Energy-efficient plasma-wakefield acceleration of particle bunches with low energy spread is a promising path to realizing compact free-electron lasers and particle colliders. High efficiency and low energy spread can be achieved simultaneously by strong beam loading of plasma wakefields when accelerating bunches with carefully tailored current profiles [M. Tzoufras et al., Phys. Rev. Lett. 101, 145002 (2008)]. We experimentally demonstrate such optimal beam loading in a nonlinear electron-driven plasma accelerator. Bunches with an initial energy of 1 GeV were accelerated by 45 MeV with an energy-transfer efficiency of $(42 \pm 4)\%$ at a gradient of $1.3 \text{ GV/m}$ while preserving per-mille energy spreads with full charge coupling, demonstrating wakefield flattening at the few-percent level.

DOI: 10.1103/PhysRevLett.126.014801

Plasma wakefields [1] driven by intense particle beams [2,3] can provide accelerating gradients in the multi-GV/m range [4–6], promising more compact accelerators for high energy physics and photon science [7–10]. Delivering bunches with low energy spread is a key requirement for realizing high-brilliance free-electron lasers [11] and high luminosity with a narrow energy spectrum in linear colliders [12]. Simultaneously, high energy-transfer efficiency is crucial for minimizing the energy consumption of such machines. The solution to both of these problems is strong beam loading, where the presence of a high-current trailing bunch changes the trajectory of in-flowing plasma-wake electrons expelled by the driver, thereby altering the longitudinal wakefield and efficiently extracting the kinetic energy of the wake [13–16]. By precisely shaping the current profile of this trailing bunch, the longitudinal wakefield can be locally flattened such that all particles experience the same accelerating gradient. Beam loading has already been experimentally demonstrated in a beam-driven plasma accelerator [17,18], resulting in high energy-transfer efficiency (up to $30\%$), but so far with relatively large energy spreads compared to the energy gain. To reach the sub-percent-level energy spread required for applications, the wakefield must be shaped with a similar level of precision. Tzoufras et al. [19] showed that in the nonlinear regime [20,21] optimal beam loading requires the use of trailing bunches with a trapezoidal current profile, precisely tailored according to the bunch location and the strength of the wakefield. Nontrapezoidal (e.g., Gaussian) current profiles can also partially flatten the wakefield, but will result in tails in the accelerated energy spectrum.

In this Letter, we experimentally demonstrate optimal beam loading of a nonlinear plasma wakefield, resulting in simultaneous preservation of per-mille energy spreads, high energy-transfer efficiency, and full charge coupling. The optimized acceleration regime was reached by employing quasitrapezoidal trailing bunches and performing a large multidimensional scan of beam and plasma parameters. Direct measurement of field flattening within the trailing bunch was performed with a novel high-resolution wakefield-sampling technique [22]. While the energy gain was modest, preservation of the small initial energy spread implies that the wakefield was flattened at the few-percent level.

The experiment was performed at the FLASHForward plasma-accelerator facility at DESY [23]. Electron bunches were provided by the FLASH linac [24]; generated with a photoelectron gun and accelerated to 1 GeV using superconducting radio-frequency (rf) cavities. The bunches were compressed by two magnetic chicanes and linearized in longitudinal phase space by a third-harmonic cavity. Three energy collimators in a dispersive section were used for detailed shaping of the current profile [25]: low- and
FIG. 1. (a) A notch collimator with an adjustable width and position, located in a dispersive section, was used to create two bunches from a chirped electron bunch. (b) The resulting current profiles were measured with a downstream TDS. (c) A discharge capillary was used to form a plasma channel. The plasma density was measured to decay exponentially (orange trendline) after the initial discharge—the density was varied by adjusting the beam arrival time. Measurements shortly after the discharge (shaded area) may be inaccurate due to temperature effects [28]. (d) Energy spectra were measured with a dipole spectrometer and a set of quadrupoles for point-to-point imaging. (e) 3D parameter scan of plasma density (1) versus notch position (2) as a function of notch width (3). Each row of plots shows, from the top, measurements at each step of the transformer ratio \( T \), energy-transfer efficiency \( \eta \) and energy-spread-to-gain ratio \( \sigma_\delta \), which were combined into an overall optimization parameter \( \Omega \) [Eq. (2)]. A full characterization was performed at the optimal operating point (red circle).

high-energy collimators for removing the bunch head and tail, respectively, and a wedge-shaped notch collimator for creating a double-bunch profile with an adjustable separation [Figs. 1(a) and 1(b)]. The bunch charge was measured before and after collimation with toroidal current trans-

tion \( \text{[Figs. 1(a) and 1(b)]} \). The bunch charge was measured to decay exponentially (orange trendline) after the initial discharge—the density was varied by adjusting the beam arrival time. Measurements shortly after the discharge (shaded area) may be inaccurate due to temperature effects [28]. (d) Energy spectra were measured with a dipole spectrometer and a set of quadrupoles for point-to-point imaging. (e) 3D parameter scan of plasma density (1) versus notch position (2) as a function of notch width (3). Each row of plots shows, from the top, measurements at each step of the transformer ratio \( T \), energy-transfer efficiency \( \eta \) and energy-spread-to-gain ratio \( \sigma_\delta \), which were combined into an overall optimization parameter \( \Omega \) [Eq. (2)]. A full characterization was performed at the optimal operating point (red circle).

The TDS was only operated with non-plasma-interacted bunches and relaxed beam focusing due to the complexity of transporting high-divergence bunches the full distance (33 m) from the plasma to the TDS measurement screen. High-quality plasma acceleration requires precise control of the transverse phase space of the incoming beam. The matching quadrupoles were set to focus the beam to a waist close to the plasma entrance with a beta function [32] of approximately 10 mm in both planes. The waist location and beta function were then measured and fine-tuned with mm precision using a novel jitter-based measurement technique [33]. An object-plane scan was performed with the imaging quadrupoles, verifying the location of the waist and measuring the horizontal divergence to be \((0.23 \pm 0.03) \text{ mrad}\) in the tail and up to \(1 \text{ mrad}\) in the head (higher due to coherent-synchrotron-radiation effects [34]). These measurements imply minimum beam sizes of \(2–10 \mu \text{m}\) and normalized slice emittances of \(1–20 \text{ mm-mrad}\) (tail to head, respectively). The vertical divergence could not be measured, but is expected to be similar to the horizontal divergence of the tail. In order to inject charge in the very back of the plasma cavity, the bunch was straightened by adjusting quadrupoles and sextupoles in the dispersive section to cancel beam tilts and curvatures, respectively [35]. A plasma density of approximately \(6 \times 10^{15} \text{ cm}^{-3}\) was found to best match the plasma-cavity length to the full (uncollimated) bunch length.

A multidimensional scan of beam and plasma parameters was performed to locate the optimal-beam-loading
operating point. Three important parameters were identified: (1) the plasma density, adjusted by changing the beam arrival time after the discharge; (2) the longitudinal position of the current-profile notch, adjusted by transverse movements of the wedge-shaped notch collimator; and (3) the width of the notch, adjusted by vertical movements of the notch collimator. While the current profile prior to collimation remained constant, the plasma density was used to change the normalized bunch length (relative to the plasma-cavity length), and the two notch parameters were used to change the separation distance and charge ratio between the two bunches. Each parameter was scanned across the full range of values where acceleration could be observed, with a total of $5 \times 13 \times 13$ steps averaged over 15 shots per step; 12,675 shots in total.

At each step, three wakefield properties were calculated from the resulting spectra to evaluate the shape of the longitudinally averaged wakefield: the transformer ratio, the energy-transfer efficiency, and the energy-speed-to-gain ratio. The longitudinally averaged transformer ratio $T$ is calculated as the mean energy gain of the trailing bunch normalized by the maximum energy loss within the driver [36]; the longitudinally averaged energy-transfer efficiency is calculated as

$$\eta = \frac{\Delta\langle E \rangle_{\text{acc}}}{\Delta\langle E \rangle_{\text{dec}}}$$

where $\Delta\langle E \rangle$ denotes the mean energy change of each bunch, $Q_{\text{acc}}$ is the final accelerated charge, and $Q_{\text{dec}}$ is the average of the initial and final decelerated charge—the best estimate of the wake-driving charge in case of charge loss from the driver. Finally, the energy-speed-to-gain ratio, $\sigma_\delta$, is calculated as the full width at half maximum (FWHM) of the accelerated spectrum normalized by the mean energy gain. All three properties ($T$, $\eta$, and $\sigma_\delta$) are dimensionless and instantaneous representations of the wakefield, and therefore allow the quality of the beam-loading process to be evaluated independently of acceleration length and gradient.

Figure 1(e) shows the measurement of the three wakefield properties. This complex parameter space has multiple optima based on the desired objective: the highest transformer ratio was measured to be $(1.61 \pm 0.01)$, the highest efficiency was $(71 \pm 4)$% (subject to systematic errors discussed below), and the lowest energy-speed-to-gain ratio was $(3.1 \pm 0.2)$% FWHM, where the quoted uncertainty represents the root-mean-square (rms) variation at the optimum step. However, a useful operating point requires all properties to be simultaneously optimized. It is therefore helpful to define a new wakefield optimization parameter,

$$\Omega = \frac{\sigma_\delta}{\eta T},$$

as an overall figure of merit. Minimizing this quantity simultaneously minimizes the energy-speed-to-gain ratio $\sigma_\delta$, while maximizing the energy-transfer efficiency $\eta$ and the transformer ratio $T$. Measurements of this optimization parameter show a distinct minimum in the parameter space. A careful characterization was performed at this optimal operating point [red circle in Fig. 1(e)], where the value of $\Omega$ was measured to be $(0.077 \pm 0.012)$—between 1 and 2 orders of magnitude lower than in previous experiments [17,18].

Figure 2(a) shows spectrometer images and spectra for a single shot at the optimal operating point: a $(490 \pm 10)$ pC driver accelerates a 100 pC trailing bunch while preserving (and slightly dechirping [37–39]) the 0.16% FWHM initial energy spread. A small negative skewness (i.e., a low-energy tail) is introduced in the accelerated spectrum, caused by imperfections in the trailing-bunch current profile compared to the ideal shape described by Tzoufras et al. [19]. To ensure good energy resolution, the spectrometer was configured to form a point-to-point image for the mean energy of the trailing bunch in spectrum measurements both with and without plasma interaction.

FIG. 2. (a) Spectrometer images at the optimal operating point [red circle in Fig. 1(e)], as well as the corresponding energy spectra, for shots with and without plasma interaction. The initial energy spread of the trailing bunch is preserved. (b) High stability is observed across 5000 consecutive shots—the energy gain is stable to within 3% rms. (c) In 6.4% of these shots, the energy spread is lower than or equal to the initial energy spread (dotted line). (d) Simultaneously, high energy-transfer efficiency is observed, distributed between 30% and 50%.

014801-3
A 5000-shot high-statistics dataset [Fig. 2(b)] shows that the energy gain was $(45.4 \pm 1.4) \text{ MeV}$—stable to 3% rms. The energy spread was fully preserved in 6.4% of these shots [Fig. 2(c)], while the rest had a median energy spread of $0.2\% \text{ FWHM}$ (a relative increase of 28%), indicating that the optimal operating point is highly sensitive to even low-level jitters in beam or plasma parameters. The energy-transfer efficiency at the optimal operating point was measured to be $(42 \pm 4)\%$ [Fig. 2(d)]. This measurement depends on the accuracy of the charge distribution across the full energy spectrum, which cannot be measured everywhere simultaneously with good resolution—the spectrum is distorted away from the imaging energy due to nonzero divergence and angular misalignments. Therefore, an imaging-energy scan was performed to measure the driver spectrum in 0.5% energy steps—the resulting spliced spectrum is shown in Fig. 2(a). This leads to an energy-efficiency correction of $-3.6$ percentage points (already accounted for in the efficiency quoted above) compared to single-shot spectra where only the accelerated bunch is imaged. This systematic effect is expected to be similar for the efficiency measurements in Fig. 1(e). Furthermore, only 94% of the initial driver charge is measured in the spectrometer. Given that the energy loss of the missing driver charge is unknown, this introduces a systematic uncertainty on the efficiency of $\pm 1.3$ percentage points.

Energy-spread preservation is only strictly meaningful if no charge is lost. Figure 3 shows a tail-collimator scan of the trailing bunch at the optimal operating point, demonstrating that full charge coupling could be achieved with appropriate collimation of the bunch tail. When the collimator is fully extracted, only $(98 \pm 9) \text{ pC}$ of the initial $(176 \pm 3) \text{ pC}$ of charge is accelerated. As the tail of the trailing bunch gets progressively removed, the accelerated charge remains approximately constant until the incoming charge equals the accelerated charge—this is caused by strong defocusing of the trailing bunch as the plasma-sheath electrons return to the axis. Beyond this point, both the incoming and accelerated charge decrease identically, showing an approximately 100% charge-coupling efficiency. Note that the charge jitter decreases significantly (from 10% to 4% rms) when transitioning into the full charge-coupling regime, indicating that if the tail of the trailing bunch reaches the back of the plasma cavity, its coupling is highly sensitive to variations of the cavity length (determined by the plasma density and driver parameters).

Direct measurement of the wakefield flattening was performed using a newly developed wakefield-sampling technique (see Ref. [22] for a complete description). The measurement consisted of a tail-collimation scan of the incoming driver and trailing bunch from tail to head, observing the energy spectrum of each slice as they are removed from the overall spectrum. This scan was performed both with and without plasma interaction in order to calculate the energy change of each slice, and repeated at the TDS to measure the longitudinal position within the current profile of each collimator position (without plasma interaction to allow the beam to be transported). Figure 4(a) shows the measured wakefield for the optimal operating point, demonstrating that it has been locally flattened by the trailing bunch at $-1.29 \text{ GV/m}$, with a variation of 2.8% rms across the 60 $\mu\text{m}$ where the signal-to-noise ratio was sufficiently high. For comparison, a measurement was also performed for the full bunch (i.e., no notch collimator) at a slightly lower density. Calculating the longitudinally averaged wakefield from the overall energy gain requires knowledge of the plasma length. Since the longitudinal plasma density profile is not known in detail, an effective length of 34.2 mm is assumed, slightly shorter than the distance between the two gas inlets (39 mm).

Beam loading can be demonstrated indirectly by comparison of the measured wakefield with an unloaded wakefield from a particle-in-cell (PIC) simulation. For this, accurate modeling of the plasma acceleration process is required. Using longitudinal-phase-space measurements from the TDS and transverse-phase-space measurements from the spectrometer and the BPMs [33], a detailed reconstruction of the 6D beam phase space was possible. The vertical slice emittance was the only parameter that could not be measured and was assumed to be similar to the
horizontal slice emittance of the tail. A flattop plasma density 4% lower than the measured central density [Fig. 1(c)] was found to best match the wakefield measurement, suggesting that any density ramps present had an effect small enough to justify a flat-top model. Simulations were performed with the 3D quasistatic code HiPACE [40] in a grid of $512 \times 512 \times 512$ cells, 4 plasma particles per cell in the wake region, a spatial resolution of 1.18 µm in all dimensions, $4.2 \times 10^6$ beam particles, and a time step of $5\omega_p^{-1}$, where $\omega_p$ is the angular plasma frequency. The simulated longitudinally averaged wakefield is consistent with the sampling measurement for both the optimal operating point and the full bunch. Repeating the optimal-operating-point simulation without a trailing bunch clearly shows that the unloaded wakefield would not have been flat, and that strong beam loading was needed to flatten the field—consistent with the high energy-transfer efficiency observed in the measurement. Simulations indicate that while the initial energy spread would also be preserved for trailing bunches with a similar Gaussian current profile, the accelerated spectrum would have longer tails compared to the quasitrapezoidal bunches used in the experiment. The spread in wakefield amplitude across the trailing bunch (weighted by charge) was reduced by approximately 40% (from 9.3% to 5.8% rms) as a result of this current-profile shaping.

In conclusion, we have experimentally demonstrated optimal beam loading in a plasma-wakefield accelerator. Optimization of the combined wakefield parameter $\Omega$ [Eq. (2)] resulted in simultaneous preservation of per-mille energy spreads, $(42 \pm 4\%)$ energy-transfer efficiency and full charge coupling for 100 pC bunches accelerated with high stability $(3\%$ rms) at a gradient of 1.3 GV/m—all in excellent agreement with simulations. This represents a major step towards precise and application-relevant plasma-wakefield accelerators. Reaching per-mille-level control of the wakefield will enable energy-spread preservation also for larger energy gains, which, combined with emittance preservation, can open the door to a new generation of free-electron lasers and particle colliders.
