press. He is currently serving as a co-guest editor of the special issue on holography for the Applied Sciences Journal. He received the OSA outstanding reviewer award in 2019 and the Reviewer Lapel pin in 2018 both from the Optical Society of America. His current research interests include computational optics, imaging, digital holography, diffractive optics and microfabrication.

SVETLANA NIKOLAevaKHONINA received the Ph.D. degree in physical and mathematical sciences. She is currently a Professor with Samara National Research University. She is also a main researcher of the Federal Scientific Research Centre (FSRRC) Crystallography and Photonics, Image Processing Systems Institute (IPSI), Russian Academy of Sciences (RAS). Her research interests include diffractive optics, singular optics, mode and polarization transformations, optical manipulating, and optical and digital image processing.

VLADIMIR V. PODLIPNOV received the Ph.D. degree in physical and mathematical sciences. He is currently a Senior lecturer with Samara National Research University. He is also a researcher of the Federal Scientific Research Centre (FSRRC) Crystallography and Photonics, Image Processing Systems Institute (IPSI), Russian Academy of Sciences (RAS). His research interests include Diffractive optics, laser technology, vacuum technology.
