ABSTRACT
The Kepler satellite mission was designed to search for transiting exoplanets and delivers single band-pass light curves of a huge number of stars observed in the Cygnus-Lyra region. At the same time, it opens a new window for asteroseismology. In order to accomplish one of the required preconditions for the asteroseismic modelling of the stars, namely knowledge of their precise fundamental parameters, ground-based spectroscopic and/or photometric follow-up observations are needed. We aim to derive fundamental parameters and individual abundances for a sample of 18 γ Dor/δ Sct and 8 SPB/β Cep candidate stars in the Kepler satellite field of view. We use the spectral synthesis method to model newly obtained, high-resolution spectra of 26 stars in order to derive their fundamental parameters like $T_{\text{eff}}$, $\log g$, $v \sin i$, $\xi$, [M/H], and individual abundances with high accuracy. The stars are then placed into the log($T_{\text{eff}}$)–log($g$) diagram and the obtained spectroscopic classification is compared to the existing photometric one. For most A- and F-type stars, the derived $T_{\text{eff}}$ values agree within the measurement errors with the values given in the Kepler Input Catalog (KIC). For hot stars, the KIC temperatures appear to be systematically underestimated, in agreement with previous findings. We also find that the temperatures derived from our spectra agree reasonably well with those derived from the SED fitting. According to their position in the log($T_{\text{eff}}$)–log($g$) diagram, two stars are expected γ Dor stars, four stars are expected δ Sct stars, and four stars are possibly δ Sct stars at the blue edge of the instability strip. Two stars are confirmed SPB variables, and one star falls into the SPB instability region but its parameters might be biased by binarity. Two of the four stars that fall into the δ Sct instability region show γ Dor-type oscillation in their light curves implying that γ Dor-like oscillations are much more common among the δ Sct stars than is theoretically expected. Moreover, one of the stars located at the hot border of the δ Sct instability strip is classified as δ Sct-γ Dor hybrid pulsator from its light curve analysis. Given that these findings are fully consistent with recent investigations, we conclude that a revision of the γ Dor and δ Sct instability strips is essential.

Key words: Stars: variables: delta Scuti – Stars: fundamental parameters – Stars: abundances.

1 INTRODUCTION
Though the primary goal of actual space missions like CoRoT (Convection Rotation and Planetary Transits, Auvergne et al. 2009) and Kepler (Gilliland et al. 2010) is to search for transiting exoplanet systems, the almost uninterrupted time series of high-quality data led to the discovery of a huge number of pulsating stars. This opened up a new era in asteroseismology, the study of stellar interiors via the interpretation of pulsation patterns observed at the surfaces of the stars.

The amount of data delivered by these space missions is huge implying the need in establishing methods of automatic
classification of the stars. In the case of Kepler data, such methods are usually based on the (single band-pass) light curves morphology and/or interpretation of the corresponding Fourier spectrum. Quite often, this leads to simultaneous assignment of the same object to different classes of variable stars. The photometric signal of e.g., an ellipsoidal variable can easily be misinterpreted by rotational modulation due to stellar surface inhomogeneities or by low-frequency stellar pulsations. Moreover, there are classes of pulsating stars like the Gamma Doradus and SPB stars showing the same type of variability in their light curves but residing at different locations in the Hertzsprung-Russell diagram. The way to discriminate between them is to derive their effective temperatures and log g. This is one reason why ground-based follow-up spectroscopic and/or multi-colour photometric observations are essential (see the ground-based follow-up campaign for Kepler asteroseismic targets as described by Uytterhoven et al. 2010a,b). Moreover, high-resolution, high signal-to-noise (S/N) spectroscopic observations allow to unravel the nature of binary and rotationally modulated stars by observing systematic Doppler shifts of all lines in the spectrum or “moving bumps” across the line profiles of certain chemical elements, respectively. The evaluated from ground-based data atmospheric parameters like effective temperature $T_{\text{eff}}$, surface gravity log g, and metallicity [M/H] can further be used for an in depth asteroseismic modelling of stars in combination with high quality photometric data gathered by the satellites.

In this paper, we focus on SPB/$\beta$ Cep and $\gamma$ Dor/$\delta$ Sct candidate stars in the Kepler field of view. The term “Slowly Pulsating B stars” (SPB) was introduced by Waelkens (1991) who detected multiperiodic brightness and colour variations for seven stars with spectral types between B3 and B9. These stars have masses between 3 and 7 M$_\odot$. The observed photometric and radial velocity (RV) variations are interpreted in terms of low degree, high radial order $n$ gravity mode pulsations characterized by intrinsic period $s_n$ (1991) who detected multiperiodic brightness and colour variations for seven stars with spectral types between B3 and B9. These stars have masses between 3 and 7 M$_\odot$. The observed photometric and radial velocity (RV) variations are interpreted in terms of low degree, high radial order $n$ gravity mode pulsations characterized by intrinsic period $s_n$. The theoretical instability strip of SPBs overlaps with the instability region of $\beta$ Cephei ($\beta$ Cep) pulsators, which have higher masses (between 8 and 18 M$_\odot$) and are typically hotter than SPB variables. $\beta$ Cep stars pulsate in low radial order pressure- ($p$-) and gravity- ($g$-) modes with periods between 2 and 8 hours (Aerts et al. 2014).

$\gamma$ Dor and $\delta$ Sct-type stars are the two other classes of variable pulsating stars where the theoretical instability strips overlap. Similar to SPB stars, $\gamma$ Dor stars pulsate in low degree, high order g-modes with periods between 0.5 and 3 days (Kaye et al. 1994). It is difficult to discriminate between $\gamma$ Dor and SPB type pulsators based on the light curve morphology and Fourier spectrum only without having information about the temperature of the star. The observed variability of the $\delta$ Sct stars is understood in terms of low-order p-modes with periods between 18 min and 8 h (Aerts et al. 2010). The fact that $\gamma$ Dor and $\delta$ Sct instability regions overlap suggests that hybrid pulsators showing both pulsation characteristics, i.e., high-order g-modes and lower-order p- and g-modes, must exist.

In this paper, we present the results of the spectroscopic analysis of 8 SPB/$\beta$ Cep and 18 $\gamma$ Dor/$\delta$ Sct candidate stars in the Kepler field of view. After deriving the fundamental parameters of our sample stars, we classify them according to the expected type of variability and compare the results to the classification expected from the Kepler light curve analysis. For every star in the sample, we additionally check the spectra for RV and line profile variation (LPV) to reveal possible binary nature of the star. The observational material and the data reduction procedure are described in Sect. 2. The method and the results of spectrum analysis are presented in Sect. 3 and 4, respectively. We discuss the results obtained for late B- early A-type stars in Sect. 5 and for intermediate A- to early F-type stars in Sect. 6. In Sect. 7 we compare our derived fundamental parameters with the KIC values, the overall conclusions are presented in Sect. 8.

## 2 OBSERVATIONS

We base our analysis on high-resolution, high S/N spectra taken with the Coudé-Echelle spectrograph attached to the 2-m telescope of the Thüringer Landessternwarte Tautenburg. The spectra have a resolution of 32000 and cover the wavelength range from 4720 to 7400 Å. Table 1 represents the journal of observations and gives the Kepler Input Catalog (KIC) number, an alternative designation, the number of obtained spectra, the visual magnitude, and the spectral type as is indicated in the SIMBAD database. The number of acquired spectra is different for different stars since we aimed to reach a S/N of about 100 for the mean, averaged spectrum of each object.

### Table 1. Journal of observations. All spectra have been taken in 2011. $N$ gives the number of acquired spectra, $V$ the visual magnitude, and SpT the spectral type as is indicated in the SIMBAD database.

The data were reduced using standard ESO-MIDAS packages. The data reduction included bias and stray-light subtraction, cosmic rays filtering, flat fielding using a halogen lamp, wavelength calibration using a ThAr lamp, and normalisation to the local continuum. All spectra were additionally corrected in wavelength for individual instrumental packages. The data reduction included bias and stray-light corrections. The data are released in quarters, i.e., periods between two activity and pulsation cycles for each star in the sample. The Kepler spectra were shifted and co-added to build the mean, high S/N averaged spectrum of each star.

We use publicly available data from Long- (time-resolution ~ 30 min.) and Short-cadence (time-resolution ~ 1 min.) Kepler data to make an additional check for binarity, stellar activity and pulsations for each star in the sample. The Kepler data are released in quarters, i.e., periods between two spacecraft rolls. For this study, we use the data from quarters Q0-Q6 (May 2009 - September 2010) where available.

### Table 2. Fundamental stellar parameters. The values labeled with "K" are taken from the KIC and given for comparison. Metallicity values labeled with "[Fe]" refer to the derived Fe abundance.

### 3 METHOD

Our code GSSP [Tkachenko et al. 2012] finds the optimum values of T eff, log g, ξ, [M/H], and v sin i from the minimum in χ² obtained from a comparison of the observed spectrum with the synthetic ones computed from all possible combinations of the above mentioned parameters. The errors of measurement (1σ confidence level) are calculated from the χ² statistics using the projections of the hypersurface of the χ² from all grid points of all parameters onto the parameter in question. In this way, the estimated error bars include any possible model-inherent correlations between the parameters. Possible imperfection of the model like incorrect
atom data, non-LTE effects, or continuum normalization are not taken into account, of course. Fossati et al. (2007, 2008) state that the continuum normalization is a source of abundance uncertainty that can raise from about 0.1 to 0.2 dex for large $v \sin i$. We corrected the observed spectra during the analysis for large-scale imperfections of the continua by adjusting them to the model continua. The errors of the fit become a bit larger in this way, due to the inclusion of additional free parameters. Thus we believe that the latter value mentioned by Fossati et al. (2007, 2008) is an upper limit given that the abundance uncertainty due to small-scale continuum imperfections should decrease with increasing number of analysed spectral lines.

In a recent study by Molenda-Zakowicz et al. (2013) the use of different methods and codes to derive atmospheric parameters for F, G, K, and M-type stars is compared, and lead the authors to conclude that the realistic accuracy in the determination of atmospheric parameters for these types of stars is ±150 K in $T_{\text{eff}}$, ±0.15 dex in [Fe/H], and 0.3 dex in log $g$, even though error calculations for individual programs might result in smaller errors. Hence, we are aware of a possible underestimation of errors in Table 2.

In order to check how reliable our error estimates on elemental abundances are, we made an additional test represented in Figure 1. We have chosen KIC 02571868, the star with large value of $v \sin i$ of about 200 km s$^{-1}$, as its broad and rather shallow lines should have a lower sensitivity to the elemental abundance changes than, e.g., the lines of slowly rotating star KIC 22127324. We would thus expect error bars to be larger for the star with broad lines, at least for the chemical elements represented by sufficient number of individual lines in the stellar spectrum (e.g., Fe). Figure 1 compares a part of the observed spectrum of KIC 02571868 with synthetic spectra computed assuming differing Fe abundance that varies within the quoted error bars of ±0.15 dex (see Table 3). These rather small changes in Fe abundance cause quite clear deviations in the synthetic spectra and hence the difference in the quality of the fit. The corresponding values of $\chi^2$ deviate from the optimal fit value by slightly more than 1σ confidence level which is assumed to represent the errors of measurement as described above. The fact that the abundances of elements like Ti, Ca, etc. are derived for slowly rotating star KIC 22127324 with lower precision than it is actually for the fast rotator KIC 02571868, is due to significant difference in atmospheric parameters, and the temperature in particular. The above mentioned elements are represented by a few, rather weak lines in the spectrum of KIC 12217324, which obviously makes estimation of their abundances more challenging in this case and facilitates an increase of the corresponding error bars.

A detailed description of the method and its application to the spectra of Kepler β Cep and SPB candidate stars as well as δ Sct and γ Dor candidate stars are given in Lehmann et al. (2013) and Tkachenko et al. (2012), respectively.
For the calculation of synthetic spectra, we use the LTE-based code SynthV [Tsymbal 1996] which allows to compute the spectra based on individual elemental abundances. The code uses pre-calculated atmosphere models which have been computed with the most recent, parallelised version of the LLmodels program [Shulyak et al. 2004]. Both programs make use of the VALD database [Kupka et al. 2004] for a pre-selection of atomic spectral lines. The main limitation of the LLmodels code is that the models are well suitable for early and intermediate spectral type stars but not for very hot and cool stars where non-LTE effects or absorption in molecular bands may become relevant, respectively.

4 RESULTS

Table 2 summarizes the results of spectrum analysis for all stars of our sample. The first four columns of the table represent correspondingly the KIC-number of the star, and effective temperature $T_{\text{eff}}$, surface gravity $\log g$, and metallicity $[M/H]$ as is indicated in the KIC. The five following columns list the stellar parameters derived from our spectra, while the last two columns represent the spectral types as estimated from $T_{\text{eff}}$ and $\log g$ given in the KIC and determined in this work, respectively. In both cases, the spectral types and the luminosity classes have been derived using an interpolation in the tables published by Schmidt-Kaler (1982). Metallicity values labeled with “(Fe)” refer to the derived Fe abundance, the corresponding measurement errors are given in Table 3. For the eight hottest stars of the sample (late B- to early A-type stars), the micro-turbulent velocity was fixed to a standard value of 2 km s$^{-1}$ because of the strong correlation between $\xi$ and $T_{\text{eff}}$ for higher temperatures (see Figure 2 in Lehmann et al. 2011). In practice, this means that the errors in $\xi$ rise up to about 1.5 km s$^{-1}$ for stars with $T_{\text{eff}} > 10 000$ K and to about 3–4 km s$^{-1}$ for stars hotter than 15 000 K. The results thus appear to be almost insensitive to the microturbulent velocity in this case.

Table 2 also lists the elemental abundances derived for each target star. The metallicity given in the second column of the table refers to the initially derived chemical composition and was used as initial guess for the determination of the individual abundances. The latter are given relative to solar values, i.e. negative/positive values refer to an under-/overabundance of the corresponding element compared to the solar composition. We assume the chemical composition of the Sun given by Grevesse et al. (2007), corresponding values are listed in the header of Table 2 below the element designation. For five stars we have reached the lower metallicity limit of $-0.8$ dex in our grid of atmosphere models (KIC 07827131, 08351193, 10974032, 11572666 and 11874676) and give the derived Fe abundance instead. In all other cases, the derived Fe abundance matches the derived metallicity within the quoted error bars.

Similar to the results reported in two of our previous papers [Lehmann et al. 2011; Tkachenko et al. 2012], we find that the temperatures listed in the KIC are in general underestimated for the hotter stars. In the following, we discuss the results on individual stars in more detail.

4.1 Late B- early A-type stars

Two of eight stars, KIC 08351193 and 10974032, are found to be metal poor with metallicities below the lower limit of $-0.8$ dex in our grid of atmosphere models. Both stars show nearly solar He abundance and overabundance of Mg compared to the derived Fe content, while the spectrum of KIC 08351193 additionally exhibits strong enhancement of Si. Both are fast rotators and hotter than is expected from the KIC. The surface gravity is consistent with the one listed in the KIC in both cases. Balona et al. (2011) reports the effective temperatures of 10 210 K and 11 000±400 K for KIC 08351193, determined from Strömgren photometry and from spectral energy distribution (SED) fitting to the combined SDSS, 2MASS, and Strömgren colours, accordingly. The first value agrees within the error bars with the one we determine spectroscopically in this study. The two spectra we obtained for KIC 10974032 is not enough to conclude about the presence of line profile variation (LPV). The light curve of this star is irregular, typical of that of an active star. The four spectra of KIC 08351193 do not show LPV either, though the star is classified as rotationally modulated by Balona et al. (2011). KIC 02859567 and 03629496: two fast rotating late B-type stars showing large deviations of the derived parameters from those listed in the KIC. Both stars show significant underabundances of Fe compared to the solar composition though consistent with the derived metallicity in both cases. Both show about solar He content and slight overabundances of Si. The spectrum of KIC 02859567 additionally exhibits an excess in Mg. Figure 2 compares the observations with two synthetic spectra computed from our optimised and the KIC parameters in a small wavelength region around H$\beta$.

The big difference in the quality of the fit is primarily explained by the difference in the assumed temperatures and confirms the conclusion made by Molenda-Zakowicz et al. (2010) that $T_{\text{eff}}$ given in the KIC is too low for stars hotter than about 7000 K. The deviation in general becomes larger the hotter the stars. No signatures of binarity nor stellar activity could be found in the light curves of both stars. KIC 03629496 is classified by Balona (2011) as a beating star with a dominant contribution in the frequency range between 2 and 4 c d$^{-1}$. KIC 02859567 in turn exhibits very low-amplitude photometric variability in the same frequency regime making it a SPB candidate.

KIC 07974841 and 08018827: Both stars show clear variability in their light curves. KIC 07974841 is found in the Washington Double Star Catalog as WDS 19466+4346. The primary and secondary components are assumed to be of 8.24 and 11.32 mag, correspondingly; the magnitude of the primary is consistent with the visual magnitude found in the SIMBAD database. The Kepler light curve of the star is too irregular to be explained by ellipsoidal effects occurring in close binary systems and is rather due to rotational modulation, stellar pulsations or a combination of both. Balona et al. (2011) classify the star as rotationally modulated SPB variable, where the rotation signal dominates the pulsation one. Our two spectra do not show any variability that could be attributed to the binary nature of the star, neither global Doppler shifts of spectral lines nor any signature of the second star in the residuals of spectrum fitting.
Table 3. Metallicity and elemental abundances relative to solar ones in dex. Metallicity values labeled with “(Fe)” refer to the derived Fe abundance.

Abundances are not evaluated
Spectra is not enough to confirm binarity spectroscopically, which is expected for such close binary systems. Our two to the primary minimum points towards a circular orbit and slightly depleted for KIC 07974841. The latter star additionally exhibits strong depletion of He while nearly solar metallicity – solar (dashed lines) and sub-solar (solid lines). Table 4 summarizes the results of classification. According to their position in the log(T_{eff})–log(g) diagram, three of the hottest stars in our sample (labels b, c, and d) are found to be SPB-type variables, one is classified as “possibly SPB” (label h), and four stars are either to cool (labels a, f, and g) or too evolved (label e) to be SPBs.

4.1.1 Position in the log(T_{eff})–log(g) diagram

In this section, we discuss the positions of the stars in the log(T_{eff})–log(g) diagram with respect to the theoretical SPB and β Cep instability strips as described by Miglio et al. Table 5 summarizes the results of classification. According to their position in the log(T_{eff})–log(g) diagram, three of the hottest stars in our sample (labels b, c, and d) are found to be SPB-type variables, one is classified as “possibly SPB” (label h), and four stars are either to cool (labels a, f, and g) or too evolved (label e) to be SPBs.
Two out of the four potential pulsators, KIC 08018827 and 12217324 (labels d and h), are claimed to be non-pulsating stars by Balona et al. (2011), who attribute their photometric variability to rotation effects. KIC 08018827 exhibits the light curve and Fourier spectrum typical of close binary systems. Binarity is expected to have an effect on the spectroscopically derived Teff and log g, and thus on the position of the star in the log(Teff)–log(g) diagram. This makes spectroscopic classification of this star rather uncertain. KIC 12217324 is found close to the cool edge of the SPB instability strip. Given that this star does not show remarkable LPV nor peculiarities in terms of individual abundances, it is considered by us as an SPB candidate pulsator.

Two out of three cool stars (labels f and g) are low metallicity stars. Moreover, for both stars the light curve morphology suggests rotational modulation due to stellar surface inhomogeneities. According to their position in the log(Teff)–log(g) diagram, these stars should not pulsate which confirms their photometric classification. KIC 02859567 (label a) is the only star among these three that shows low-amplitude SPB-type pulsations in its Fourier spectrum but is clearly outside the corresponding theoretical instability region.

According to its position in the diagram, KIC 08324268 (label e) is too evolved to be an SPB variable. However, the LPV detected in the spectra of this star is so strong that it prevents the derivation of individual abundances and might affect the derived fundamental parameters. Thus, similar to KIC 08018827, the spectroscopic classification of this star is rather uncertain.

4.2 Intermediate A- to early F-type stars

In this section, we discuss a sub-sample of 18 γ Dor/δ Sct candidate stars. Twelve out of these 18 stars are divided into three arbitrary groups, “Stars with composite spectra”, “Stars showing clear LPV”, and “Stars with peculiar abundances”, according to their type of spectrum variability. Finally, we classify the stars according to their positions in the log(Teff)–log(g) diagram and compare the results with the classification expected from the analysis of Kepler light curves.

4.2.1 Stars with composite spectra

KIC 04180199, 11572666, and 11874676: three rapidly rotating stars exhibiting similar photometric and spectroscopic characteristics. The spectra are characterized by sharp central cores superimposed on the broad absorption features extending typically from −300 to +300 km s\(^{-1}\). Figure 7 (top) shows LSD-profiles computed from nine individual spectra of KIC 04180199. The profiles are shifted in Y-axis for clarity. The lines have broad wings and timely variable sharp central cores. The bottom panel of Figure 7 compares the observed spectrum of KIC 04180199 with two synthetic spectra computed from our optimised parameters and convolved with different v\(\sin i\) of 180 km s\(^{-1}\) and 30 km s\(^{-1}\). The positions of the majority of the spectral lines in the green spectrum coincide with the sharp features seen in the observed spectrum. The fact that both sharp and broad components are stationary in RV excludes binarity as a cause of the observed spectrum variability.

Mantegazza & Pureti (1996) report the detection of the composite spectrum of the δ Sct star X Caeli (HD 32846). Its spectral lines show a complex behaviour with sharp central cores superimposed on broad absorption features. The narrow core absorption was found to be stable in time both in shape and position, excluding stellar pulsations or orbital motion as first sight causes. Moreover, the radial velocity of the core was found to be comparable to that of the stellar barycenter making it improbable that it comes from a foreground star, for example. The authors thus suggest a model consisting of a δ Sct variable star exhibiting broad spectral lines that has a circumstellar shell characterized by the narrow absorption cores superimposed on the photospheric lines of the central object. Our stars show similar behaviour with the exception that the narrow absorption core seems to be variable on a short time scale (cf. Figure 4 top). None of the stars is referred as a binary in the literature. Instead, KIC 04180199 and 11572666 have been classified by Vuyterhoeven et al. (2011) as hybrid γ Dor-δ Sct and KIC 11874676 as δ Sct pulsators.

All three stars have low metallicities with clear enrichment of Si, Mg, and possibly C in their atmospheres. The difference between the derived and the KIC temperatures does not exceed 400 K in the worst case of KIC 11874676.

Table 4. Classification of late B- to early A-type stars based on their position in the log(Teff)–log(g) diagram.

| KIC number | Diagram | Variability | Other | label |
|------------|---------|-------------|-------|------|
| 03629496   | beating (SBP)?\(^2\) | SPBs | rotation+SBP\(^1\) | b |
| 07974841   | SPBs | rotation \(^1\)/binary \(^3\) | d |
| 08018827   | rotation \(^1\) | possibly SPB | rotation | h |
| 12217324   | possibly SPB\(^3\) | too cool | rotation | a |
| 08351193   | too cool | rotation\(^1\) | g |
| 10974032   | too evolved | rotation\(^1\) | e |
| 08324268   | too evolved | rotation\(^1\) | e |

\(^1\)Balona et al. (2011), \(^2\)Balona (2011), \(^3\)this paper (light curve morphology, visual inspection)
while the deviations in log \( g \) are more remarkable and reach 0.6 dex in the case of KIC 11572666. Given the complexity of the spectra described above, both the fundamental parameters and the individual abundances are uncertain.

4.2.2 Stars showing clear LPV

KIC 02987660, 07827131, 08489712, and 10537907: These are four stars showing remarkable line profile variations in their spectra. Figure 8 shows individual LSD spectra of KIC 02987660 as an example of bumps moving across the profile, possibly caused by stellar oscillations. Two of the stars, KIC 02987660 and 07827131, are reported by Uytterhoeven et al. (2011) to be correspondingly \( \delta \) Sct and \( \gamma \) Dor-type pulsators, while the two others, KIC 09351622 and 10537907, are found to be of \( \gamma \) Dor-\( \delta \) Sct hybrid type. All four stars show individual abundances consistent with the derived metallicity within the errors of measurement.

4.2.3 Stars with peculiar abundances

KIC 05356349: Though the star is in the Washington Double Star Catalog (WDS J19196+4035AB), Uytterhoeven et al. (2011) classify it as a single star of \( \gamma \) Dor-\( \delta \) Sct hybrid type. Our two spectra are not enough to conclude on binarity. Some peculiarities in individual abundances are detected, however. Ti and Cr are found to be underabundant by correspondingly 0.6 and 0.5 dex compared to the metallicity of the star, while Mg is enhanced by roughly the same value.

KIC 07827131: This star was first reported to be variable by Magalashvili & Kumsishvili (1976). It is classified as \( \delta \) Sct hybrid pulsator by Uytterhoeven et al. (2011). According to our findings, this is a low-metallicity star with unusually low Ti content (\(-1.85\) dex compared to the solar composition) and an enrichment of Si of about 0.6 dex compared to the derived metallicity. As for the previously discussed object, we have only two spectra which is not enough to conclude on either LPV or binarity.

KIC 09351622, 09291618, and 10096499: These are three stars with an enhanced Si content, up to 0.9 dex compared to the derived metallicity in the case of KIC 09015335. According to Uytterhoeven et al. (2011), two stars, KIC 08489712 and 09291618, are pure \( \gamma \) Dor and \( \delta \) Sct variables, accordingly, while the third star, KIC 08915335, has a light curve and Fourier spectrum characteristic of \( \gamma \) Dor-\( \delta \) Sct type hybrid pulsators. None of the three stars shows remarkable LPV nor Doppler shifts of spectral lines pointing to binarity.

4.2.4 Position in the \( \log(T_{\text{eff}}) - \log(g) \) diagram

Figure 9 shows the positions of all intermediate A- to early F-type stars of our sample in the \( \log(T_{\text{eff}}) - \log(g) \) diagram, together with the \( \delta \) Sct (solid lines) and \( \gamma \) Dor (dashed lines) observational instability strips as given by Rodríguez & Breger (2001) and Handler & Shobbrook (2002), accordingly. Table 5 classifies the stars according to their type of variability, listing the classifications expected from their location in the \( \log(T_{\text{eff}}) - \log(g) \) (Figure 9) and derived by Uytterhoeven et al. (2011) from the frequency analysis of the Kepler light curves. We find three stars (labels m, v, and z) which are too hot and five stars (l, n, r, and s) which are too evolved to be \( \gamma \) Dor or \( \delta \) Sct variables. Four of them, KIC 05356349, 07827131, 08489712, and 08915335 (labels m, q, r, and s), exhibit peculiar individual abundances and have been discussed in detail in the previous section. KIC 12153021 (label z) does not show any remarkable variability in its light curve nor in the spectra and seems to be a constant star. Three further stars, KIC 04989000, 05437206, and 10096499 (labels l, n, and v) have been found by Uytterhoeven et al. (2011) to show both \( \gamma \) Dor- and \( \delta \) Sct-type pulsations, thus they appear to be hotter from our spectroscopic analysis than it is expected from the photometric classification.
5 STELLAR TEMPERATURES FROM SPECTRAL ENERGY DISTRIBUTIONS

The effective temperature of the stars can be estimated from the spectral energy distribution (SED). For our target stars, the SED was constructed from literature photometry, using 2MASS (Skrutskie et al. 2006), Tycho B and V magnitudes (Høg et al. 1997), USNO-B1 R magnitudes (Monet et al. 2003) and TASS I magnitudes (Droege et al. 2006), supplemented with CMC14 r' magnitudes (Evans et al. 2002) and TD-1 ultraviolet flux measurements (Carnochan 2006).

The SED can be significantly affected by interstellar reddening. We have, therefore, estimated this effect from the equivalent widths of the interstellar Na D lines present in our spectra. E(B − V) was calculated using the relation given by Munari & Zwitter (1997). For resolved multi-component interstellar Na D lines, the equivalent widths of the individual components were measured. The total E(B − V) in these cases is the sum of the reddening per component, since interstellar reddening is additive (Munari & Zwitter 1997).

The SED was de-reddened using the analytical extinction fits of Seaton (1979) for the ultraviolet and Howarth (1983) for the optical and infrared.

$T_{\text{eff}}$ values were determined by fitting solar-composition Kurucz (1993) model fluxes to the de-reddened SED. For that, the model fluxes were convolved with photometric filter response functions. A weighted Levenberg-Marquardt non-linear least-squares fitting procedure was used to find the solution that minimized the difference between the observed and model fluxes. Since log $g$ is poorly constrained by the SED, we fixed log $g=4.0$ for all the fits. The results are given in Table 5. The uncertainties in $T_{\text{eff}}$ include the formal least-squares error and adopted uncertainties in $E(B − V)$ of ±0.02 and log $g$ of ±0.5 added in quadrature.

Figure 10 compares the spectroscopically derived effective temperatures with those obtained from the SED fitting. There are four stars (KIC 03629496, 07827131, 08351193, and 08489712) for which the difference between the two temperatures is larger than the quoted error bars, otherwise the values agree within the error of measurement. For all four stars the SED temperatures are higher than the spectroscopic value. Two stars, KIC 07827131 and 08351193, are low metallicity objects both showing remarkable enhancement of Si abundance. This peculiarity can possibly explain the observed disagreement in temperatures. KIC 08489712 also shows peculiar behaviour in the sense of significant over- and underabundances of Si and Ti, accordingly. There is no obvious reason why the two temperatures differ by about 800 K for KIC 03629496, however.

6 COMPARISON WITH THE KEPLER INPUT CATALOG

Figs. 11 and 12 compare the spectroscopically derived atmospheric parameters ($T_{\text{eff}}$, log $g$, and [M/H]) with the KIC values. The typical errors of the KIC data of ±200 K for $T_{\text{eff}}$ and of ±0.5 dex for both log $g$ and metallicity are assumed. As it was for the first time reported by Molenda-Zakowicz et al. (2010) and later on confirmed by Lehmann et al. (2011).
In the KIC (cf. Figure 11). We think that this deviation from the cool objects in our sample both showing large discrepancy of more than 1500 K between spectroscopic and KIC temperatures. Thus, it is not surprisingly at all that they also show large deviations of the spectroscopically derived log \( g \) from the KIC values. KIC 03629496 additionally has larger \( \Delta[M/H] \) than it would be expected from the observed general tendency for this parameter. In the case of KIC 08324268 neither our derived fundamental parameters nor the KIC values provide satisfying fit of the observed spectrum, whereas our parameters are much more appropriate than the KIC ones for KIC 03629496 (cf. the bottom panel of Figure 14 for the quality of the fit).

\[ KIC 10096499: \] The deviation of the optimised \( g \) from the KIC value is larger than it would be expected from the general tendency for this parameter. Our spectroscopic parameters provide a much better fit of the observations than the KIC values. Figure 15 illustrates the quality of the spectrum fit by two synthetic spectra computed from our optimised and KIC parameters.

\[ KIC 04989900: \] This star is an obvious outlier in the \([M/H] - \Delta[M/H]\) plane. The KIC metallicity of \(-1.87\) is much lower than our optimised value. Fig. 14 compares the observed (black, solid line) spectrum with two synthetic spectra computed from our optimised (red, dashed line) and the KIC (green, dotted line) fundamental parameters. It can be seen that the KIC-based fit seriously underestimates the strengths of the metal lines.

### 7 CONCLUSIONS

We used the spectral synthesis method to determine the fundamental atmospheric parameters of 26 stars in the Kepler satellite field of view, of which 18 were proposed to be \( \gamma \) Dor/\( \delta \) Sct candidate pulsators (Uytterhoeven et al. 2011), and compare our values with those listed in the Kepler Input Catalog. Similar to the results reported by Molenda-Zakowicz et al. (2010) and Lehmann et al. (2011), the KIC temperatures are systematically underestimated for stars hotter than about 7000 K. The same conclusion is valid for our stars: most of the stars from intermediate A- to late B- spectral type have spectroscopic temperatures remarkably higher than those listed in the KIC. The stars of later spectral types and thus of lower temperatures show good agreement with the KIC values, with the coolest object.

KIC 08324268: These are the two hottest stars in our sample both showing large discrepancy of more than 1500 K between spectroscopic and KIC temperatures. Thus, it is not surprisingly at all that they also show large deviations of the spectroscopically derived \( \log g \) from the KIC values. KIC 03629496 additionally has larger \( \Delta[M/H] \) than it would be expected from the observed general tendency for this parameter. In the case of KIC 08324268 neither our derived fundamental parameters nor the KIC values provide satisfying fit of the observed spectrum, whereas our parameters are much more appropriate than the KIC ones for KIC 03629496 (cf. the bottom panel of Figure 14 for the quality of the fit).

Table 6. Stellar Effective Temperatures from Spectral Energy Distributions

| KIC          | \( E(B-V) \) | \( T_{\text{eff}} \) | SED Notes |

*indicates multi-component interstellar Na D lines

Parameters. The given error bars are the combined spectroscopic and KIC errors. Stars that are outliers with respect to the observed general tendency are marked by their KIC numbers and discussed in the following.

\[ KIC 03629496 \] and \[ 08324268 \]: These are the two hottest stars in our sample both showing large discrepancy of more than 1500 K between spectroscopic and KIC temperatures. Thus, it is not surprisingly at all that they also show large deviations of the spectroscopically derived \( \log g \) from the KIC values. KIC 03629496 additionally has larger \( \Delta[M/H] \) than it would be expected from the observed general tendency for this parameter. In the case of KIC 08324268 neither our derived fundamental parameters nor the KIC values provide satisfying fit of the observed spectrum, whereas our parameters are much more appropriate than the KIC ones for KIC 03629496 (cf. the bottom panel of Figure 14 for the quality of the fit).

\[ KIC 10096499: \] The deviation of the optimised \( g \) from the KIC value is larger than it would be expected from the general tendency for this parameter. Our spectroscopic parameters provide a much better fit of the observations than the KIC values. Figure 15 illustrates the quality of the spectrum fit by two synthetic spectra computed from our optimised and KIC parameters.

\[ KIC 04989900: \] This star is an obvious outlier in the \([M/H] - \Delta[M/H]\) plane. The KIC metallicity of \(-1.87\) is much lower than our optimised value. Fig. 14 compares the observed (black, solid line) spectrum with two synthetic spectra computed from our optimised (red, dashed line) and the KIC (green, dotted line) fundamental parameters. It can be seen that the KIC-based fit seriously underestimates the strengths of the metal lines.

Figure 10. Comparison between the effective temperatures derived spectroscopically (open circles) and from the SED fitting (stars). The stars are sorted by the spectroscopic value starting with the coolest object.
we find that the photometric KIC $T_{\text{eff}}$ values are systematically underestimated for stars hotter than about 7000 K. Deviations that may reach several thousands Kelvin for hot stars (see e.g., Lehmann et al. 2013) are probably due to the interstellar reddening that was not properly taken into account when estimating the KIC temperatures.

Comparing the spectroscopically derived values of $[\text{M/H}]$ and $\log g$ with the KIC values, we find hints to a correlation of the deviations with the parameter values itself. The correlation is stronger for $[\text{M/H}]$. Four stars show larger deviations from this general tendency. Except for KIC 08324268 that shows strong LPV, our parameters provide a much better fit of the observed spectrum than the KIC values, however.

Comparison between the spectroscopically derived temperatures and those obtained from the SED fitting reveals a good agreement for all but four stars. For three stars, KIC 07827131, 08351193, and 08489712, chemical composition peculiarities (particularly, Si and Ti abundances) might be a possible reason for the observed discrepancy.

The spectroscopically derived values of $T_{\text{eff}}$ and $\log g$ allow us to place the stars in the $\log(T_{\text{eff}})$-$\log(g)$ diagram and classify them by checking their location relative to the theoretical SPB/β Cep (for B-type stars) and observational γ Dor/δ Sct (for A- and F-type stars) instability strips. Our spectroscopic classification was then compared to the photometric one for both B-type (Balona 2011; Balona et al. 2011) and A- and F-type (Uytterhoeven et al. 2011) stars. We confirm two SPB pulsators, KIC 03629496 and 07974841, and find two more stars, KIC 08018827 and 12217324, that fall into or lie close the SPB instability region but were classified by Balona et al. (2011) as rotationally modulated stars. We detected a clear signature of eclipses in the light curve of KIC 08018827. Binarity can have an impact on the spectroscopically derived $T_{\text{eff}}$ and $\log g$ which in turn biases the classification according to the type of variability. No such hints including LPV have been found for KIC 12217324. Three other stars, KIC 02859567, 08351193, and 10974032, are too cool to be SPBs and too hot to be δ Sct variables. According to the photometric classification, however, one of these stars (KIC 02859567) is possibly a SPB pulsator while the variability of two others is attributed to rotation effects. Finally, we find one star, KIC 08324268, which is too evolved to be a SPB pulsator but its spectroscopic parameters might be biased by strong LPV detected in the spectra.

Among the A-F type stars of our sample, we find two γ Dor pulsators (KIC 04180199 and 11572666) and four δ Sct stars lying in the expected region of the $\log(T_{\text{eff}})$-$\log(g)$ diagram. Two out of these four stars show δ Sct oscillations in their light curves, in one star δ Sct and γ Dor-typical oscillations co-exist, and one star is a pure γ Dor pulsator. Four further stars, KIC 02859567, 08351193, and 10974032, are located at the hot border of the δ Sct instability region. These stars are classified by us as “possibly δ Sct” pulsators and one of them surprisingly shows γ Dor-typical oscillations in its light curves. Furthermore, we found eight stars that are either too hot or too evolved to be γ Dor- or δ Sct-type variables, though all but one show characteristic γ Dor-like pulsations in their light curves.

Uytterhoeven et al. (2011) presents a general characterization of 750 candidate A-F type stars in the Kepler field of view and find strong evidence for the existence of γ Dor and δ Sct stars beyond the edges of the current observational instability strips. The authors conclude that a revision of the instability strips is needed in order to accommodate the Kepler δ Sct and γ Dor stars. The same conclusion is drawn by Grigahcène et al. (2010) concerning theoretical γ Dor and δ Sct instability strips. The authors characterize a sample of 234 stars showing δ Sct and γ Dor frequencies in their light curves and find that the boarders of theoretical instability strips are not a good match for the observations. Similar to the findings of these two groups, we found that γ Dor-typical oscillations are much more com-

Figure 11. Same as Fig. 10 but for comparison with the KIC values (filled boxes).

Figure 12. Comparison of the spectroscopically derived metallicity $[\text{M/H}]$ (top) and surface gravity $\log g$ (bottom) with the KIC values. The solid lines represent linear fits to the data points after removing the marked outliers.
