Summary CA19-9, a serum marker for pancreatic cancer, gives false-negative results in patients who are negative for the Lewis blood group phenotype. To determine whether other markers may compensate for this drawback, serum levels of CA50, Span-1, sialyl SSEA-1 and Dupan-2 were assayed and compared with those of CA19-9 in 207 normal subjects and in 200 patients with pancreatic carcinoma whose Lewis blood group phenotypes were confirmed. In normal subjects with the Lewis negative phenotype, the serum levels of CA50 and Span-1, as well as CA19-9, were significantly low, whereas those of sialyl SSEA-1 were independent of the Lewis blood group phenotype. Serum levels of Dupan-2 were significantly higher in normal subjects with the Le(a–b–) phenotype as compared with those with Le(a–b+). The sensitivity for pancreatic carcinoma was 81% for CA19-9, 84% for CA50, 82% for Span-1, 51% for sialyl SSEA-1 and 63% for Dupan-2. Among the 39 CA19-9 negative patients, 13 were determined as being Lewis negative by the serum dot-ELISA technique. Although the positive rates were essentially comparable when each marker was combined with CA19-9, a highly elevated serum level of Dupan-2, which strongly suggested the presence of malignancy, was most frequently encountered in 39 patients who were not diagnosed by CA19-9 assay, especially those with Lewis negative blood groups. With regard to the three other markers, we found few patients with a highly elevated serum level in either the Lewis-negative or -positive groups. We conclude that Dupan-2 tended to be elevated in patients with pancreatic cancer who were negative for the Lewis blood group phenotype.

CA19-9 is generally accepted as being the most reliable serum marker for diagnosing pancreatic carcinoma (Koprowski et al., 1979; Del Villano et al., 1983). However, its clinical application is limited to patients with the corresponding Lewis antigen phenotype because those individuals with the Le(a–b–) phenotype cannot synthesise sialyl Lewis A (CA19-9) (Pour et al., 1988; Hirano et al., 1987). A variety of other tumour markers, including CA50 (Lindholm et al., 1983; Holmgren et al., 1984), sialyl SSEA-1 (Fukushi et al., 1984; Kannagi et al., 1986), Dupan-2 (Metzgar et al., 1982; Metzgar et al., 1984; Sawabu et al., 1986; Chung et al., 1990) and Span-1 (Chung et al., 1987; Kiriyama et al., 1990) have recently been reported as being useful for diagnosing pancreatic carcinoma. These markers would be expected to compensate for this diagnostic limitation of CA19-9. However, there are no publications concerning the incidence of CA19-9 negative cases of pancreatic cancer as related to the Lewis blood group system. Few reports have considered which marker may compensate for this drawback of CA19-9. The objective of this paper was to clarify this clinical issue. Accordingly, we studied the influence of the Lewis blood group system on each of those assays by measuring their serum levels in normal subjects with various Lewis blood groups and in patients with pancreatic carcinoma confirmed to have the Lewis-negative phenotype.

We performed the serum dot-enzyme-linked immunosorbent assay (dot-ELISA) for Lewis antigens in 200 patients with confirmed pancreatic carcinomas to identify those with a Lewis-negative blood phenotype. A higher prevalence of Le(a–b–) phenotype has been reported in such conditions as alcoholic cirrhosis, alcoholic pancreatitis (Stigendal et al., 1984) and normal pregnancy (Hammer et al., 1981). Although the exact mechanism for this phenomenon is unclear, the amount of antigen absorbed onto the cell membrane from plasma is decreased in those conditions. In a previous report we showed that, in pancreatic cancer, the Lewis blood group antigen is frequently lost from the erythrocytes leading to false-negative results in haemagglutination testing, even in the presence of Lewis antigen in serum or saliva (Hirano et al., 1987). The expression of incompatible Lewis blood-group antigen has also been observed in the erythrocytes and saliva of other cancer patients (Yazawa et al., 1988). Many patients with pancreatic cancer showed Le(a–b–) phenotype by the haemagglutination technique and frequently had elevated serum levels of CA19-9. However, Le(a–b–) patients with elevated CA19-9 levels were determined to be Lewis positive by the serum dot-ELISA test. Lewis blood group antigens were rarely observed in the sera of Le(a–b–) patients with lower serum CA19-9 levels by this technique. Accordingly, serum dot-ELISA was considered to be a reliable test for determining the Lewis negative phenotype of patients with pancreatic cancer who produce little or no CA19-9.

Materials and methods

Normal subjects and Lewis blood group typing

Citrated blood was collected from 207 apparently healthy subjects, 97 men and 110 women whose mean age was 47.9 ± 10.4; range 23 to 75 years. The Lewis phenotype of their erythrocytes was determined by the conventional haemagglutination test performed by mixing one drop of red blood cells suspended in saline with one drop of a solution of anti-Le4 and anti-Le6 monoclonal antibodies (Chemibiomed, Edmundton, Canada) respectively.

Identification of Lewis-negative phenotype in patients with pancreatic carcinoma

Serum dot-ELISA was performed in 200 patients with pancreatic carcinoma according to the method of Hawkes et al. (Hirano et al., 1987; Hawkes et al., 1982). Serum samples were dropped onto nitrocellulose membrane, blocked with 5% normal goat serum (Dakopats, Glostrup, Denmark), and reacted with the anti-Le6 and anti-Le6 antibodies (9-fold dilution). The membrane was then exposed to peroxi-}

not develop for either antibody, the patient was considered to be Lewis antigen-negative.

Assays for tumour markers
In addition to CA19-9, we assayed four other tumour markers in clinical use: CA50, sialyl SSEA-1, Dupan-2 and Span-1. The following commercial diagnostic kits were used: CA19-9, radioimmunoassay (RIA) kit (Centecor, Inc. Pennsylvania, USA); CA50, time-resolved fluoroimmunoassay kit (Pharmacia, Upsala, Sweden); sialyl SSEA-1, RIA kit (Otsuka Assay, Tokushima, Japan); Dupan-2, enzyme-immunoassay (ELA) kit (Kyowa Medix, Tokyo, Japan); and Span-1, RIA kit (Dainabot, Tokyo, Japan). All assays were performed according to the manufacturer's instructions. A positive serum level for each marker was defined as being greater than 37 for CA19-9, 35 for CA50, 38 for sialyl SSEA-1, 150 for Dupan-2, and 30 U ml⁻¹ for Span-1. A highly elevated level which strongly suggested the presence of malignant tumour was defined as greater than 150 for each CA50 and Span-1, 60 for sialyl SSEA-1 and 400 U ml⁻¹ for Dupan-2 according to previous studies (Kawa et al., 1990; Kobayashi et al., 1991; Sawabu et al., 1986).

Statistical analysis
Differences among the three Lewis phenotypes in the normal subjects were evaluated by analysis of variance using the Bonferroni method (Wallenstein et al., 1980) after the logarithmic conversion of values. Differences between the two groups of Lewis phenotype was carried out by the Chi-square test with Yates' correction. A level of $P < 0.05$ was accepted as statistically significant.

Results

Comparison of tumour marker levels for three Lewis phenotypes in normal subjects (Table I)
In the 207 normal subjects the prevalence of each Lewis phenotype was as follows: $\text{Le}(a+b-)$ 19%, $\text{Le}(a-b+) 66\%$ and $\text{Le}(a-b-) 15\%$. A significant difference in the serum levels of CA19-9 was found among the three Lewis phenotypes. Serum levels of CA19-9 in the $\text{Le}(a-b-)$ subjects were significantly lower ($P < 0.05$) than those of the $\text{Le}(a+b-)$ and $\text{Le}(a-b+)$ subjects. Similar results were obtained with CA50. Serum levels of Span-1 were significantly lower ($P < 0.05$) in the $\text{Le}(a-b-)$ subjects as compared to the $\text{Le}(a+b-)$ subjects, but there were no significant differences among the other groups. For sialyl SSEA-1, there were no significant differences among the three groups of Lewis phenotypes. Interestingly, the serum levels of Dupan-2 were significantly higher in the group with the $\text{Le}(a-b-)$ phenotype as compared with that with the $\text{Le}(a+b-)$ phenotype.

Serum tumour marker levels in 200 patients with pancreatic carcinoma and Lewis phenotype determined by dot-ELISA
The positive rate for each marker in the patients with pancreatic cancer was as follows: $81\%$ for CA19-9, $84\%$ for CA50, $82\%$ for Span-1, $51\%$ for sialyl SSEA-1 and $64\%$ for Dupan-2 (Figure 1). A total of 39 patients were not diagnosed by the CA19-9 assay; the number of positive cases for each marker among them was similar (Table II) leading to a similar positive rate when those results were combined with those of CA19-9 assay (Figure 1). Of those 39 CA19-9 negative patients, 13 were Lewis-negative by dot-ELISA. These 13 Lewis-negative cases were positive for each of the other markers as follows: seven for Dupan-2, five for Span-1, four for sialyl SSEA-1, and three for CA50 (Table II). In addition, the serum levels of Dupan-2 were highly elevated in five of the 13 Lewis negative cases, although only one of the 26 Lewis positive cases showed a marked elevation of this marker (Tables II, III). Concerning the other markers, markedly elevated serum levels were less frequently observed in the Lewis negative or positive groups not diagnosed by the CA19-9 assay (Tables II, III). From these observations, we conclude that the serum levels of Dupan-2 tended to be elevated in the Lewis negative patients as compared to other markers.

Discussion
In this study, the prevalence of each Lewis group in the normal subjects was similar to that described in our previous reports (Hirano et al., 1987) and to findings of another study conducted in normal Japanese controls (Hasekura et al., 1983; Yazawa et al., 1988). Serum levels of CA19-9 were significantly lower in normal subjects with the $\text{Le}(a-b-)$ phenotype as compared to those with other Lewis phenotypes, $\text{Le}(a+b-)$ or $\text{Le}(a-b+)$. These findings agree with previous reports (Pour et al., 1988; Hirano et al., 1987) and support the validity of the methods used in this study. Although the production of both CA50 and Span-1 were believed to be independent of the Lewis system (Lindholm et al., 1983; Chung et al., 1987), the serum levels of both markers in the $\text{Le}(a-b-)$ group were significantly lower than those in $\text{Le}(a-b+)$ group. The possible explanation for this discrepancy was that the monoclonal antibody (MoAb)

| 8       | 0      | 11   | 9      | 29           | 8       |
| 9       | 30     | 40   | 772    | 114          | 735     |
| 10      | 0      | 0    | 7      | 25           | 43      |
| 11      | 0      | 1    | 6      | 54           | 55      |
| 12      | 0      | 46   | 44     | 46           | 349     |
| 13      | 5      | 1    | 3      | 25           | 93      |

C-50 and the MoAb Span-1 also reacted to the CA19-9 (Masson et al., 1985). Because the serum levels of CA50 in the Le(a-b-) group were also significantly lower than those in the Le(a-b+) group as seen in the results with CA19-9, the affinity of the MoAb C50 for CA19-9 was presumed to be stronger than that of the MoAb Span-1. These findings agree with Masson’s observation that the plasma expression of CA50 is similar to that of CA19-9 with reference to Lewis blood cell status (Masson et al., 1990). The serum sialyl SSEA-1 levels were independent of the Lewis system according to its type II structure. In addition, from this result we confirmed that the MoAb FH-6, the MoAb for sialyl SSEA-1, had no affinity for CA19-9. The point of greatest interest arose from the fact that the serum levels of Dupan-2 in the Le(a-b-) group were significantly higher than those in the Le(a-b+) group. We could not find any similar studies in the published literature.

The objective of this study was to identify a marker that might compensate for the drawback of the CA19-9 assay in diagnosing pancreatic cancer with special reference to the Lewis blood group system. Overall, we found no difference in the positive rates when each marker was combined with the CA19-9 assay. These findings are consistent with our previous results (Kawa et al., 1990; Kobayashi et al., 1991). However, among the 39 patients negative for CA19-9 a highly elevated level which strongly suggested the presence of malignancy was most frequently seen in Dupan-2 as compared with the other three markers. Using the dot-ELISA technique, we confirmed that one-third of the CA19-9 negative patients had the Lewis-negative phenotype. Concerning the Lewis blood group system, the prevalence of cases with a highly elevated levels of Dupan-2 was significantly higher in the 13 patients with the Lewis-negative group as compared to 26 patients with the Lewis-positive group. These results support the hypothesis that Dupan-2 may be highly elevated in some patients with pancreatic cancer who are Lewis-negative as well as in normal controls. With regard to the three other markers, we found a few patients with a highly elevated serum level in either the Lewis-negative or positive groups. This unfavourable result could be anticipated from observations with reference to Lewis blood cell status obtained in normal subjects. Accordingly we conclude that Dupan-2 was the most reliable test for diagnosing pancreatic cancer in Lewis-negative patients who were not diagnosed by the CA19-9 assay. Previous reports indicate that CA19-9 and Dupan-2 were sufficiently independent to complement each other but could not be substituted for each other (Sawabu et al., 1986; Cooper et al., 1990).

It is not known why the level of Dupan-2 is higher in patients with the Le(a-b-) blood cell status. While the amino acid sequence of the Dupan-2 antigen has been shown to be a tandem repeat of 20 amino acids in approximately two-thirds of its protein sequence (Lan et al., 1990), the structure of the Dupan-2 determinants remains to be elucidated. Previous study has shown that it is a sialylated sugar chain (Lan et al., 1985). The accelerated synthesis of this antigen in individuals who are Lewis negative suggests that its structure may be similar to the sialylated forms of Lewis (CA50), which is considered to be a precursor of CA19-9, and which cannot be converted to it by those who are Lewis negative (Hansson et al., 1985) (Figure 2). In addition, the MoAb of Dupan-2 is considered to have little affinity for sialyl Lewis (CA19-9). Immunochemical study has demonstrated that Dupan-2 antigens are present in patients who cannot manufacture CA19-9 (Tempero et al., 1989). Further study is required to reveal the structure of Dupan-2.

In conclusion, the combined assay of Dupan-2 and CA19-9 is useful for diagnosing the patient with pancreatic cancer, because the Dupan-2 assay complements that for CA19-9 with respect to the Lewis blood group system.
