Background: Polybrominated diphenyl ethers (PBDEs) are widely used flame retardants that bioaccumulate in human tissues. Their neurotoxicity involves dysregulation of calcium ion (Ca2+) signaling; however, specific mechanisms have yet to be defined.

Objective: We aimed to define the structure–activity relationship (SAR) for PBDEs and their metabolites toward ryanodine receptors type 1 (RyR1) and type 2 (RyR2) and to determine whether it predicts neurotoxicity.

Methods: We analyzed [3H]ryanodine binding, microsomal Ca2+ fluxes, cellular measurements of Ca2+ homeostasis, and neurotoxicity to define mechanisms and specificity of PBDE-mediated Ca2+ dysregulation.

Results: PBDEs possessing two ortho-bromine substituents and lacking at least one para-bromine substituent (e.g., BDE-49) activate RyR1 and RyR2 with greater efficacy than corresponding congeners with two para-bromine substituents (e.g., BDE-47). Addition of a methoxy group in the free para position reduces the activity of parent PBDEs. The hydroxylated BDEs 6-OH-BDE-47 and 4’-OH-BDE-49 are biphasic RyR modulators. Pretreatment of HEK293 cells (derived from human embryonic kidney cells) expressing either RyR1 or RyR2 with BDE-49 (250 nM) sensitized Ca2+ flux triggered by RyR agonists, whereas BDE-47 (250 nM) had negligible activity. The divergent activity of BDE-49, BDE-47, and 6-OH-BDE-47 toward RyRs predicted neurotoxicity in cultures of cortical neurons.

Conclusions: We found that PBDEs are potent modulators of RyR1 and RyR2. A stringent SAR at the ortho and para position determined whether a congener enhanced, inhibited, or exerted nonmonotonic actions toward RyRs. These results identify a convergent molecular target of RyR1 and RyR2 with potent activity of both isoforms that predicts cellular neurotoxicity and therefore could be a useful tool in risk assessment of PBDEs and related compounds.

Key words: calcium, hydroxylated PBDE, methoxylated PBDE, neurotoxicity, polybrominated biphenyl ether (PBDE), ryosyne receptor (RyR).

Environmental Health Perspectives 119:519–526 (2011). doi:10.1289/ehp.1002728 [Online 24 November 2010]

Worldwide use of chemically stable polybrominated diphenyl ethers (PBDEs) as flame retardants in consumer products has increased since the 1970s (Costa et al. 2008). Levels of PBDEs in the environment (Hale et al. 2003; Law et al. 2006; Oros et al. 2005) and tissues of invertebrates, fish, birds, and mammals have increased in the last 30 years (Yogui and Sericano 2009). In humans, PBDEs have been detected in numerous tissues, with serum concentrations reported as high as 50 ng/g lipid (Petreas et al. 2003). PBDE concentrations in breast milk doubled every 5 years between 1972 and 1997 (Rahman et al. 2001; She et al. 2007). The predominant routes of exposure are diet and inhalation (Allen et al. 2007; Costa et al. 2008; Rose et al. 2010; Schecter et al. 2005). PBDEs with less than five bromine substituents, such as 2,2’,4,4’-tetrabromodiphenyl ether (BDE-47) and 2,2’,4,4’,5-pentabromodiphenyl ether (BDE-99), have attracted the greatest concern because they show the greatest bioaccumulation (Darnerud et al. 2001) and can be formed by debromination of higher-substituted PBDEs (Gerecke et al. 2005; Stapleton et al. 2006; Stapleton and Dodder 2008).

PBDEs share structural similarities to a subset of the polychlorinated biphenyls (PCBs) that have more than one chloro-substituent in the ortho position, in particular, noncoplanarity of their phenyl rings. Like the ortho-substituted PCBs (Denison and Nagy 2003; Van den Berg et al. 2006), PBDEs (Peters et al. 2004) have very weak or negligible activity at the aryl hydrocarbon receptor, but disrupt calcium ion (Ca2+) signaling in several cell types (Dingemans et al. 2008, 2010). One mechanism by which ortho-substituted PCBs disrupt Ca2+ signaling and contribute to neurotoxicity is via interactions with ryanodine receptors (RyRs) (Pessah et al. 2010; Wong and Pessah 1996). For example, 2,2’,3,5’,6-pentachlorobiphenyl (PCB-95) at nanomolar concentrations sensitizes RyR Ca2+ channels in rat hippocampal microsomal preparations (Pessah et al. 2010; Wong et al. 1997a), and alters neuroplasticity in rat hippocampal slices (Kim et al. 2009). Developmental exposure to PCB-95 or Aroclor 1254 results in behavioral abnormalities in rats and altered patterns of RyR expression in brain (Schantz et al. 1997; Wong et al. 1997b; Yang et al. 2009). In rats exposed perinatally, PCB-95 alters the balance of excitatory/inhibitory currents and disrupts the tonotopic map of the primary auditory cortex (Kenet et al. 2007). Identification of RyRs as a relevant molecular target in PCB neurotoxicity may be generalized to related noncoplanar persistent organic pollutants such as PBDEs. Evidence of a convergent mechanism by which PCBs and PBDEs disrupte RyRs would be of toxicological significance considering that these tightly regulated Ca2+ channels reside within specialized regions of sarcomplasmic/endoplasmic reticulum (SR/ER) membrane where they contribute to and regulate essential aspects of Ca2+ signaling (Pessah et al. 2010).

In the present study we examined the structure–activity relationship (SAR) of PBDEs and their metabolites toward the two major RyR isoforms found in the brain and striated muscle (RyR1 and RyR2). Our findings indicate that PBDEs are potent modulators of both RyR isoforms. Para- and ortho-substitutions are a key structural determinant of this activity and are predictive of their neurotoxicity.
Materials and Methods

Materials. We purchased neat certified 2,2′-dibromodiphenyl ether (BDE-4), 4,4′-dibromodiphenyl ether (BDE-15), 2,2′,4′-tribromodiphenyl ether (BDE-47; 98.4% pure), 2,2′,3,4′-tetrabromodiphenyl ether (BDE-42; 100% pure), and 4,4′-dibromodiphenyl ether (BDE-99; 100% pure), the hydroxylated BDEs 6-OH-BDE-47 (98.6% pure) and 4-OH-BDE-49 (97.8% pure), and PCB-95 (99.1 ± 4% pure) from AccuStandard (New Haven, CT) and verified purity and composition by gas chromatography-mass spectrometry through the Superfund Research Program Analytical Core. Methoxyderivatives were provided by A. Bergman (Stockholm University, Stockholm, Sweden). [3H]Ryanodine ([3H]Ry, specific activity 60 Ci/mmol) was obtained from Perkin-Elmer New England Nuclear (Wilmington, DE). 4-Chloro-m-cresol (4-CmC), diphenyl ether (DE), rapamycin, and Ca2+ ionophore A23187 were purchased from Sigma-Aldrich (St. Louis, MO, USA).

Animal care. All animal procedures were performed under protocol approved by the University of California–Davis Institutional Animal Care and Use Committee.

Membrane preparations. Microsomal membrane preparations enriched in RyR1 or RyR2 were isolated from skeletal muscle and heart, respectively, from male New Zealand White rabbits (Charles River Laboratories, Hollister, CA) as described previously (Mack et al. 1992; Zimanyi and Pessah 1991). We prepared brain microsomes from mouse neocortical tissue as described previously for the rat (Wong et al. 1997a).

[3H]Ry binding assays. We determined the amount of specific [3H]Ry binding to microsomal membranes in the absence and presence of PBDE or their metabolites, a measure of how RyR activity is affected, as previously described (Pessah et al. 2009). See Supplemental Material (doi:10.1289/ehp.1002728) for details. At least eight concentrations of each congener were tested in triplicate in at least three independent binding assays. The concentration–response curves were analyzed by curve fitting using GraphPad Prism Software (version 5; GraphPad Software, La Jolla, CA).

Microsomal Ca2+ flux measurements. We measured PBDE-induced release of Ca2+ actively accumulated by microsomal vesicles in the presence of ATP as previously described (Pessah et al. 2006). See Supplemental Material (doi:10.1289/ehp.1002728) for details. Initial Ca2+ release rates were calculated for at least eight PBDE concentrations, including vehicle control. The half-maximal rates of Ca2+ release (EC50) were determined by curve fitting of three experiments.

Ca2+ imaging of HEK293 cells. We followed the method for growing human embryonic kidney [human embryonic kidney 293 (HEK293); RyRnull] cells in culture and the protocols for transfection and selection protocols for HEK293 cells that stably express RyR1 (HEK293[RyR1]) or RyR2 (HEK293[RyR2]) as described previously (Pessah et al. 2009). Sixteen hours after introduction of vehicle or PBDE, cells were loaded with the Ca2+ indicator Fluo-4 to measure cytoplasmic Ca2+ changes in response to challenges with RyR activators caffeine or 4-chloro-m-cresol (4-CmC). See Supplemental Material (doi:10.1289/ehp.1002728) for additional details.

Primary culture of mouse and rat cortical neurons. High-density cultures of cortical neurons were dissociated from postnatal day 0–2 Sprague-Dawley rats (Charles River Laboratories) for electrophysiological measurements (Yang et al. 2009) or C57BL/6 (B6) mice (Charles River Laboratories) for neuronal viability measurements as previously described (Chen et al. 2010). See Supplemental Material (doi:10.1289/ehp.1002728) for details.

Multielectrode array (MEA) recording and data analysis. MEAs with a central 0.88-mm2 recording matrix of 64 multielectrodes (MedP545A; AutoMate Scientific, Berkeley, CA) were precoated with poly-l-lysine (0.5 mg/mL; Sigma Chemical Co., St. Louis, MO) and laminin (10 µg/mL; Invitrogen, Carlsbad, CA, USA). Dissociated rat cortical cells were plated onto the MEAs at a density of 1 × 104 cells/MEA. Cultures were maintained in Neurobasal–A (Invitrogen) supplemented with B27 (Invitrogen) as previously described (Wayman et al. 2006). Half of the medium was replaced twice weekly with fresh Neurobasal-A containing B27. At 21 days in vitro, cortical neurons grown on MEAs were placed into the MED 64CH Integrated Amplifier interface and spike activity was recorded using Mobius software (both from AutoMate Scientific).

Baseline activity was recorded for 10 min at 37°C. Cultures were then exposed to vehicle by adding 1 µL DMSO into MEA cultures containing 1 mL culture medium (final concentration 0.1%). Washes were performed as described previously (Chen et al. 2010). See Supplemental Material (doi:10.1289/ehp.1002728) for additional details.

Figure 1. Ortho-bromines are essential for PBDE activity toward FKBP12-RyR1 complex. Abbreviations: Rap, rapamycin; RR, ruthenium red. (A) Microsomes enriched in RyR1 protein were incubated in the presence of either BDE-4 or BDE-15 in [3H]Ry binding buffer. (B) Addition of 20 µM BDE-4 (arrow) to microsomal vesicles subsequent to SERCA-dependent Ca2+ accumulation in the presence of ATP (loading phase) resulted in net Ca2+ release. Inhibition of RyR1 by 1 µM RR blocked the Ca2+ release triggered by BDE-4 (10 µM). (C) Concentration–effect curve for BDE-4–triggered Ca2+ release (EC50 = 9.6 ± 0.2 µM; n = 4). Addition of vehicle to the Ca2+-loaded vesicles did not cause Ca2+ release (Vehicle). (D) Concentration–dependence inhibition of BDE-4–enhanced [3H]Ry binding to RyR1 by Rap (5 µM BDE-4 with 0–200 µM Rap); Rap alone had negligible effects on [3H]Ry binding to RyR1, n = 3 independent experiments in triplicate. (E) Pretreatment of microsomal vesicles with Rap 2 min before loading vesicle with Ca2+ (arrow) inhibited Ca2+ release triggered by subsequent addition (dotted arrow) of 5 µM BDE-4 but did not inhibit caffeine-induced Ca2+ release. (F) Concentration–effect relationship of Rap inhibition of BDE-4 triggered Ca2+ release; n = 4.
0.1% DMSO), and activity was recorded for 10 min. Subsequently, cultures were exposed to either BDE-47 or BDE-49 by adding 1 µL 1,000x stock solution in DMSO to the well. Cultures were sequentially exposed to increasing concentrations of PBDE, and activity was recorded for 10 min after each addition. We analyzed spontaneous spike activity using the Spike Sorting and DC filter applications in Mobius. Spikes greater than three times the baseline noise were scored. The number of spikes per 10 min recording session was determined (for electrodes showing activity), and the mean spike number per MEA was calculated. Three MEAs from three independent dissections were analyzed per PBDE.

**Tetrazolium-based MTS assay.** We performed the MTS [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium] assay to test cell viability in cultured mouse cortical neurons after 48-hr exposures to BDE-47, BDE-49 or 6-OH-BDE-47 using the CellTiter 96 Cell Proliferation Assay kit (Promega, Madison, WI) as previously described (Chen et al. 2010). See Supplemental Material (doi:10.1289/ehp.1002728) for additional details.

**Results**

Ortho-bromine substitution is required for PBDE activity toward RyR1. We first tested the minimal structural requirement for PBDE activity toward RyR1 using [3H]Ry binding analysis to microsomes. Neither unsubstituted diphenyl ether nor BDE-15 (≤ 20 µM) altered the amount of specific binding of [3H]Ry to RyR1, a measure of receptor activation (Pessah et al. 1987). In contrast, BDE-4 significantly enhanced specific binding of [3H]Ry to RyR1, increasing occupancy 14-fold at 20 µM when measured with suboptimal Ca2+ in the assay buffer (Figure 1A). This finding indicates that BDE-4 is an efficacious activator of RyR1 when measured under buffer conditions that promote a closed-channel conformation.

Antipyrlyazo-III is a low-affinity membrane impermeable dye that allows quantification of Ca2+ fluxes across vesicles (Baylor et al. 1983). Spectroscopic detection of antipyrlyazo-III absorbance changes in free Ca2+ in the extravesicular solution. Ca2+ was actively loaded into microsomes via the SR/ER Ca2+ ATPase (SERCA) by bolus additions of Ca2+ to the assay buffer containing ATP (Ca2+-loading phase). After the loading phase was complete (the dye signal re-established baseline), addition of BDE-4 (1–20 µM) elicited a net release of Ca2+ (net Ca2+ efflux; Figure 1B). The PBDE EC50 value was 12.0 ± 0.8 µM under conditions that mimic the resting state of most mammalian cells (i.e., ~ 100 nM free Ca2+ at the cytoplasmic face of RyR1). BDE-4-triggered Ca2+ release was fully blocked by ruthenium red (RR; 1 µM), an RyR blocker (Figure 1B). EC50 values were calculated from plots of the initial rate of Ca2+ release as a function of BDE-4 concentration (Figure 1C). BDE-15 and unsubstituted diphenyl ether at concentrations ≤ 20 µM did not elicit detectable release of accumulated Ca2+ in the microsomal transport assay (not shown).

 Activation of the Ca2+ channel by ortho-substituted PCBs requires an intact association of RyR1 with its accessory protein FK506-binding protein 12 kDa (FKBP12) (Wong and Pessah 1997). Consistent with this mechanism, enhancement of [3H]Ry binding to RyR1 by BDE-4 (5 µM) was inhibited by inclusion of rapamycin in the assay (2 min preincubation) to disrupt the RyR1-FKBP12 complex (Figure 1D). The importance of the FKBP12 complex in mediating the efficacy of BDE-4 toward RyR1 was further verified by measuring active uptake and release of Ca2+ from the same membrane vesicles used for [3H]Ry binding analysis. Addition of BDE-4 (5 µM) to vesicles actively loaded with Ca2+ caused release of accumulated Ca2+, and this response was inhibited in vesicles pretreated with rapamycin in a concentration-dependent manner (Figure 1E,F). Rapamycin eliminated BDE-4–triggered Ca2+ release without inhibiting caffeine-induced Ca2+ release (Figure 1E), indicating that PBDEs sensitize RyR1 via a mechanism previously reported for PCBs.

**Para substitution of environmentally relevant PBDEs determines RyR1 and RyR2 activity.** Because para-chloro-substitutions of PCBs significantly influence activity toward RyR1 (Pessah et al. 2006), we investigated whether para-bromo-substitutions similarly influence the activity of PBDEs toward RyRs, using congeners with higher bromination that are environmentally relevant. We used a more activating basal buffer condition in these experiments to detect both activating and inhibiting actions of PBDEs on RyR activity. Figure 2A shows that BDE-47 weakly enhanced binding of [3H]Ry to RyR1.
RyR1 (maximum, ~145% of vehicle control at 10 µM), whereas BDE-49 and BDE-17 enhanced binding >450% relative to vehicle control (EC_{50} = 2 µM). BDE-42 showed intermediate activity (250% of vehicle control at 10 µM) (Figure 2A). A similar SAR was observed with RyR2 (Figure 2B). At concentrations that maximally enhance RyR1, BDE-17 and BDE-49 (10 µM) increased [^{3}H]Ry binding to RyR2 by approximately 300%, whereas BDE-42 was intermediate (200%), and BDE-47 had negligible activity. A similar SAR was identified with [^{3}H]Ry binding to cortical membrane preparations that contain a mixture of RyR1 and RyR2 (see Supplemental Material, Figure 1 (doi:10.1289/ehp.1002728)). Collectively, these data indicate that in addition to two ortho-bromines, one unsubstituted para position is critical for enhancing RyR activity.

**Para-methoxy diminishes but does not eliminate RyR1 activity.** To further test the hypothesis that the para substitution is an important determinant of RyR activity, we examined the activity of para-methoxy metabolites using [^{3}H]Ry binding and Ca^{2+} flux analyses of RyR1. Addition of a methoxy substituent at the 4 or 4′ positions of BDE-17, BDE-42, or BDE-49 significantly reduced the apparent efficacy by >2-fold in [^{3}H]Ry binding experiments (see Supplemental Material, Figure 2A (doi:10.1289/ehp.1002728)). However, addition of methoxy to the 5 position of BDE-47 did not alter activity toward RyR1. Addition of BDE-49 (10 µM) subsequent to loading vesicles with Ca^{2+} in the presence of ATP elicited a very robust efflux of the accumulated Ca^{2+}, and the release could be completely blocked by the RyR channel blocker RR (see Supplemental Material, Figure 2B, top). 4′-Methoxylated-BDE-49 (10 µM) added to the Ca^{2+}-loaded vesicles under identical assay conditions elicited a much slower release of Ca^{2+} than the parent congener, and these effects were blocked by RR (see Supplemental Material, Figure 2B, middle). In contrast, BDE-47 (10 µM) did not sufficiently sensitize RyR1 to produce net Ca^{2+} efflux from the vesicles in the presence of the strong SERCA pump activity present in this assay (see Supplemental Material, Figure 2B, bottom).

Rapamycin pretreatment selectively negates PCB-49-induced Ca^{2+} release. As predicted by results with BDE-4 (Figure 1B), microsomes preincubated with 20 µM rapamycin or vehicle 2 min before the Ca^{2+}-loading phase greatly diminished subsequent response to BDE-49 (2 µM). However, regardless of the pretreatment protocol, the RyR1 channels remained responsive to 4-CMC (see Supplemental Material, Figure 3 (doi:10.1289/ehp.1002728)).

Hydroxylation can differentially influence PBDE activity toward RyR1. OH-BDE metabolites have been found in maternal and fetal blood (Qiu et al. 2009); therefore, we tested the activity of the environmentally relevant hydroxylated metabolites 6-OH-BDE-47 and 4′-OH-BDE-49 toward RyR1 using [^{3}H]Ry binding analysis (Figure 3A). Unexpectedly, 4′-OH-BDE-49 exhibited a nonmonotonic concentration–effect relationship, activating RyR1 at approximately 350% of vehicle control at 5 µM but having reduced efficacy at higher concentrations (<200% of vehicle control at 10 µM). Interestingly, 6-OH-BDE-47 inhibited [^{3}H]Ry binding in a concentration-dependent manner, with complete inhibition observed at 10 µM (Figure 3A). Because the rate of [^{3}H]Ry binding to RyRs is too slow to detect transient activation of RyR1 if it occurred, we proceeded to test whether 6-OH-BDE-47 had temporally distinct actions, initially activating and subsequently blocking RyR1 channel activity, by measuring the actions of this congener on microsomal Ca^{2+} fluxes. Indeed, microsomal vesicles rapidly released their accumulated Ca^{2+} when acutely challenged with 6-OH-BDE-47 (10 µM), and this effect was completely blocked by RR (Figure 3B). In addition, microsomal vesicles preincubated with 6-OH-BDE-47 at 37°C (<2 hr) significantly inhibited 4-CMC-induced Ca^{2+} release (Figure 3C), indicating that prolonged incubation does subsequently block RyR1, as predicted from [^{3}H]Ry binding studies (Figure 3A).

**Nanomolar BDE-49, but not BDE-47, sensitizes RyR-mediated Ca^{2+} release in intact cells.** To determine whether the different efficacies of BDE-47 and BDE-49 toward RyRs extend to RyR-dependent signaling events in intact cells, we tested the activity of the two congeners toward HEK293null cells (which lack any expression of RyRs) and HEK293 cells, which stably express either RyR1 (HEK293^{RyR1}) or RyR2 (HEK293^{RyR2}) (see Supplemental Material, Figure 4A,D (doi:10.1289/ehp.1002728)). Cells of each genotype were pretreated with 250 nM BDE-49 or BDE-47 for 16 hr before loading them with the Ca^{2+}-sensitive dye Fluo-4. Once loaded with Ca^{2+} indicator, cells were imaged to detect changes in cytoplasmic Ca^{2+} ([Ca^{2+}]_{cyt}) before and after challenge with RyR agonists caffeine or 4-CMC (Fessenden et al. 2000). HEK293^{RyR1} responded to brief (10-sec) focal application of caffeine with a Ca^{2+} transient whose amplitude was concentration dependent.

![Figure 3](image-url)
PBDEs dysregulate ryanodine receptors

Pretreatment of HEK293RyR1 cells with BDE-49 enhanced caffeine-induced Ca\(^{2+}\) release, resulting in larger transient amplitudes than vehicle control (\(p < 0.05\)) at lower caffeine concentrations (see Supplemental Material, Figure 4B,C). In contrast, BDE-47 did not alter caffeine responses compared with vehicle control. HEK293null cells failed to respond to RyR1 agonists even when pretreated with BDE-49 (see Supplemental Material, Figure 4B). HEK293RyR2 cells responded vigorously to a brief puff of 4-CmC (1 mM) in contrast to HEK293null cells (see Supplemental Material, Figure 4E). HEK293RyR2 cells pretreated for 16 hr with BDE-49, but not BDE-47, showed significantly larger Ca\(^{2+}\) transient amplitudes (~180%; \(p < 0.05\)) compared with vehicle controls (see Supplemental Material, Figure 4F).

**RyR activity predicts neurotoxic potential.** Considering the widely divergent activities of BDE-47 and BDE-49 on RyR1 and RyR2, both of which are expressed in brain, we tested whether their differential effects on RyR activity predict neurotoxicity. First, we examined how these PBDEs influence spontaneous electrical spiking activity of cortical neurons cultured on microelectrode arrays (MEA). MEAs have been used increasingly to assess altered development of neural networks and excitotoxicity caused by xenobiotics (Johnstone et al. 2010). Cortical neurons cultured on MEA probes exhibited spontaneous spike (action potential) activity at 21 days in vitro (Figure 4A,B). Sequential exposure to increasing concentrations of BDE-49 (0, 0.2, 20, and 200 nM) at 10-min intervals significantly increased the number of spontaneous spikes, whereas BDE-47 (<200 nM) did not alter spike activity relative to the control period (Figure 4B,C).

**Figure 4.** Cortical neurons show excitotoxicity to BDE-49 and 6-OH-BDE-47, but not BDE-47. (A) Primary cultured rat cortical neurons on MEA (21 days in vitro); bar = 100 µm. (B) Representative raster plot of spike trains over a 6-sec period in neurons exposed acutely to vehicle, BDE-47, or BDE-49. (C) BDE-49, but not BDE-47, increases spontaneous spike activity in a concentration-dependent manner; data are presented as mean ± SE (n = three arrays per treatment group). (D) Micrographs of neurons after 48 hr exposure to vehicle, BDE-47 (10 µM), or BDE-49 (5 µM or 10 µM) between 6 and 8 days in vitro. Compared with neurons exposed to vehicle and BDE-47, BDE-49–exposed neurons showed pronounced morphological changes, including fasciculation and decreased soma diameter; bar = 150 µm. (E) BDE-49 (5 and 10 µM) and 6-OH-BDE-47 (10 µM), but not BDE-47, significantly decreased cell viability as assessed using the MTS assay.

* \(p < 0.05\) compared with vehicle control by ANOVA with post hoc Tukey’s test.

**\(p < 0.01\).**
We next determined whether exposures to BDE-47 and BDE-49 at higher concentrations (low micromolar) and for longer times (48 hr) influence the viability of cortical neuron cultures. Compared with vehicle controls, cultures exposed to 5 and 10 µM BDE-49 invariably showed loss of phase-bright cell bodies, decreased soma diameter, extreme fasciculation of processes, and a tendency for the monolayer to pull up off the substrate (Figure 4D). In contrast, no overt morphological abnormalities were observed in neurons exposed to BDE-47 (5 µM, 48 hr). Cell viability assessed using the MTS assay confirmed that BDE-49 (>5 µM) significantly decreased neuronal cell viability by >50% (p < 0.05). A potentially significant finding is that 6-OH-BDE-47 (10 µM), a major metabolite of BDE-47, also caused significant loss of cell viability (Figure 4E).

Discussion
The relatively high levels of PBDEs recently measured in young children in North America (Herbstman et al. 2010), and especially California (Rose et al. 2010), escalates concerns about their effects on human and environmental health that were raised a decade ago (Darnerud et al. 2001). Levels of the most abundant congeners in serum—BDE-47, BDE-99, and BDE-100—in children <72 months of age have been reported to be associated with lower scores on tests of cognitive, behavioral, and physical development (Herbstman et al. 2010). PBDE levels were also correlated with impairments in fine psychomotor abilities and attention but improved coordination, visual perception, and behavior (Rose et al. 2009). Similarly, in utero or postnatal exposure to PBDEs resulted in hyperactivity in rats (Kuriyama et al. 2005; Suvorov et al. 2009) and mice (Viberg et al. 2004). Exposure to PBDEs in neonatal mice resulted in learning deficits in visual discrimination tasks (Dufault et al. 2005).

Despite the mounting evidence that PBDEs cause developmental neurotoxicity, the principal molecular targets responsible for this toxicity have not been identified. PBDEs are usually found in combination with other persistent organic pollutants such as PCBs, tri-closan, and p,p’-DDE (p,p’-dichlorodiphenyl-dichloroethylene), each of which has been shown to alter Ca^{2+} homeostasis, in part by dysregulating RyR channels (Ahn et al. 2008; Morisseau et al. 2009; Pessah et al. 2010). RyRs, along with inositol 1,4,5-trisphosphate receptors (IP3Rs), are a family of Ca^{2+} channels in endoplasmic or sarcoplasmic reticulum, broadly expressed in both excitable cells (striated muscles, neurons) and nonexcitable cells (dendritic cells, T lymphocytes) (Pessah et al. 2010). RyRs assemble as very large homotetrameric structures with a molecular weight >2 MDa and consist of a very large cytoplasmic assembly (the foot region) and a relatively small transmembrane assembly composed of six putative transmembrane passes with a central ion-conducting pore. All three isoforms of RyRs are expressed in the central nervous system but are differentially distributed among specific brain regions, cell types, and cell regions, reflecting their participation in specialized functions (Pessah et al. 2010). Environmental toxicants that have a potential for altering RyR function can influence neuronal excitability, alter synaptic plasticity, and activate cytosolic and nuclear transcriptional events implicated in activity-dependent dendritic growth (Pessah et al. 2010).

The SAR of PBDEs toward RyR1 and RyR2 indicate that the location of ortho- and para-bromine substituents significantly influence the level of activation of RyRs, as highlighted by divergent activities of BDE-47 and BDE-49, and is unrelated to differences in lipophilicity. In this regard, the free concentration of BDE-49 is likely to be significantly lower than those added to the assays used in this study. This aspect of SAR is similar to that observed with the influence of para-chlorines on PCB activity toward RyR1 and RyR2 (Pessah et al. 2006). In this respect, the larger bromine substitution at the para positions more dramatically reduces PBDE activity than the corresponding chlorine substitutions on PCBs and may be because of steric interference. The similarity in structure–activities with ortho and para substitutions suggests a common mechanism for their effects on RyR activity. In support of a convergent mechanism, the activity of PCBs, bastadins, and PBDEs toward RyR1 can be selectively eliminated by using rapamycin to disrupt the RyR1-FKB12 complex (Chen et al. 1999; Pessah et al. 2006; Wong and Pessah 1997), an accessory protein important in fine-tuning the gating properties of RyR1 channels (Brillantes et al. 1994).

The results from the present study show that 6-OH-BDE-47 produces temporally defined biphasic actions on microsomal Ca^{2+} release is consistent with results obtained by Dingemans et al. (2008) showing that acute exposure of PC12 cells to 6-OH-BDE-47 promotes Ca^{2+} release from intracellular Ca^{2+} stores. [3H]Ry binding analysis reflects the activity of RyR channels at steady-state conditions for the radioligand (3 hr) and apparently fails to detect the initial channel activation elicited by 6-OH-BDE-47. However Ca^{2+} flux measurements clearly show that the immediate actions of this congener are activation of RyR1 and release of Ca^{2+} accumulated in microsomal vesicles, whereas prolonged exposure significantly attenuates 4-CmC–induced Ca^{2+} release. Our results reveal that OH-PBDEs have complex biphasic actions on RyR function and SR/ER Ca^{2+} transport properties that depend not only on the local concentration but also on the length of the exposure.

The complex interactions of OH-BDEs leading to activation or inhibition of RyR1 channels appear to mirror the complex SAR described with naturally occurring macrocyclic bromotyrosine toxins from Ianthella basta, termed “bastadins” (Chen et al. 1999; Mack et al. 1994). The reduced toxicophore that confers RyR activity resides within the eastern and western noncoplanar bromocatechol ether moieties that resemble OH-BDE (Masuno et al. 2006). The bromine and hydroxy substituents about the diphenylether can result in either channel activation or channel inhibition. Our results with OH-BDEs suggest an underlying mechanism for the results reported by Dingemans et al. (2008, 2010), who identified a number of 4-OH, 5-OH, and 6-OH metabolites of BDE-47 and BDE-49 that at 5–20 µM were more potent at mobilizing Ca^{2+} from ER and/or mitochondrial stores than their respective parent structures when applied to unstimulated (resting) PC12 cells. A high concentration of BDE-47 (20 µM) enhanced the Ca^{2+} transient amplitude triggered by bolus addition of extracellular K+, whereas other PBDE congeners lacked significant influence (Dingemans et al. 2010). Interestingly hydroxylation at the 4, 5, and 6 positions of BDE-47 or BDE-49 (2–20 µM) significantly inhibited depolarization-triggered Ca^{2+} transient amplitude. These previously reported effects of PBDEs and OH-PBDEs could be explained, at least in part, by their actions on RyR channels as we describe here. Sensitization of RyRs in resting cells by OH-PBDEs could result in chronic Ca^{2+} leakage and depletion of ER stores. This could account in large part for both the rapid and delayed rises in cytoplasmic Ca^{2+} previously observed by Dingemans et al. (2008, 2010). The suppression of the Ca^{2+} transient amplitude triggered by depolarization subsequent to 20 min pretreatment with 2 and 20 µM OH-PBDE (Dingemans et al. 2010) would be expected to cause partial or complete depletion of ER stores as a direct consequence of submaximal or maximal activation of RyR channels, respectively. Interestingly, 4-OH-BDE-49 shows a nonmonotonic concentration–response relationship toward RyR1. In contrast, BDE-49 is a very efficacious activator of RyRs in [3H]Ry binding studies, potently sensitizes caffeine- or 4-CmC–triggered Ca^{2+} release in HEK293 cells that express RyRs, and is a potent excitotoxin toward primary cortical neurons. In this regard, 48 hr exposure to BDE-47 <10 µM does not promote loss of neuronal viability, whereas BDE-49 does. These observations are apparently at odds with reports that developmental exposure to BDE-47 causes developmental neurotoxicity.
in rodents (Dingemans et al. 2007; Suvorov et al. 2009). One interpretation of this discrepancy is that RyR-independent mechanisms mediate the adverse effects of BDE-47 on the developing nervous system. An alternative suggestion supported by our data is that the neurotoxic effects of BDE-47 observed in vivo are mediated by 6-OH-BDE-47 rather than the parent congener; the lack of effect of the parent compound on either spontaneous activity or cell viability in cultured cortical neurons reflects the limited metabolic capacity of this in vitro model.

The present study indicates that [3H]Ry binding studies are a rapid means of defining SARs that predict neurotoxic PBDEs, much like its use to identify neurotoxic PCBs (Pessah et al. 2010). The toxicological significance of these findings is illustrated by a recent report by (Miller et al. 2009) that BDE-47, which is not typically measured in human samples, was detected in gestational tissues from women in southeast Michigan at levels comparable with BDE-28. BDE-49 comprised 17% of the total PBDE concentration in these tissues. This observation is consistent with reports identifying BDE-49 as a major contributor in that most exposure studies fail to account for congeners with the greatest neurotoxic potential. The present study is the first to identify RyR1 and RyR2 as direct targets of both PBDEs and their hydroxylated metabolites. Certain logical functions (Pessah et al. 2010). Certain...
