(Dated: November 11, 2015)

We investigate Yang-Lee zeros of grand partition functions as truncated fugacity polynomials of which coefficients are given by the canonical partition functions $Z(T, V, N)$ up to $N \leq N_{\text{max}}$. Such a partition function can be inevitably obtained from the net-baryon number multiplicity distribution in relativistic heavy ion collisions, where the number of the event beyond $N_{\text{max}}$ has insufficient statistics, as well as canonical approaches in lattice QCD. We use a chiral random matrix model as a solvable model for chiral phase transition in QCD and show that the closest edge of the distribution to real chemical potential axis is stable against cutting the tail of the multiplicity distribution. The similar behavior is also found in lattice QCD at finite temperature for Roberge-Weiss transition. In contrast, such a stability is found to be absent in the Skellam distribution which does not have phase transition. We compare the number of $N_{\text{max}}$ to obtain the stable Yang-Lee zeros with those of critical higher order cumulants.

I. INTRODUCTION

Phase transition in quantum chromodynamics (QCD) is one of the central subjects in high energy nuclear physics both theoretically and experimentally. First principle lattice QCD (LQCD) calculations have shown that the transition from quark-gluon plasma (QGP) to hadronic matter is of crossover type at physical quark masses, in which order parameters and thermodynamic quantities change smoothly as functions of temperature. At finite baryon density, one expects that the nature of the transition can change. Unfortunately, little is known about the state of matter at high baryon density from LQCD calculations because of the difficult in numerical simulation at finite baryon chemical potential. Various approximation methods applied so far seem to work only $\mu < T$ or a small volume or heavy quark mass region. Nevertheless, effective models which implement relevant symmetries in QCD and large $N_c$ studies have shown that rich phase structure exists in high density. In particular, if there is a first order phase transition at $T = 0$ and large $\mu$, there must be a critical point (CP) at which the first order phase transition line terminates and the transition becomes second order. Existence of CP is supported by many chiral effective models, but its location depends on the detail of the models.

Stimulated by these theoretical results, the first beam energy scan program at Relativistic Heavy Ion Collider (RHIC) has been carried out in search for the CP. Since lower colliding energies leaves the incident nucleons in the central region, one expects to explore higher baryon density region at lower energies. There are a number of observables which might have potential to indicate the transition from QGP to hadronic matter. Among them, event-by-event fluctuations of conserved charges are intimately connected to critical behavior associated with the phase transition. Measurements of the net-proton number fluctuations as a proxy of the net-baryon one and net electric charges have been presented for Au+Au collisions at various energies from $\sqrt{s_{NN}} = 7.7$ GeV to 200 GeV. Given the fact that multiplicity of different particle species are well described by statistical models, one may regard event-by-event fluctuations of conserved charges as those of the grand canonical ensembles at chemical freeze-out temperature $T$ and baryonic chemical potential $\mu$. Through systematic analyses of the location of $(T, \mu)$ corresponding to each colliding systems, one can map experimental measurements for property of the matter on $T - \mu$ plane. Furthermore, recent LQCD results at physical quark masses indicate that the crossover region coincides with the chemical freeze-out at least for $\mu < T$. One may look for remnant of the chiral criticality in the crossover region, originating from second order phase transition in the vanishing quark mass.

Property of the transition can be characterized by behavior of fluctuations of conserved charges as well as an order parameter and its fluctuations. In the case of the chiral phase transition in QCD, the chiral order parameter or quark-antiquark condensate $\langle \bar{q}q \rangle$ couples to quarks carrying the baryon number and the electric charge. Thus, the second order chiral phase transition in the chiral limit at finite temperature is characterized...
by not only divergent fluctuation of the order parameter but also higher order cumulants of the net baryon number and the net electric charge. The divergence of the conserved charge fluctuations is governed by the critical exponent of the specific heat $\alpha$ which depends on the universality class QCD belongs to. Although it is not completely determined yet, recent simulations indicate $O(4)$ in the three dimensions, as conjectured by Pisarski and Wilczek. In this case, the first divergent cumulant appears at the sixth order. At finite but small quark masses, the divergence is replaced by sign change, owing to the property of the universal $O(4)$ scaling function. At nonzero net baryon number density, the divergence at $2n$-th order cumulants in the chiral limit appears at $n$-th order one. The tricritical point in the chiral limit becomes the CP, where the second order cumulants diverge. The chemical freeze-out line may locate at lower temperature than the chiral phase boundary such that measured fluctuations might not reflect those at the phase transition. Nevertheless, the existence of the CP is accompanied by anomalous behavior of the cumulants such as negative third and fourth order cumulants around the CP and may lead to non-monotonic behavior of the higher order cumulants as functions of $\sqrt{s_{NN}}$. Indeed, the measured net-proton number cumulants in seem to follow this expectation, although still inconclusive due to uncertainty.

The measurement of the cumulants is based on event-by-event multiplicity distribution. Once the fluctuations are regarded as those of the grand canonical ensemble, the multiplicity distribution can be identified with unnormalized probability distribution.

While the cumulants are expressed by central moments of the probability distribution, it is convenient for theoretical studies to compute them by differentiating the thermodynamic pressure with respect to chemical potentials. Recently, one of the authors (K.M.) investigated the probability distribution of the net baryon number in models with phase transitions. It turns out that sufficient information on the tail in the probability distribution is responsible for the critical behavior of the higher order cumulants and that the remnant of the $O(4)$ criticality can be characterized by narrower tail than the corresponding reference distribution. In the probability distribution, such information on the phase transition is encoded in the $N$ dependence of the canonical partition function $Z(T, V, N)$.

Since the grand partition function is more straightforward in relativistic quantum field theories where the number of particles are not definite, computations of the canonical partition function are not generally easy. In Ref. Hasenfratz and Toussaint proposed that the canonical partition function, $Z(T, V, N)$, is calculated through the Fourier transformation of the grand canonical partition function, $Z(T, V, \mu)$, evaluated at pure imaginary $\mu$. The difficulty associated with the complex fermion determinant is replaced by the highly oscillating integral which requires extraordinary numerical precision.

Nevertheless, the probability distribution gives further insights into property of the system including phase transitions.

In Ref. one of the authors (A.N.) pointed out that one can extract the fugacity parameter $\lambda = e^{\mu/T}$ at the chemical freeze-out and construct $Z(T, V, N)$ for the net baryon number without any assumption on the property of equilibrium $P(N)$. Furthermore, once $Z(T, V, N)$ is known, one can obtain the grand partition function $Z(T, V, \mu)$ as a series of fugacity. This enables us to apply Yang-Lee theory for the phase transition. For recent reviews, see, e.g.,, , in which zeros of the partition function give information on the thermodynamic property of the system. The zeros of the partition function are distributed on a line in the complex plane of an external parameter and its density grows up with the system volume, then finally coalesce into the line in the thermodynamic limit. This property leads us, in principle, to obtain the location and order of the phase transition from the distribution of the zeros. Even in the absence of the phase transition, the zeros accumulated on the edge of the distribution exhibit singular behavior. This singularity, known as Yang-Lee edge singularity, can be regarded as a CP in the complex plane and gives influence on the thermodynamics on the real axis.

In both experiments and the canonical approach in LQCD, $Z(T, V, N)$ at large $N$ requires such high statistics that obtained information is limited to some finite $N$, thus one has to truncate the fugacity polynomial there in reconstructing the grand partition function. The purpose of this paper is to clarify this point. We employ a solvable model for the chiral phase transition in QCD. We present the Yang-Lee zeros in a chiral random matrix model, both for the exact grand partition function and for the reconstructed one as a truncated function. We discuss effects of the truncation on the distribution of the Yang-Lee zeros and compare it with the spurious zeros of the Skellam partition function, originated from the truncation.

In the next section, we briefly summarize the general relation among the probability distribution, partition functions, and Yang-Lee zeros. A chiral random matrix model and its Yang-Lee zeros are presented in Sec. We demonstrate differences of the truncation effects on the Yang-Lee zeros between the models with and without phase transition in Sec. Implications for heavy ion experiments are discussed in Sec. Section is devoted to concluding remarks. Detailed expressions for partition functions in the chiral random matrix model are given in the Appendix.
II. GENERAL FRAMEWORK

We start from experimentally measured data of net-baryon number multiplicity distribution \( \mathcal{P}(N) \), where \( N \) is the net-baryon number. In real experiments one measures the net-proton number \( \Delta N_{p} = N_{p} - N_{\bar{p}} \). In principle one can reconstruct \( \mathcal{P}(N) \) from \( \mathcal{P}(\Delta N_{p}) \), \( \mathcal{P}(N_{p}) \) and \( \mathcal{P}(N_{\bar{p}}) \) \cite{54}. In this study we entirely assume the isospin invariance and regard \( \mathcal{P}(\Delta N_{p}) \) as a proxy of \( \mathcal{P}(N) \). The shape of the distribution depends on the colliding energies, centrality etc. The net-baryon number can take any value as long as it can be packed within the system volume. Owing to limited statistics, however, we do not observe such states that have too large \( N \) far from its mean value \( \bar{M} \). Thus, we define the possible minimum and maximum of \( N_{\min} \) and \( N_{\max} \) as

\[
\mathcal{P}(N < N_{\min}) = 0, \\
\mathcal{P}(N > N_{\max}) = 0.
\]

In thermal equilibrium, probability distribution of the net-baryon number in the grand canonical ensemble reads, for the fugacity factor \( \lambda = e^{\mu/T} \),

\[
P(T, V, N, \mu) = \frac{Z(T, V, N)\lambda^{N}}{Z(T, V, \mu)},
\]

where \( Z(T, V, \mu) \) is the grand partition function

\[
Z(T, V, \mu) = \text{Tr}[e^{-(\hat{H} - \mu \hat{N})/T}]
\]

and \( Z(T, V, N) \) is the canonical partition function

\[
Z(T, V, N) = \text{Tr}[e^{-\hat{H}/T} \delta_{\hat{N}, N}].
\]

Assuming the measured multiplicity distribution is the equilibrium one, one finds \( N \) dependence of \( \mathcal{P}(N) \) comes from \( Z(T, V, N)\lambda^{N} \). Using the charge-conjugate symmetry \( Z(T, V, -N) = Z(T, V, N) \), one can determine \( \lambda \) from \( \mathcal{P}(N) \) and obtain the canonical partition function

\[
Z(T, V, N) = \mathcal{P}(N)\lambda^{-N}.
\]

Because of limited range of \( N \) \cite{1}, the canonical partition function \( \mathcal{P}(N) \) can be obtained for \( N \in [\text{max}(0, N_{\min}), N_{\max}] \). For the energy scan range in RHIC experiments, \( N_{\min} < 0 \), i.e., there are a few events in which more anti-protons are observed than protons, except for \( \sqrt{s_{NN}} = 7.7 \text{ GeV} \) where \( N_{\min} = 1 \) \cite{14}. Note that we need only \( N \geq 0 \) thanks to the charge conjugate symmetry. Thus, in most cases, one can extract the canonical partition function for \( -N_{\max} \leq N \leq N_{\max} \).

This limitation in \( N \) also applies to theoretical approaches such as model studies \cite{22, 41, 42} and lattice simulations \cite{54, 55}. In the former, the canonical partition functions have been calculated using a projection formula

\[
Z(T, V, N) = \frac{1}{2\pi i} \int d\lambda \frac{Z(T, V, \lambda)}{\lambda^{N+1}},
\]

where integration contour \( C \) in complex \( \lambda \) plane can be arbitrary, but it is convenient to take the unit circle \( \lambda = e^{i\theta} \). Then the formula becomes

\[
Z(T, V, N) = \frac{1}{2\pi} \int_{-\pi}^{\pi} d\theta \cos(N\theta)Z(T, V, \theta)
\]

where \( \theta \) is related to an imaginary chemical potential \( -i\mu/T \). In Refs. \cite{22, 41, 42}, thermodynamic potential \( \Omega = -pV \) in Landau theory \cite{41} and in chiral quark-meson model \cite{22, 42} was used through \( Z(T, V, \theta) = e^{-\Omega(T, \theta)/T} \). Owing to the rapid oscillation in large \( N \), it turned out that the numerical integration in double precision works up to \( \mathcal{P}(N) \approx 10^{-12} \).

In lattice QCD simulations, two approaches can provide the canonical partition functions, i.e., (i) the fugacity expansion of the fermion determinant \cite{54} and (ii) Hasenfratz and Toussaint method \cite{43}. In the fugacity expansion, we must diagonalize a matrix whose rank is proportional to the lattice spacial volume. This requires large computational resource and currently one cannot go to simulations on large lattices. In the method (ii), as \( N \) increases, more accuracy is needed, and consequently \( N \) cannot go to very large.

Once the canonical partition function \( Z(T, V, N) \) is obtained, one can also construct a truncated grand canonical partition function as a series in \( \lambda \)

\[
Z^{\text{tr}}(T, V, \lambda; N_{\max}) = \sum_{N=-N_{\max}}^{N_{\max}} Z(T, V, N)\lambda^{N}.
\]

Owing to the truncation of the series at \( N = -N_{\max} \) and \( N_{\max} \), this partition function is an approximation of the exact partition function which could be obtained if one can take \( N_{\max} = N^{*} \) with \( N^{*} \) being the number of net-baryons fulfilling the system volume \cite{17}. For lattice QCD at finite temperature with \( N_{c}^{3} \times N_{t} \) lattice, \( N^{*} \approx 2N_{c}^{3} \) \cite{57}. Thus, one needs to establish relations of physical quantities obtained from the truncated partition function \cite{58} with those from the exact partition function. As seen in the summation running from \(-N_{\max}\), relativistic partition functions contain negative powers of \( \lambda \). The suppression of high \( N \) contribution to \( Z \) cannot be realized by small \( \lambda \). One needs to know large \( N \) behavior in \( Z(T, V, N) \).

Similar studies on higher order cumulants of the net-baryon number have been carried out in Ref. \cite{42}, in which sufficiently large \( N_{\max} \) depending on the order of the cumulants is shown to be necessary to obtain a correct value of the cumulants. In this paper, we focus on Yang-Lee zeros for the baryon chemical potential.

The zeros of the partition function in complex chemical potential plane can be obtained by solving an equation

\[
Z(T, V, \mu) = 0,
\]

1 In Ref. \cite{55}, \( N^{*} \) was derived for the quark fugacity series as \( N_{q} = 2N_{c}N_{s}^{3} \)
for complex \( \mu \). Owing to the negative powers of the fugacity, the equation is a polynomial one in \( \lambda \) with order \( 2N^* \). For the truncated partition function \( Z^{tr} \), one needs to solve

\[
Z^{tr}(T, V, \mu; N_{\text{max}}) = 0
\]

of which the order of the polynomial is \( 2N_{\text{max}} \).

In the exact case, the roots have both real and imaginary part and its distribution in the complex chemical potential plane is expected to form a line, which crosses the real axis at the transition point in the thermodynamic limit. The behavior of the distribution depends on the nature of the phase transition. In Ref. \[58\], the behavior of the Yang-Lee zeros around the CP was studied by using a chiral random matrix model. The singularity associated with the CP appears as a branch point in complex \( \mu \) plane and its property is shown to be connected with the universality. In lattice QCD, the phase transition between different \( Z(N_c) \) sector in the deconfined phase, Roberge-Weiss phase transition, has been recently analyzed from a view point of Yang-Lee zeros \[55\]. In this work, we use a chiral random matrix model similar to used in Ref. \[58\] but with an extension to periodic property in imaginary chemical potential as it is necessary to have integer net baryon number.

The partition function is written as a polynomial in \( \lambda = e^{\mu/T} \). Since a complex root \( \lambda_1 \) is accompanied with its conjugate \( \lambda_1^* \) and the charge conjugate symmetry implies \( 1/\lambda_1 \) and \( 1/\lambda_1^* \) are also roots, only the roots located in the first quadrant of the complex \( \mu \) plane are independent. In practice, it is convenient to use Joukowski transformation \( \omega = \lambda + 1/\lambda = 2 \cosh(\beta \mu) \) and reorganize the series in terms of \( \omega \) to reduce the number of roots to search for. Using a property of Chebychev polynomial \( T_n(\cosh x) = \cosh(nx) \), one finds

\[
\lambda^N + \frac{1}{\lambda^N} = 2 \cosh(\beta \mu N) = 2T_N(\cosh(\beta \mu)) = 2T_N(\omega/2).
\]

Then Eq. (8) reduces to a series expression containing only positive powers. After expanding the Chebychev polynomial by Eq. (A7), one finds,

\[
Z^{tr}(T, V, \omega; N_{\text{max}}) = Z(T, V, N = 0) + \sum_{n=1}^{N_{\text{max}}} nZ(T, V, n) + \sum_{k=0}^{[n/2]} (-1)^k \frac{(n-k-1)!}{k!(n-2k)!} \omega^{-2k}.\]

This formula could be also useful to compare a relativistic system with nonrelativistic ones. The roots of \( \omega \) space is easily converted into those in \( \lambda \) and \( \mu \) plane as

\[
\frac{\mu}{T} = \pm \cosh^{-1} \frac{\omega}{2}
\]

Taking both signs, one can finds all the roots in the complex \( \mu \) and \( \lambda \) plane.

### III. CHIRAL RANDOM MATRIX MODEL

In this section, we introduce a chiral random matrix model which is an effective model for the spontaneous chiral symmetry breaking in QCD. Since this model is analytically solvable in the chiral and thermodynamic limit \[59\] and analytic expression for the partition function in finite volume is known \[59\], we find this model as the most suitable one for the present purpose. An apparent shortcoming of the model for applying to the net baryon number probability distribution is lack of periodicity in imaginary chemical potential, which is a consequence of \( U(1)_B \) symmetry. Thus, we first extend the model to exhibit the appropriate periodicity and the phase structure in the imaginary baryon chemical potential.

In QCD, the partition function has a periodicity \( 2\pi/N_c \) in the imaginary quark chemical potential \( \theta_q = \theta/3 \), thus \( 2\pi \) in the baryon number. LQCD simulations have shown that there is no phase transition in imaginary baryon chemical potential at temperatures below chiral crossover temperature and thermodynamic quantities smoothly behave as \( \sim \cos \theta \). This fact combined with Eq. (7) implies that the phase transition at large baryon number density is encoded in higher Fourier coefficients of the smoothly oscillating function.

#### A. Partition function and thermodynamics

We start with a partition function of the chiral random matrix model with \( N_s \) sites given in \[59\]

\[
Z_{RM} = \int \mathcal{D}X \exp \left(-\frac{N_s}{\sigma^2} \text{Tr}XX^\dagger \right) \det^{N_f}(D + m)
\]

where \( \sigma \) denotes the variance of the random matrix \( X \) which has \( N_s \times N_s \) dimension and \( D \) is the \( 2N_s \times 2N_s \) matrix approximating the Dirac operator. At \( T = \mu = m = 0 \), \( \sigma \) is the only dimensionful parameter. We use it as a unit of mass in the model and put \( \sigma = 1 \) in expressions below.

The Dirac operator takes the form

\[
D = \begin{pmatrix}
0 & iX + iC \\
ix^\dagger + iC & 0
\end{pmatrix}
\]

The matrix \( C \) describes the effect of temperature and chemical potential. In Ref. \[59\], it was chosen as

\[
C_k = a\pi T + \frac{b \mu}{iN_c}
\]

for one half of eigenvalues and

\[
C_k = -a\pi T + \frac{b \mu}{iN_c}
\]

for the other half\(^2\) with \( a \) and \( b \) being the dimensionless

---

\(^2\) Note that \( \mu \) is the chemical potential of the baryon number, thus \( \mu/N_c \) stands for that of the quark number.
The linear ansatz for the matrix $C$ \[16\]-\[17\] accounts for the fact that there are the two smallest Matsubara frequencies $\pm \pi T$. This model does not have any thermal distribution which gives the fugacity factor $e^{\mu/T}$ thus nor the periodicity in imaginary chemical potential, since it appears as a result of summation over the Matsubara frequencies. In order to make the partition function periodic, we perform a following replacement

$$
\frac{b}{N_c}\mu + i\pi a T = \pi a T \left( i + \frac{b}{a\pi N_c} \mu \right) \quad (18)
$$

$$
\rightarrow \pi a T \left( i + \frac{b}{a\pi N_c} 2\sinh \frac{\mu}{2T} \right) \quad (19)
$$

which gives a periodicity $2\pi T$ in $\mu_f$ to the partition function. Compared to the original linear ansatz, this replace does not change anything at $\mu = 0$ but alters the phase structure at $\mu > 2T$.

The phase structure of the model is easily evaluated by taking $N_s \rightarrow \infty$ limit. Introducing an auxiliary $N_f \times N_f$ complex matrix field $\phi$ and performing the Gaussian integration with respect to $X$, one obtains the partition function \[63\]

$$Z_{RM} = \int D\phi \exp[-N_s \Omega(\phi)] \quad (20)$$

where $\Omega(\phi)$ stands for the effective potential. Then the partition function can be determined by the minimum of the potential, which is evaluated at the saddle point $\phi_0$ of the integrand:

$$\frac{\partial \Omega(\phi)}{\partial \phi} \bigg|_{\phi = \phi_0} = 0, \quad (21)$$

and

$$\lim_{N_s \rightarrow \infty} \frac{1}{N_s} \ln Z_{RM} = -\min_{\phi} \Omega(\phi). \quad (22)$$

The saddle point $\phi_0$ is related to the chiral condensate through

$$\langle \bar{\psi} \psi \rangle = \frac{1}{N_f V_4} \frac{\partial \ln Z_{RM}}{\partial m}, \quad (23)$$

$$= \frac{1}{N_f V_4} \frac{N_s}{\sigma} 2 \text{Re} \text{Tr} \phi_0 \quad (24)$$

where the four dimensional volume $V_4$ corresponds to $N_s$ such that $N_s$ represents the typical number of the instanton (or anti-instanton) in $V_4$. For real $m$, one expects $\phi_0$ is a real matrix proportional to the unit matrix. Therefore, the saddle point can be obtained by solving \[24\] for the potential

$$\Omega(\phi)/N_f = \phi^2 - \frac{1}{2} \ln \left\{ \left( \phi + m \right)^2 - \tilde{T}^2 \left( A \sinh \frac{\mu}{2T} + i \right)^2 \right\} \quad (25)$$

where

$$\tilde{T} = \pi a T \quad (26)$$

and

$$A \equiv \frac{2b}{a\pi N_c}. \quad (27)$$

In the chiral limit $m = 0$, one finds that $\phi_0 = 1$ at $T = \mu = 0$ and a second order phase transition occurs at $T = 1/(\pi a)$ and $\mu = 0$, where $\phi_0$ continuously approaches to zero. Thus, $\phi_0$ can be regarded as an order parameter of the chiral phase transition.

The parameters in the model, $\sigma$, $a$, and $b$, are determined as follows. The only dimensionful parameter $\sigma$ is estimated to be $\sigma \sim 100$ MeV through Eq. \[24\] by putting $\langle \bar{\psi} \psi \rangle \sim 2$ fm$^{-3}$ at $T = \mu = 0$. Since $T_c = 1/(\pi a)$ at $\mu = 0$, putting $T_c = 160$ MeV yields $a = 0.2$. The remaining parameter $b$ connects the model to the density scale. With the linear ansatz for $C$ \[16\]-\[17\], one finds the first order phase transition at $T = 0$ and $b\mu/N_c = 0.528$. We follow the choice of Ref. \[53\] and put $b = 0.13$, corresponding to the first order transition point at $\mu_c \approx 1200$ MeV, though we do not have the same phase diagram as Ref. \[53\] owing to the implementation of the periodicity \[16\]-\[17\].

Figure\[1\] shows the phase diagram of the modified random matrix model \[24\] in the chiral limit and in the presence of a small explicit symmetry breaking, $m = 0.05$, respectively. In the chiral limit, second order line continues with decreasing temperature down to $T > T_3$ and $\mu < \mu_3$, where $T_3 \approx 0.731T_c$ and $\mu_3 \approx 4.504$ is the location of the tricritical point (TCP). Below $T_3$, there is the first order phase transition line. At finite quark mass, the second order line is replaced by smooth crossover and TCP becomes CP with slightly decreased temperature and increased chemical potential, $T_{CP} = 0.675T_c$.\[54\]
and \( \mu_{\text{CP}} = 4.72 \), respectively. While these structures are the same as those in Refs. \([58, 59]\), the apparent singularity at \( T = 0 \) in the periodic parametrization significantly modifies the phase boundary at low temperature. We stress that our purpose in this paper is to explore the property of partition function zeros rather than determination of the phase structure.

With the parameter set for \( a, b \) and \( \sigma \), we find that this form also gives a reasonable thermodynamic quantities at imaginary chemical potential \(^3\) Figure 2 displays the behavior of the order parameter \( \phi_0 \) in the imaginary baryonic chemical potential \( \theta = \mu/b/T \). One sees that our parameterization \(^{19}\) gives the correct periodicity \( 2\pi \) and expected temperature dependence such as larger amplitude at higher temperature below \( T_c \). Owing to lack of a \( Z(3) \) sector such as the Polyakov loop background, this model does not exhibit the Roberge-Weiss phase transition \(^{62}\) at high \( T \).

At finite \( N_s \), the partition function can be expressed as \(^{58}\)

\[
Z_{\text{RM}} = \sum_{k_1, k_2 = 0}^{N_s/2} \binom{N_s/2}{k_1} \binom{N_s/2}{k_2} (N_s - k_1 - k_2)! F_1(k_1 + k_2 - N_s; 1; -m^2 N_s)(-N_s T^2/4)^{k_1+k_2} \times (i + A \sinh \frac{\mu}{2T})^{2k_1} (i - A \sinh \frac{\mu}{2T})^{2k_2}.
\]

where an irrelevant constant factor is ignored and \( F_1(a, b, x) \) denotes the confluent hypergeometric function. One may directly obtain zeros of this partition function, but one needs to expand \( Z \) in a series of the fugacity \( \lambda \) to examine effects of tails in the probability distribution function. We put the details in the Appendix \(^A\) and write down only the result for the canonical partition function, for \( \delta = |k_1 - k_2| \).

\[
Z(T, N_s, N) = \sum_{k_1, k_2 = 0}^{N_s/2} \binom{N_s/2}{k_1} \binom{N_s/2}{k_2} (N_s - k_1 - k_2)! F_1(k_1 + k_2 - N_s; 1; -m^2 N_s)(-N_s T^2/4)^{k_1+k_2} \times \left( \sum_{k_4 = 0}^{k_1+k_2-k_3} \binom{k_4}{k_3} \frac{2(2-A^2)}{A^2} \frac{(\delta - k_3 - 1)!}{(\delta - k_3)^!(2k_3)!} \sum_{k_5 = 0}^{k_1+k_2-k_4} \binom{k_5}{k_3} \frac{2(2-A^2)}{A^2} \frac{(\delta - k_3 - 2k_4 - k_5 + 2)!}{(\delta - k_3 - 2k_4 - k_5 + 2)^!(2k_3 - 2k_4)!} \right)
\]

\[
N_{\text{max}} = N_s \text{ in Eq. } (28), \text{ one recovers the exact grand partition function } (28). \text{ The computation of the zeros requires a special care in numerical digits as cautioned in literature }^{16, 67}. \text{ We perform the calculations in } 50-300 \text{ digits utilizing FMLIB package }^{68} \text{ in fortran } 90.
\]

Figure 3 shows the distribution of the Yang-Lee zero of the periodic chiral random matrix model in the complex \( \omega \) plane, for \( m = 0 \) and at \( T/T_c = 0.99 \). The distribution of the zeros is symmetric with respect to the horizontal axis because the partition function is an even order polynomial of \( \omega \) and a root has its complex conjugate. The solid line in Fig. 3 stands for Stokes boundary, which can

---

\(^3\) Note that in Refs. \([58, 59]\) the coefficients in the temperature and chemical potential are absorbed into \( T \) and \( \mu \). While the qualitative phase structure does not depend on the parameters in the linear ansatz, it does so when one employs the periodic parametrization \(^{19}\).
be regarded as an extension of the phase boundary to a complex chemical potential plane. In the thermodynamic limit $N_s \to \infty$, it satisfies

$$\text{Re}\left(\frac{\partial^2 \Omega(\phi)}{\partial \phi^2}\right) > 0,$$

$$\text{Re}\Omega(\phi = \phi_{0,1}) = \text{Re}\Omega(\phi = \phi_{0,2}),$$

where the first condition ensures the well-defined partition function at the saddle point of integrand in Eq. (20) and the second condition denotes the continuity of the real part of pressure at the boundary. $\phi_{0,1}$ and $\phi_{0,2}$ stand for the two out of five solutions of the gap equation $\partial^2 \Omega/\partial \phi^2 = 0$ and give the minimum of $\text{Re}\Omega$ in both sides of the boundary, respectively. The density of the zeros increases with $N_s$ and turns into the cut which constitutes the Stokes boundary in the thermodynamic limit.

This is clearly seen in Fig. 3. There are two branch points located on the real axis. Since $\omega = \lambda + 1/\lambda > 0$ for real $\mu$, the one at $\text{Re}\omega = \omega_c = 3.4 > 0$ corresponds to the second order phase transition point in real $\mu$, while the other one, $\text{Re}\omega = -634.4$ is located on the line $\text{Im}\mu/T = \pi$. The Stokes boundary exhibits a closed curve, reflecting the periodicity in imaginary $\mu$ and existence of the phase boundary at real $\mu$ axis and $\text{Im}\mu/T = \pi$.

The phase structure can be more intuitively understood by going to complex $\mu$ plane. Figure 4-left displays the distribution of the same Yang-Lee zeros as in Fig. 3 but the zeros in $\text{Re}\mu < 0$ are omitted since their locations are trivial according to the charge conjugate symmetry $\mu \to -\mu$. The branching point on the horizontal axis indicates the second order phase transition point. The Stokes boundary extends to both direction in imaginary $\mu$ and ends up at the other branch point. Note that the branch points at $\text{Im}\mu/T = -\pi$ and $\pi$ are essentially the same because of the periodicity. We refer to [63, 71] for behavior of the order parameter in complex $\mu$ plane and related topics. The zeros distribute along the boundary and becomes more dense for large $N_s$, but distance to the real axis is not so close for these values of $N_s$. The behavior of the density of the zeros is related to a property of the thermodynamic potential which can be described by an analogy to electrostatics [58]. In this case, $\text{Re}\Omega$ can be regarded as the electrostatic potential on the $(\text{Re}\mu/T, \text{Im}\mu/T)$ plane and the normal component of the electric field $E = -\nabla(\text{Re}\Omega)$ to the Stokes boundary has a discontinuity of which amount is proportional to the density of the zeros. We confirmed that in this model these discontinuities at large $\text{Re}\mu$, where the zeros are dense, are much larger than those at small $\mu$, following the expectation. Although the density of the zeros far from the branching point is a model-dependent feature dependent on the shape of the Stokes boundary, it is governed by the universality near the branch point on the real axis as pointed out in Ref. [58].

Effects of the finite but small quark mass can be seen in the right panel of Fig. 4 where the distribution of Yang-Lee zeros for $m = 0.05$ at the same temperature is displayed. Owing the explicit chiral symmetry breaking, the phase transition becomes a crossover such that the branch point on the real axis moves to above. As a result, there are two branch points of which are complex conjugate each other. The same thing occurs also to the branch point at $\text{Im}\mu/T = \pm\pi$. Here we emphasize that these complex singularities are, albeit unphysical, indicating existence of a chiral phase transition in the chiral limit. These are also known as Yang-Lee edge singularities [52]. The critical point at finite density (See Fig. 1) is realized by coalescence of the branch points close to real $\mu$ axis when temperature is decreased [53]. As seen in Fig. 4-right, the Yang-Lee zeros are fairly on the boundary line and exhibit expected behaviors.

**IV. YANG-LEE ZEROS FROM TRUNCATED PARTITION FUNCTIONS**

As described in Sec. II, the connection of net baryon number multiplicity distribution with the reconstructed grand partition function could potentially enables us to extract the Yang-Lee zeros from experimental data. Since the results presented in the previous section correspond to $N_s = N^*$, i.e., no information on the exact partition function is lost, we need to evaluate whether one can obtain the correct distribution of the Yang-Lee zeros when the fugacity expansion is truncated. Furthermore, even if one starts from a partition function which does not exhibit any phase transition such as an ideal Boltzmann gas, the truncation produces the zeros of partition function because it is a polynomial of order
In this section we investigate in detail the effects of the truncation on the distribution of the Yang-Lee zeros.

A. Random matrix model

Figures 5 and 6 display the distribution of the Yang-Lee zeros from the truncated partition function of the periodic chiral random matrix model for various $N_{\text{max}}$ and $m = 0.05$.

Hereafter we set $N_s = 60$. We confirmed the following results do not depend on the specific choice of $N_s$. We plot only the first quadrant in complex $\mu$ plane according to the symmetry structure of the distribution.

The left panel in Fig. 5 shows the case of $T = T_c$, at which transition is of crossover type as seen in the branch point at $(\text{Re} \mu/T, \text{Im} \mu/T) = (3, \pi/4)$. For $N_{\text{max}} = 60 = N_s$, the zeros are located on the Stokes boundary (dashed line). Reducing $N_{\text{max}}$ by one, i.e., removing $Z(N = 60)$ from the series, one sees a drastic change in the distribution. The distribution of the zeros at large Re$\mu$ and Im$\mu$ splits into the two lines, but the rest of the zeros remains unchanged. Further reduction of $N_{\text{max}}$ substantially modifies the distribution such that the splitting occurs closer to the edge closer to the real $\mu$ axis. Nevertheless, up to $N_{\text{max}} = 21$, the edge of the distribution which is the closest Yang-Lee zero to the real $\mu$ axis remains the same. Beyond $N_{\text{max}} = 20$, the distribution no longer holds the information on the exact Yang-Lee zeros thus the apparent relation to the phase boundary is lost.

The behavior with respect to changing $N_{\text{max}}$ does not depend on temperature or corresponding phase transition. In the right panel of Fig. 6, we plot the result of the same analysis for $T = T_{\text{CP}} = 0.675T_c$ where the branch point appears on the real axis, indicating the critical point. Reflecting the location of the branch point, the edge of the distribution also become closer to the real axis compared to the crossover case. The edge is stable against decreasing $N_{\text{max}}$ down to $N_{\text{max}} = 19$, then it starts to deviate slowly when decreased further. This is so also in the case of first order phase transition ($T = 0.67T_c$) depicted in Fig. 6. The branch point is hidden in unphysical Riemann sheets and the edge is very close to the real axis.

We also note that there is always a zero at $\text{Im} \mu/T = \pi$ when $N_{\text{max}}$ is odd. These zeros look special since it corresponds to negative real axis in both complex $\lambda$ and $\omega$ plane. However, this is a mathematical consequence because in this case the truncated partition function is an odd order polynomial, thus it has at least one real root. As seen in Figs. 5 and 6, it becomes the edge of one of the lines bifurcating from the exact Yang-Lee zeros.

These results indicate the stability of the edge does not depend on the detail of the phase structure, although the location of the edge seems to be connected with the shape of the Stokes boundary which is model dependent through the $\mu$ dependence of the partition function. In particular, the present results are obtained by employing the periodicity in the random matrix model which does not correctly take into account degrees of freedom with baryon charges.

Note that $T_c$ is defined for $m = 0$. Thus it is slightly lower than the chiral crossover temperature for $m = 0.05$. 

FIG. 4. Yang-Lee zeros of the periodic random matrix model in complex $\mu$ plane. The left panel corresponds to the case of $T = T_c$, $N_s = 20$, $m = 0.05$, $T = 0.99T_c$. Right panel shows the case with a finite but small quark mass, $m = 0.05$ at the same temperature.
presumably reflect the unusual curvature of the phase boundary in Fig. 4. Therefore, we note that the shape of the distribution itself might not be relevant for realistic situations. Nevertheless, below we shall see that the stability of the edge is specific to the case with a phase transition.

Figure 6 displays distribution of the Yang-Lee zeros for a lattice QCD data [54]. While calculations in the confinement phase is still numerically difficult thus we do not see clear indications of a phase transition at low $T$, the Roberge-Weiss (RW) transition provides us a well-

B. Lattice QCD

FIG. 5. Distribution of the Yang-Lee zeros from the truncated partition function of the periodic chiral random matrix model for $m = 0.05$. Left and right panels stand for $T = T_c$ and $T = T_{CP}$, respectively.

FIG. 6. Same as Fig. 5, but for $T = 0.6T_c$.

FIG. 7. Distribution of Yang-Lee zeros for a lattice QCD data [54].
defined phase transition in high temperature quark-gluon plasma phase, though at imaginary chemical potential. In this figure, the data are calculated on $8^3 \times 4$ lattices and $\beta = 1.89$ which corresponds to $T/T_c \simeq 1.94$. A more detailed analysis in lattice QCD with different lattice set-ups can be found in Ref. [53]. Since quark mass is heavy, the calculation is not relevant for chiral phase transition. The RW transition is regarded as a transition from one $Z(3)$ sector to another one when single quarks can be excited owing to deconfinement and is known to exhibit a first order phase transition at $\text{Im} \mu / T = \pm \pi / 3$. In terms of baryon chemical potential, the transition lines reduce to $\text{Im} \mu / T = \pm \pi$ which is shown as a dotted line in Fig. 7. A brief explanation of the Roberge-Weiss phase boundary can be found in Appendix B. Since it is hard to compute $Z(N)$ near $N = N^*$, the canonical approach in lattice QCD lacks large $N$ contribution when one constructs the truncated partition function \[ \text{truncated} \]. One sees that in Fig. 7 the behavior of the distribution of the Yang-Lee zeros against changing $N_{\text{max}}$ is similar to that of the random matrix model, despite the completely different origin of the phase transition. Therefore, we expect the similar splitting behavior of the distribution also appearing in Refs. [46, 53] is also due to the truncation effect. Indeed, $N_s$ and $N_{\text{max}}$ dependence of the Yang-Lee zero shown in Ref. [53] agrees with the truncation effects discussed here. We expect that the bifurcation of the zero starts at large Re$\mu$ by improving the fugacity expansion, but one needs to take $N_{\text{max}} = N^*$ to completely produce the Yang-Lee zero along the transition line. In the RW transition where the transition point at $\text{Im} \mu / T = \pm \pi$, the edge of the distribution is the closest zero to the imaginary axis. One sees that this point is also stable against changing $N_{\text{max}}$. This fact suggests that the stability of the edge is not specific to the random matrix model or chiral phase transition but might be a general property of the distribution when partition function is truncated.

C. Skellam distribution

Finally we examine a model without phase transition in order to check whether the stability of the edge is specific to phase transition or not. We employ the Skellam distribution [71] of which probability distribution of the net baryon number $N$ is given by

\[ P^S(N) = \left( \frac{N_B}{N_{\bar{B}}} \right)^{N/2} I_N(2\sqrt{N_B N_{\bar{B}}}) e^{-(N_B + N_{\bar{B}})} \]  \hspace{1cm} (32)

where $N_B$ and $N_{\bar{B}}$ denote the thermal averages of the numbers of baryons and anti-baryons, respectively. The mean $M$ and variance $\sigma^2$ of the distribution are given by $M = N_B - N_{\bar{B}}$ and $\sigma^2 = N_B + N_{\bar{B}}$, respectively. For $N_B = N_{\bar{B}}$, The distribution becomes symmetric and the argument of the modified Bessel function $I_N(x)$ is reduced to $2N_B = \sigma^2$. This distribution can be derived from non-interacting Boltzmann gas [18], thus the canonical and grand canonical partition functions read

\[ Z(N) = I_N(\sigma^2) \hspace{1cm} (33) \]

\[ Z(\lambda) = \exp \left[ \frac{\sigma^2}{2} \left( \lambda + \frac{1}{\lambda} \right) \right] \hspace{1cm} (34) \]

where the temperature and volume dependence is encoded in $\sigma^2$. Obviously the grand partition function (34) does not have any roots thus no phase transition exists. When one constructs the truncated grand partition function from the canonical partition function, however, there exist complex roots. Consequently, one might see these spurious zeros even if the system does not have any phase transition, when one constructs the partition function through the fugacity expansion.

Here we investigate such spurious zeros from the Skellam partition function [88] such that it has the same variance with the random matrix model at $N_s = 60$, $T = T_c$ and $m = 0.05$ of which distribution of the Yang-Lee zeros is displayed in Fig. 5. Since the information on the phase transition is encoded in the tail of the probability distribution $P(N)$, the Skellam distribution with the same variance serves a useful reference distribution [29]. The probability distribution of the random matrix model and corresponding Skellam distribution are shown in Fig. 8-left. Both distributions almost agree for small $N$, according to the same $\sigma^2$, but the deviation appears in the tail of the distribution with tiny probability.

Figure 8-right shows the distribution of zeros of the truncated partition function for the Skellam distribution with $\sigma^2 = 0.365$. Except for a splitting of the distribution for $N_{\text{max}} \geq 70$ which is similar to those in the random matrix model, the distributions consist almost parallel lines moving to large real $\mu$ direction as $N_{\text{max}}$ increases. This behavior reflects the fact that all the zeros go away to infinity as $N_{\text{max}} \to \infty$ since the exact grand partition function does not have roots. Remarkably, the edges of the distributions also move together with the rest of zeros, in contrast to the random matrix model and lattice QCD. Furthermore, one notes that the distributions for $N_{\text{max}} \leq 20$ in the random matrix model, shown in Fig. 8 resemble those from the Skellam distribution. This observation indicates that the stability of the edge against $N_{\text{max}}$ is a consequence of the existence of phase transition and information on the phase transition is lost for too small $N_{\text{max}}$.

V. DISCUSSION

A. Comparison with $N_{\text{max}}$ for cumulants

In the previous section, we have shown that the edge of the distribution of the Yang-Lee zeros remains unchanged when the tail part of the canonical partition function is missing. In practice, this property gives implications for necessary statistics in heavy ion studies of the net-baryon number fluctuations and in lattice QCD.
random matrix model at $T = T_c$ and $m = 0.05$, and the corresponding Skellam distribution. For sufficiently large volume, it was shown

**TABLE I.** $N_{\text{max}}$ necessary for reconstructing $i$-th order cumulants and edge of the Yang-Lee zeros from $Z(N)$ in the random matrix model at $T = T_c$ and $m = 0.05$.

| $N_{\text{c}}$ | $N_{\text{max}}^{(2)}$ | $N_{\text{max}}^{(4)}$ | $N_{\text{max}}^{(6)}$ | $N_{\text{max}}^{(8)}$ |
|----------------|------------------------|------------------------|------------------------|------------------------|
| 60             | 3                      | 4                      | 6                      | 21                     |
| 80             | 3                      | 5                      | 6                      | 26                     |
| 100            | 4                      | 5                      | 7                      | 30                     |

calculations. Since the sufficient $N_{\text{max}}$ to see the stable edge depends on the system volume, here we compare it with corresponding $N_{\text{max}}^{(i)}$ for $i$-th order cumulants. Here we consider only even order ones for net-baryon number at $\mu = 0$, since we are looking at $Z(T, V, N)$ rather than $P(N)$ which becomes asymmetric with respect to $N$ at $\mu > 0$. Thus the first central moment $\delta N = N - \langle N \rangle = N$. The second, fourth and sixth order cumulants $c_n (n = 2, 4, 6)$ read

$$c_2 = \langle (\delta N)^2 \rangle$$  
$$c_4 = \langle (\delta N)^4 \rangle - 3\langle (\delta N)^2 \rangle^2$$  
$$c_6 = \langle (\delta N)^6 \rangle - 15\langle (\delta N)^4 \rangle\langle (\delta N)^2 \rangle + 30\langle (\delta N)^2 \rangle^3$$  

The property of the higher order cumulants of net-baryon number probability distribution for changing $N_{\text{max}}$ was studied in Ref. [42] by using a chiral quark-meson model. For sufficiently large volume, it was shown that $N_{\text{max}}^{(i)}$ for the cumulants approximately scale with $\sqrt{V}$.

We summarize the values of each $N_{\text{max}}$ in Table I. The calculations are done for $T = T_c$ and $m = 0.05$ in the random matrix model. Owing to the narrow $Z(N)$, even the sixth order cumulant for $N_{\text{c}} = 100$ only requires $N_{\text{max}}^{(6)} = 7$, i.e., $-7 \leq N \leq 7$ to reconstruct it from $Z(T, V, N)$, while the edge of Yang-Lee zeros demands $N_{\text{max}}^{(6)} = 21$. The small $N_{\text{max}}^{(6)}$ implies the system volume is not large enough to exhibit $\sqrt{V}$ scaling regime of the cumulants. This can be understood from the small value of $\sigma^2$ in the random matrix model calculations. The rapid decay of $P(N)$ give a rather weak dependence of $N_{\text{max}}$ for the higher order cumulants. For a sufficiently large volume, one expects that $P(N)$ resembles Gaussian near the peak, while the probability distribution (Fig. 8) has a sharp peak. Thus we cannot assess the value of $N_{\text{max}}$ needed in a realistic situation relevant for heavy ion collisions. Moreover, the baryon number carried in this model is not a physical one, as mentioned above. All we can say is that one may need much more statistic than higher order cumulants.

**B. Skellam distribution for large volume**

In the fluctuation measurements at RHIC, observed $P(N)$ can be well described by the Skellam distribution and deviation from the Skellam distribution exists in the tail, resulting in higher order cumulants different from the Skellam case. The obtained variance reaches $\sigma^2 \sim 10^{16}$ at the most central bin. Thus it is instructive to give a reference for the distribution of the spurious Yang-Lee zeros based on the Skellam distribution. Here we pick up the data for $\sqrt{\sigma_{NN}} = 7.7$ GeV at the most central bin, which gives $\sigma^2 = 14.89$ and $M = 14.41$ with available bin
from $N = 0$ to $N = 34$\footnote{The data for $N = 0$ and $N = 34$ have only 1 event.} As mentioned in Sec. \ref{sec:results} one can construct $Z(N)$ from $-34 \leq N \leq 34$ according to charge conjugation symmetry \cite{46}. In the Skellam distribution for $\sigma^2 = 14.89$, we find that $N_{\text{max}}^{(i)} = 13, 20$ and 26 for second, fourth and sixth order cumulant, respectively. Note that these $N_{\text{max}}^{(i)}$ apply to the cumulants at $\mu = 0$. The data does not have enough statistic for the sixth order cumulant at freeze-out $\mu$.

We plot the distribution of the Yang-Lee zeros for the constructed Skellam distribution with $\sigma^2 = 14.89$. The basic feature is the same as the small $\sigma^2$ case (Fig. 8). The line of zeros moves toward infinity as $N_{\text{max}}$ increases.

One sees that some zeros below $N = 30$ appear on the imaginary $\mu$ axis, which corresponding to the unit circle in complex fugacity plane. This means that, for a large volume case, the zeros can appear on the imaginary axis when the tail of the $Z(N)$ is not provided. In the Skellam distribution, these zeros can be obtained directly by looking at the truncated partition function on the imaginary $\mu$ axis, for $\lambda = e^{i\theta}$,

\begin{equation}
Z_{\text{Skellam}}^{\text{tr}}(\theta) = 2 \sum_{N=-N_{\text{max}}}^{N_{\text{max}}} I_N(\sigma^2) \cos N\theta, \tag{38}
\end{equation}

which converges into Eq. \ref{eq:yang_lee} with oscillations giving zeros on imaginary $\mu$.

VI. CONCLUDING REMARKS

In this paper, we present analyses on partition function zeros which can be obtained from a truncated series of the fugacity expansion. By solving an extended chiral random matrix model which has a periodicity in the imaginary chemical potential, we compare the exact location of the Yang-Lee zeros and those obtained from the truncated series. We found that the edge of the distribution of the zeros is insensitive to the truncation of higher order terms in the fugacity expansion to some degree. We found the similar behavior in lattice QCD at high temperature in the context of the Roberge-Weiss phase transition. This observation indicates that those higher order terms may have limited influences in search for the location of the phase boundary in lattice QCD calculations and heavy ion experiments. Although the distribution of zeros exist in systems without phase transition, due to the truncation, the zeros closest to the real $\mu$ axis are stable against truncation if the system has a phase transition or crossover. The spurious zeros in the Skellam distribution moves toward infinity against the truncation. Therefore, one can distinguish whether the distribution is related to the phase transition or not by looking at the stability of the edge of the distribution against the truncation.

Although the information on the Stokes boundary is lost in the case of too small $N_{\text{max}}$, we expect that it does not mean that all the relevant information on the phase transition gets lost in the truncated partition function. This expectation follows from the fact the sixth and higher order cumulants at $\mu = 0$ should be influenced by the phase transition and the truncated series is still able to reproduce them. It would be interesting to see how the distributions of the zeros in the small $N_{\text{max}}$ cases in Figs. 5-6 are related to the remnant of the phase transition.

The order of the truncation in the fugacity series to obtain the stable edge of the Yang-Lee zeros, $N_{\text{max}}$, is nevertheless found to be much larger than those for higher order cumulants. We cannot make a quantitative assessment on realistic values for heavy ion experiments due to the lack of connection in the model to the real world. We hope that such an estimate becomes feasible in the near future.

Appendix A: Derivation of the canonical partition function in a chiral random matrix model

In the following, we derive an analytic expression for $Z(T, N_s, N)$ from Eq. (23). First we rewrite the $\mu$ dependent part in terms of the fugacity $\lambda = e^{\mu/T}$.

Since

$$\operatorname{Re} \left[ (A \sin \frac{\mu}{2T} + i)^{2k_1} (A \sin \frac{\mu}{2T} - i)^{2k_2} \right] \quad (A1)$$

$$= (A^2 \sin^2 \frac{\mu}{2T} + 1)^{k_1 + k_2} \cos[2(k_1 - k_2)\phi] \quad (A2)$$

where

$$\tan \phi = \left( A \sin \frac{\mu}{2T} \right)^{-1}, \quad (A3)$$

and imaginary part vanishes after summation over $k_1$ and $k_2$, using the Chebychev polynomial

$$T_{k_1-k_2} (\cos 2\phi) = \cos[2(k_1 - k_2)\phi] \quad (A4)$$

and

$$\cos 2\phi = \left( A^2 \sin^2 \frac{\mu}{2T} - 1 \right) / \left( A^2 \sin^2 \frac{\mu}{2T} + 1 \right), \quad (A5)$$

we have the partition function $Z$ as

$$Z = \sum_{k_1, k_2 = 0}^{N_s/2} \binom{N_s/2}{k_1} \binom{N_s/2}{k_2} (N_s - k_1 - k_2)!$$

$$\times I_1(k_1+k_2-N_s;1; -m^2 N_s)(-N_s \bar{T}^2 A^2/4)^{k_1+k_2}$$

$$\times \left( \frac{\lambda + 2(2 - A^2)}{A^2} \right)^{k_1+k_2}$$

$$\times T_{k_1-k_2} \left( \frac{\lambda + \lambda^{-1} - 2(A^2 + 2)/A^2}{\lambda + \lambda^{-1} - 2(A^2 - 2)/A^2} \right). \quad (A6)$$

Expanding the Chebychev polynomial by the following expression

$$T_n(x) = \begin{cases} 1 & n = 0 \\ n \sum_{k=0}^{n} (-2)^k \binom{n+k-1}{n-k}! (1-x)^k & n \geq 1, \end{cases} \quad (A7)$$

and using binomial expansion in the third line of (A6), we can express $Z$ in terms of $\lambda + \lambda^{-1}$. We obtain Eq. (23) by applying the projection $[69]$. Note that maximum power of $\lambda$ is given by $N_s$.

Appendix B: Roberge-Weiss transition as a thermal cut

In this appendix, we give a brief explanation of the cut arising from the Fermi distribution function and apply it to the Roberge-Weiss transition in QCD.

1. Thermal cut in free Fermi gas

The thermodynamic potential of the free Fermi gas is given by

$$\Omega_f \sim - \int \frac{d^3 p}{(2\pi)^3} \ln[1 + e^{-\beta(E_p - \mu)}] \quad (B1)$$

where $E_p = \sqrt{p^2 + m^2}$. When the chemical potential $\mu$ has an imaginary part, $\mu_I = \theta T$, the imaginary part gives a phase in front of the Boltzmann factor:

$$1 + e^{-\beta(E_p - \mu)} = 1 + e^{i\theta} e^{-\beta(E_p - \mu R)} \quad (B2)$$

where $\mu = \mu_R + i\mu_I$. Therefore, for $\theta = \pm \pi$, the phase gives $-1$ and the thermodynamic potential has a logarithmic cut at $\theta = \pm \pi$ and $m \leq \mu_R < \infty$. The antiparticle term also gives the cut symmetric with respect to the imaginary axis. In Ref. [73], it is pointed out that the branch point singularity limits the convergence radius when one tries to analytically continue the results in the imaginary chemical potential to the real one. Since this cut originates from the Fermi distribution, the same analytic structure appears in chiral models with fermions [69].

2. Roberge-Weiss transition

In QCD at high temperature, quarks are deconfined and have a light mass owing to chiral restoration. Since the deconfinement can be expressed as a breaking of $Z(N_c)$ symmetry, it is useful to resort to chiral effective models with the Polyakov loop background [74–76], which successfully describe the Roberge-Weiss transition [64, 65, 77]. Then, the relevant leading single quark contribution to the thermodynamic potential reads

$$\Omega_{qq} \sim - \int \frac{d^3 p}{(2\pi)^3} \ln[1 + 3\Phi e^{-\beta(E_p - \mu_q)}] \quad (B3)$$

$$+ (\mu_q \rightarrow -\mu_q, \Phi \rightarrow \bar{\Phi})$$

where $\mu_q = \mu/3$ is the quark chemical potential and $\Phi$ is the the expectation value of the Polyakov loop. For antiquark contribution, the conjugate $\bar{\Phi}$ couples to the thermal distribution. At the imaginary chemical potential, Polyakov loop $\Phi$ acquires a complex phase $\varphi$. One may express $\Phi = |\Phi|e^{i\varphi}$. Then the thermodynamic contribution becomes

$$1 + 3\Phi e^{-\beta(E_p - \mu_q)} = 1 + 3|\Phi| e^{i(\varphi - \theta_q)} e^{-\beta(E_p - \mu_q, n)} \quad (B4)$$
The phase of the Polyakov loop $\varphi$ varies as a function of the imaginary quark chemical potential $\theta_q$. The Roberge-Weiss transition at $\theta_q = \pi/3$ can be understood as a transition from one $Z(3)$ sector with $\varphi = 0$ to another one $\varphi = -2\pi/3$ [32]. Then, the coupling between $\varphi$ and $\theta_q$ gives the prefactor $-1$ in front of the Boltzmann factor. Moreover, $|\Phi| \sim 1$ in the deconfined phase and the prefactor 3 allow this function to have the singularity at $\mu_q R = 0$. This feature gives the cut drawn as RW transition line in Fig. 7. A derivation based on the Gaussian $P(N)$ can be found in Ref. [55]. In the confinement phase where $|\Phi| \sim 0$, this term is suppressed and the thermal cut from the quark does not appear.
