OUTLINE

INTRODUCTION

The main objective of glaucoma surgery is to preserve visual function by preventing disease progression. In addition to traditional methods, several minimally invasive glaucoma surgery (MIGS) procedures have been described as a result of the quest for an ideal surgical procedure for glaucoma. Minimally invasive glaucoma surgery procedures have a good safety profile in mild-to-moderate glaucoma but are less likely to achieve low intraocular pressure (IOP) needed for patients with advanced or refractory glaucoma. In addition, MIGS procedures had been anticipated to be less effective than traditional glaucoma filtering procedures and to be ineffective after conventional incisional surgery.1 The recently popular XEN gel implant (Allergan, Dublin, CA, USA) is one of the MIGS devices which creates an external drainage fistula in a similar concept to trabeculectomy without conjunctival or scleral dissection. The goal of the XEN surgery is to lower IOP through subconjunctival filtration of aqueous humor while minimizing the risk of complications associated with conventional glaucoma surgery.2

The XEN implantation has shown good results, including IOP control with the potential to keep the patient free of medication and the risk of complications was comparable to that of trabeculectomy.3,4 Therefore, it is claimed that the XEN gel stent can be used in patients with advanced and refractory glaucoma.1,4–7 Previous studies have reported successful results with XEN implantation in the superonasal quadrant in patients who had undergone failed prior glaucoma interventions.7–10 A recent comparative report has also shown that inferior implantation of XEN stent was as efficient as in the superior quadrant as a first-line intervention in naive glaucoma patients.11 However, no previous comparative report has also shown that inferior implantation of XEN stent was as efficient as in the superior quadrant as a first-line intervention in naive glaucoma patients. However, no previous

MATERIALS AND METHODS

This retrospective clinical study adhered to the tenets of the Declaration of Helsinki and was approved by the Local Ethics Committee (LEC). The requirement for informed consent was waived by the LEC. The electronic health records were reviewed and patients with refractory glaucoma who underwent XEN surgery for failure of trabeculectomy were included in the study. All patients underwent a trabeculectomy with mitomycin-C (MMC) application. MMC was used in 4 cases and no MMC was used in 2 cases. The most common reasons for failure of trabeculectomy were hypotony, severe peribulbar leakage, and bleb failure. The mean follow-up period was 12 months, and the 12-month IOP was recorded for all patients.

RESULTS

Mean IOP reduced by 49.3% from 24.14 ± 2.74 mm Hg preoperatively to 12.23 ± 2.89 mm Hg at month 12 (p < 0.001). Medication usage reduced from 3.71 ± 0.47 medications preoperatively to 1.31 ± 0.55 at month 12 (p = 0.003). Adverse events included transient slight intracameral hemorrhage (5 eyes, 35.7%), second trabeculectomy required (2 eyes, 14.3%), and numerical hypotony (IOP < 5 mm Hg, in 3 cases, 21.4%), all of which resolved spontaneously. Six eyes (42.8%) required postoperative bleb needling to further reduce IOP. There were no cases of vision loss, stent exposure, hypotony, lower eyelid malposition, bleb dysesthesia, or bleb-related infection.

CONCLUSION: XEN gel stent implantation in the inferonasal quadrant can be considered a viable surgical option for patients with a history of previously failed trabeculectomy requiring further IOP lowering.

Clinical significance: To the best of our knowledge, this is the first case series describing the outcome of inferonasal implantation of XEN gel stent following failed trabeculectomy.

Keywords: Inferonasal quadrant, Minimally invasive glaucoma surgery, Refractory glaucoma, Trabeculectomy, XEN gel stent.

after a failed trabeculectomy between September 2016 and June 2018 were included.

We included patients with open-angle glaucoma (OAG), eyes not reaching the target IOP despite trabeculectomy under maximal medication. Exclusion criteria included blepharitis, the presence of diabetes mellitus, angle-closure glaucoma, and history of uveitis or ocular trauma resulting in conjunctival scarring.

Patients underwent a complete preoperative clinical examination that included: age, gender, best-corrected visual acuity (BCVA), adjusted IOP (using Goldmann applanation tonometry), gonioscopy, anterior segment, and retinal examination including evaluation of the optic nerve head cupping. The type of glaucoma, history of surgery, and medications (a fixed combination agent was counted as two medications) were also recorded. The BCVA was expressed according to the Snellen charts. The preoperative IOP was the mean value of the last two measurements before surgery.

All patients were evaluated before the procedure and 1 day, 1 month, 3 months, 6 months, and 12 months after XEN45 gel implantation. Complete success criteria were defined as a postoperative IOP of <18 mm Hg with a >20% reduction from preoperative value without medication or further surgical interventions (except needling). Qualified success was defined as a postoperative IOP of <18 mm Hg with a >20% decrease from baseline, with or without medication, and without any secondary intervention (except needling) at the 12-month follow-up.

XEN45 Gel Stent Implantation Procedure
All operations were performed as a stand-alone procedure by the same glaucoma specialist under topical anesthesia. After standard surgical preparation, the target point was marked in the inferonasal quadrant, 3 mm from the limbus. The surgeon aimed to insert the stent as inferiorly as possible, as far as the speculum or eyebrow technically allowed. Ten minutes before the procedure, 0.1 mL of Mitomycin C solution (0.01% MMC, 10 μg) was injected into the inferonasal sub-Tenon's space, 3–4 mm away from the target point. In cases without MMC, hydrodissection was performed with a balanced salt solution (BSS). After a 19 g clear corneal incision from the temporal limbus, preservative-free 1% lidocaine and a cohesive viscoelastic was applied into the anterior chamber. The preloaded injector of the XEN45 gel stent was placed through the superior temporal corneal incision. The injector needle was then directed across the anterior chamber where the implantation was planned in the lower quadrant. After the needle was inserted through the iridocorneal angle, it was pushed forward in an intracameral pathway. When the needle tip was seen under the conjunctiva, it was rotated to the side and then the stent was released. The injector was removed, and the location of the stent was controlled. After extraction of the viscoelastic material, irrigation was performed to ensure bleb formation. The surgery was ended by hydrating corneal incision.

All patients used topical moxifloxacin (0.5%) and prednisolone acetate (1%) eye drops, 4 times a day. Topical steroid dosage was tapered 4 weeks after surgery. Anti-glaucoma medication was completely stopped after surgery. During the follow-up period, needling or trabeculectomy decisions were given at the discretion of the same specialist. The needling was performed under topical anesthesia without any additional drug. Subconjunctival adhesions were released by moving a 27-gauge needle. Ocular examination data, intraoperative and postoperative complications were obtained through chart review.

Statistical Analysis
All statistical analyses were performed using Statistical Package for the Social Sciences (SPSS, Inc., Chicago, IL, USA), version 25. The descriptive statistics applied were count and percentage for categorical variables, and mean, the standard deviation for numeric variables. Rates within the groups were compared using the paired t-test. As the numerical variables did not follow a normal distribution, independent two-group comparisons were made using the Wilcoxon signed-rank test. A p value < 0.05 was taken to be statistically significant.

RESULTS
The XEN gel stent was implanted into 14 glaucoma patients (9 females, 5 males) with insufficient IOP control despite trabeculectomy. The mean age of the patients was 63.4 ± 9.7 (52–80) years. Eight patients had pseudoexfoliative glaucoma and six were primary OAG cases. One case had undergone more than one surgery (two trabeculectomy and an Ex-Press shunt [Alcon Laboratories, Ft. Worth, TX, USA] surgery). All patients underwent a stand-alone XEN stent implantation procedure. Nine patients were treated with MMC-augmented implantation. Mitomycin C could not be used in five patients due to the shortage of the drug supply. All patients completed all follow-up visits (from day 1 to month 12). The mean follow-up duration was 14.2 (range 12–18) months. Demographics and baseline data of the patients are shown in Table 1.

Table 2 shows the IOP levels and the change in the number of medications over time. There was a statistically significant reduction in the IOP values and medication use compared with preoperative values at all time intervals. The mean IOP was significantly reduced from a mean baseline value of 24.14 ± 2.74 mm Hg to a mean value of 9.43 ± 3.41 mm Hg on day 1, 12.64 ± 4.63 mm Hg at month 1, 12.00 ± 3.74 mm Hg at month 3, and 13.85 ± 3.24 mm Hg at month 6. The mean postoperative IOP was 12.23 ± 2.89 mm Hg after 12 months of follow-up, which represents a 49.3% decrease (Fig. 1).

The mean number of baseline medications was 3.71 ± 0.47, reducing to a mean number of 1.31 ± 1.55 medication used after 12 months of follow-up, which represents a 61% decrease. Seven (50%) patients were medication-free for at least 12 months. Complete success was achieved in 50% of patients, while 85.7% showed qualified success.

The most frequent complication was transient slight intracameral hemorrhage (five eyes, 35.7%) during surgery. Three patients (21.4%) had numerical hypotony (IOP <5 mm Hg without complications) which resolved spontaneously within the early postoperative period, with no long-term consequence. Postoperatively, six eyes (42.8%) required a single bleb needling to achieve further IOP reduction in the eyes with failed bleb. Five patients underwent a needling procedure during the 1st month and one patient during the 3rd month. Of these, two eyes (14.3%) were managed with superior re-trabeculectomy during the 4th month and the 12th month due to failure to achieve the targeted IOP despite needling. There were no cases of vision loss, stent exposure, hypotony, choroidal effusion, lower eyelid malposition, bleb dysesthesia, or bleb-related infection (Fig. 2).

DISCUSSION
This study is the first case series in which XEN gel implantation was undertaken in the inferonasal quadrant after failed trabeculectomy.
Table 1: Demographics and clinical characteristics of patients

| Parameter                                   | Male         | Female       |
|---------------------------------------------|--------------|--------------|
| Gender, n (%)                               | 5 (35.7)     | 9 (64.3)     |
| Age, mean ± SD (range)                      | 63.4 ± 9.7 (52–80) |             |
| Operated eye, n (%)                         | Right        | Left         |
| Preoperative lens status, n (%)             | Phakic       | Pseudophakic |
| Aphanic                                      | 0 (0)        |              |
| Operated eye, n (%)                         | Right        | Left         |
| Diagnosis, n (%)                            | Primary open-angle glaucoma | Pseudoexfoliative glaucoma |
| Preoperative BCVA, mean ± SD (LogMAR)       | 0.16 ± 0.21  |              |

XEN Stent Implantation after Failed Trabeculectomy

Figs 2A to D: (A) The XEN gel stent (arrow) is visible under the conjunctiva with a flat bleb in the right eye; (B) The appearance of an inferonasally located diffuse filtering bleb (*) in the left eye at month 12; (C) Anterior segment photography after XEN stent surgery in the patient who had undergone two failed trabeculectomies and Ex-Press shunt surgery; (D) View of the XEN gel stent in the iridocorneal angle on gonioscopy in the same patient.

The first-year results showed that the inferonasal implantation of the XEN stent was effective in terms of IOP and anti-glaucoma medication reduction. We also observed that half of the cases achieved target IOP without eye medication at 12 months. We achieved a 49.3% mean IOP reduction and 61% glaucoma medication reduction at month 12 from baseline. The changes in IOP and medications were also comparable to outcomes of previous studies with XEN stent.

Traditionally, GDD implantation is the preferred surgical approach in patients with failed trabeculectomy. Subsequent procedures may also include a bleb needling, revision, or a second trabeculectomy. However, all surgical approaches have potential challenges that are often specific to the procedure and are generally have a higher probability of failure than primary trabeculectomy.

The patients in the current study were suitable candidates for a repeat trabeculectomy or a tube shunt surgery as a second surgical option. In the light of studies examining the effect of XEN stent on the corneal endothelium, it may be a good alternative to traditional surgeries, especially considering endothelial cell loss caused by repetitive surgeries. Our clinical experience and available literature have suggested that XEN gel stent surgery is less invasive, easier, and faster to apply, with a low rate of severe complications, hence we have been encouraged to prefer it in these patients.

The superonasal region is the suggested quadrant for XEN implantation. However, a new bleb that is created adjacent to a superiorly located, failed bleb after a trabeculectomy can affect the bleb function and increase the risk of complications due to changes in tenon and conjunctival tissue. Functional bleb formation may not occur due to fibrosis and adhesions, which may indicate the need for needling, second revision surgery, or increase the probability of failure. The application of a second antimetabolite for XEN gel stent or GDDs to the same site may further increase conjunctival damage.

It is necessary to pay attention to the potency, concentration, and exposure time of the selected antimetabolite due to differences in the wound healing response in sequential surgeries. Consequently, the conjunctival support of the implant will be weakened, and the extrusion of the stent will be unavoidable. The earlier reports described implant exposure in patients who underwent XEN implantation in the nasal quadrant close to a scarred bleb after a prior failed glaucoma procedure. XEN stent exposure poses a great risk for late-onset leakage, blebitis, or endophthalmitis. In addition, placing the stent more nasally, further away from the scar tissue may provide surgical convenience. However, a hypertrophic intra-palpebral bleb formation or dysesthesia may occur in nasal localized blebs after XEN surgery or as previously documented after trabeculectomy.

Previous studies reported that the placement of GDD inferiorly has been demonstrated to be safe and effective if there was a conjunctival scarring or a preexisting GDD in the superior quadrant. There are very few articles regarding the efficacy of the XEN stent in patients with failed glaucoma filtration surgeries for refractory glaucoma. Sandhu and Dorey reported that a patient with juvenile OAG who underwent implantation of Ahmed glaucoma valves twice, after a failed trabeculectomy, has achieved adequate IOP reduction after XEN surgery. It has been reported that a patient with refractory neovascular glaucoma was successfully managed with a XEN stent after cyclophacoagulation failed and other surgical options were unsuitable.

Although it is difficult to report a detailed safety analysis due to the low number of patients, inferonasal implantation is well tolerated and no new serious safety concerns have been identified differently from the classical localization. There was no vision loss or sight-threatening complication. Inferonasal implantation slightly complicates the surgical procedure in some cases due to the eyebrow. We think the success rate in our small case series is acceptable, especially given the likelihood that these patients have refractory glaucoma and require more invasive surgeries. Another advantage of the stent that should be kept in mind is that it does not pose a challenge to possible subsequent filtration surgeries. In our series, secondary surgeries were required in two cases due to uncontrolled IOP at 4 or 12 months in each case. We suggest that inferonasal XEN stent implantation is an effective option for eyes with failed trabeculectomy, averting conventional incisional surgery in 85.7% of glaucoma cases.

The XEN gel stent shows promise for patients with glaucoma, but the procedure has been associated with several complications. Although these complications are rare, some of them may result in severe vision loss. Fortunately, bleb-
related infections after XEN surgery have been reported in the upper quadrant blebs in a few cases. In our study, we were concerned about the inferiorly located formation of the subconjunctival bleb and the use of MMC as a risk factor. The presumed risk factors for bleb-related infections have been evaluated in several studies. However, all reports indicate that the risk of endophthalmitis in the inferior filtering blebs is associated with trabeculectomy. Caronia et al. recommended trabeculectomy at the inferior limbus as a possible option for eyes in which the surgical options are limited. However, the filtration blebs associated with the XEN gel stent show some differences from those associated with trabeculectomy. In contrast to the thin-walled perilimbal bleb of a trabeculectomy, the XEN stent usually creates a low, posterior and diffuse bleb formation. Consequently, bleb morphology is not only an important indicator for IOP control after glaucoma surgery but also a predictor of bleb-related complications.

Although XEN surgery does not require conjunctival or scleral dissection or sutures, the anti-scarring medications that we use with trabeculectomy are often applied to achieve functional blebs. In our study, we applied MMC as the most frequently used agent through dissection or sutures, the anti-scarring medications that we use with trabeculectomy, the XEN stent usually creates a low, posterior and diffuse bleb formation. Consequently, bleb morphology is not only an important indicator for IOP control after glaucoma surgery but also a predictor of bleb-related complications.

In the comparative study by Hengerer et al., similar (42.8%) of our study was comparable to those previously published intervention. We do not prefer to use a second MMC injection while in prior studies, needling was not considered a second surgical intervention. We do not prefer to use a second MMC injection while needling to avoid possible complications. The bleb needling rate (42.8%) of our study was comparable to those previously published reports. In the comparative study by Hengerer et al. similar success rates were reported between inferonasal and superonasal implantation. However, the needling rate was lower in the inferior quadrant (27% against 45%). They attributed this positive effect to the lower tension of the lower eyelid. As a result, to minimize complications, patients should be evaluated for the presence of uncontrolled diabetes, eyelid deformities, and blepharitis. Similarly, preoperative conjunctival assessment in the implantation site is required to achieve adequate IOP reduction and for the success of XEN surgery.

Several limitations of this study should be noted. First of all, the population of the retrospective study included only a small group of glaucoma patients with a limited duration of follow-up. In some cases, MMC could not be used during surgery or needling due to the shortage of the drug supply. These differences between cases may affect the interpretation of the results. A detailed comparative analysis was not evaluated due to low numbers in the groups with and without MMC.

**Conclusion**

The current study reveals that the XEN stent implantation in the inferior quadrant can be considered a viable surgical option for glaucoma patients with a history of failed trabeculectomy who require further IOP lowering. Additional prospective studies with larger patient cohorts are required to assess long-term success and to better characterize the late-onset complications after XEN surgery.

**Clinical Significance**
