Improvements on “Fast space-variant elliptical filtering using box splines”

Kunal Narayan Chaudhury and Sebanti Sanyal *

Abstract

It is well-known that box filters can be efficiently computed using pre-integrations and local finite-differences [2]. By generalizing this idea and by combining it with a non-standard variant of the Central Limit Theorem, a constant-time or $O(1)$ algorithm was proposed in [3] that allowed one to perform space-variant filtering using Gaussian-like kernels. The algorithm was based on the observation that both isotropic and anisotropic Gaussians could be approximated using certain bivariate splines called box splines. The attractive feature of the algorithm was that it allowed one to continuously control the shape and size (covariance) of the filter, and that it had a fixed computational cost per pixel, irrespective of the size of the filter. The algorithm, however, offered a limited control on the covariance and accuracy of the Gaussian approximation. In this work, we propose some improvements by appropriately modifying the algorithm in [3].

Keywords: Linear filtering, Gaussian approximation, Central limit theorem, Anisotropic Gaussian, Covariance, Box spline, Cartesian grid, Running sum, $O(1)$ algorithm.

1 Introduction

A space-variant filter is one where the shape and size of the filter is allowed to change from point-to-point within the image. Unlike the more standard convolution filter, the efficient computation of space-variant filters (diffusion filters) remains a challenging problem in computer vision and image processing [9]. It has been shown that efficient algorithms for space-variant filtering can be designed using spline kernels, particularly when the space-vari-ance is in terms of the scale (or size) of the kernel. For instance, Heckbert

*Correspondence: K. N. Chaudhury (kchaudhu@math.princeton.edu).
proposed an algorithm for adaptive image blurring using tensor-products of polynomial splines, where the image is filtered with kernels of various scales using repeated integration and finite-difference [4]. Based on similar principles, namely, the scaling properties of B-splines, Munoz-Barrutia et al. have developed an algorithm for fast computation of the continuous wavelet transform at different scales [10]. The idea was extended in [12] to perform space-variant filtering using Gaussian-like functions of arbitrary size. This was done by approximating the Gaussian using separable B-splines. The flip side of using a separable construction, however, was that it offered limited steerability and ellipticity. More recently, it was shown in [3] that this limitation could be fixed using certain non-separable splines called the box splines [7]. This, however, did not solve the problem completely as the associated filtering algorithm offered only a limited control on the accuracy of the Gaussian approximation. In this paper, we address these algorithmic limitations and provide some simple solutions. To introduce the problem and to fix the notations, we briefly recall the main results in [3]. While we keep the presentation as self-contained as possible, we have avoided reproducing all the technical details, and refer the readers to original paper for a more complete account.

1.1 Background

The key idea behind the fast $O(1)$ algorithm for Gaussian filtering in [3] is the use of a single global pre-integration, followed by local finite differences. At the heart of this is the following non-standard form of the Central Limit Theorem

\textbf{Theorem 1.1} (Gaussian approximation, [3]). \textit{For a given integer $N \geq 2$, let $\theta_k = (k - 1)\pi/N$ for $1 \leq k \leq N$. Then}

\[ \lim_{N \to \infty} \prod_{k=1}^{N} \text{sinc} \left( \frac{\sigma \sqrt{\frac{6}{N}} (x \cos \theta_k + y \sin \theta_k)}{2 (x^2 + y^2)} \right) = \exp \left( -\frac{\sigma^2}{2} (x^2 + y^2) \right). \] (1)

This result tells us that the Gaussian can be approximated by the product of rescaled sinc$^2$ functions that have been uniformly spread out over the half-circle. Note that each term in the product in (1) is obtained through a rotation and rescaling of sinc$(u)1(v)$, the tensor-product between the sinc

\footnote{We refer the interested reader to [5] for an interpretation of this result in the probabilistic setting.}

\footnote{We define sinc$(t)$ to be 1 at the origin and $\sin(t)/t$ otherwise.}
function and the constant function of unit height. The main idea behind (1) is that sinc(t) behaves as 1 − t²/6 + O(t⁴) close to the origin, so that 

\[ \text{sinc}(t/\sqrt{N})^N \approx \exp(-t²/6) \] when \( N \) is large compared to \( t \).

So how exactly does this observation lead to an \( O(1) \) algorithm for approximating Gaussian filters? By \( O(1) \), we mean that the cost of filtering is independent of the size of the filter. It is clear that the right side of (1) is simply the Fourier transform of the Gaussian

\[ g(x, y) = \frac{1}{2\pi\sigma} \exp \left( -\frac{x^2 + y^2}{2\sigma^2} \right). \]

On the other hand, the product in (1) can be related to the box distribution \( \text{Box}_a(x)\delta(y) \), where

\[ \text{Box}_a(t) = \begin{cases} 
1/a & \text{for } -a/2 < t \leq a/2, \\
0 & \text{otherwise},
\end{cases} \]

and \( \delta(y) \) is the delta function. Indeed, using the rotation-invariance and the multiplication-convolution property of the Fourier transform, we see that the left side of (1) is the Fourier transform of

\[ \text{Box}_{a_1}(x \cos \theta_1 + y \sin \theta_1)\delta(x \sin \theta_1 - y \cos \theta_1) \ast \cdots \ast \text{Box}_{a_N}(x \cos \theta_N + y \sin \theta_N)\delta(x \sin \theta_N - y \cos \theta_N), \tag{2} \]

where every \( a_k \) equals \( \sigma\sqrt{24}/N \). This gives us the dual interpretation of (1) in the space domain, namely that \( g(x, y) \) can be approximated using the convolution of uniformly rotated box distributions. This idea is illustrated in Figure 1. The function in (2) turns out to be a compactly-supported piecewise polynomial of degree \( \leq N - 2 \), popularly called a box spline. Note that we could as well replace the sinc function in (1) by any other “bump” function that looks like an inverted parabola around the origin, e.g. the cosine function as used in [8]. However, not every such function would be the Fourier transform of a simple, compactly-supported function such as the box function.

Applied to a continuously-defined function \( f(x, y) \), this means that we can approximate the Gaussian filtering \( (f*g)(x, y) \) by successive convolutions with a fixed number of rotated box distributions. Now, note that the convolution of \( f(x, y) \) with \( \text{Box}_a(x \cos \theta + y \sin \theta)\delta(x \sin \theta - y \cos \theta) \) amounts to doing one-dimensional convolutions of \( \text{Box}_a(t) \) with profiles of \( f(x, y) \) sampled along \( L_{\theta} = \{(x, y) : x \cos \theta - y \sin \theta = 0\} \) and lines parallel to \( L_{\theta} \). For example, the convolution of \( f(x, y) \) with \( \text{Box}_a(x)\delta(y) \) is given by one-dimensional
convolutions of $\text{Box}_a(t)$ with the profiles of $f(x,y)$ along the $x$-coordinate and lines parallel to it. The idea in [3] was to decompose the convolution with a box distribution into two steps:

- Pre-integration of the scan profiles along $L_{\theta_k}$ ($1 \leq k \leq N$) and lines parallel to it. This resulted in the so-called *running sum*.

- Application a finite-difference mesh to the running sum at each pixel, where the mesh parameters were determined by the scales $a_1, \ldots, a_N$.

By doing so, the cost of the convolutions with the box distributions was reduced to the cost of (1) and (2), which is clearly $O(1)$ per pixel irrespective of the values of $a_1, \ldots, a_N$.

This idea was then extended to perform the more challenging space-variant filtering. This was based on the observation that by adjusting the scale of the box spline along each direction $\theta_1, \ldots, \theta_k$, one could control the anisotropy of the box spline. From the algorithmic perspective, this meant that we could change the filter at every pixel simply by changing the finite-difference mesh. This resulted in a fast algorithm for space-variant (or, non-convolution) filtering that had the same $O(1)$ complexity.
In particular, for the case \( N = 4 \), corresponding to \( \theta_1 = 0, \theta_2 = \pi/4, \theta_3 = \pi/2, \theta_4 = 3\pi/4 \) in \([2]\), a simple algorithm was developed that allowed one to control the covariance simply by adjusting the scales \( a_1, \ldots, a_4 \) in \([2]\). We continue to use \( \beta_a(x, y) \) to denote this four-directional box spline, where we call \( a = (a_1, a_2, a_3, a_4) \) the scale-vector. The algorithm for the four-directional box spline proceeded in two steps. In the first step, the running sum was obtained by pre-integrating the image along the directions \( 0, \pi/4, \pi/2, \) and \( 3\pi/4 \). This was done using fast recursions. To keep the running sum on the Cartesian grid, a step size of unity was used along the horizontal and vertical directions, while a step of \( \sqrt{2} \) was used along the diagonals. In the second step, a 16-tap finite-difference mesh was applied at point of the running sum, where the taps of the mesh was determined by the scale-vector. This produced the final filtered image. We refer the readers to Algorithm 1 in \([3]\) for further details. Henceforth, we will refer to this as the BoxFilter algorithm. More recently, similar ideas have also been applied in the field of computer graphics \([6]\). By adapting the same algorithm, an efficient technique for detecting blobs in cell images was also proposed in \([11]\).

The anisotropy of \( \beta_a(x, y) \) was specified using three parameters, its size \( (s_a) \), elongation \( (\rho_a) \), and orientation \( (\theta_a) \). These were defined using the eigen decomposition of the covariance matrix of \( \beta_a(x, y) \),

\[
C_a = \begin{pmatrix}
\int \int x^2 \beta_a(x, y) \, dxdy & \int \int xy \beta_a(x, y) \, dxdy \\
\int \int xy \beta_a(x, y) \, dxdy & \int \int y^2 \beta_a(x, y) \, dxdy
\end{pmatrix}.
\]

(3)

The size was defined as the sum of the eigenvalues, the elongation as the ratio of the larger to the smaller eigenvalue, and the orientation as the angle (between 0 and \( \pi \)) of the top eigenvector. In fact, the covariance of \( \beta_a(x, y) \) was explicitly computed to be

\[
C_a = \frac{1}{24} \begin{pmatrix}
2a_1^2 + a_2^2 + a_3^2 & a_2^2 - a_4^2 \\
2a_3^2 + a_2^2 + a_4^2 & a_4^2 - a_2^2
\end{pmatrix}.
\]

(4)

This resulted in the following formulas in terms of the scale-vector:

\[
s_a = \frac{1}{12} \sum a_k^2, \quad \rho_a = \frac{\sum a_k^2 + \sqrt{D}}{\sum a_k^2 - \sqrt{D}}, \quad \text{and} \quad \tan \theta_a = \left( \frac{a_3^2 - a_1^2 + \sqrt{D}}{a_3^2 - a_1^2 - \sqrt{D}} \right),
\]

(5)

where \( D = (a_1^2 - a_3^2)^2 + (a_2^2 - a_4^2)^2 \).

The scale vector was to control the anisotropy of the filter at every pixel, and this was done, in effect, by controlling the tap positions of the finite-difference. Note that \( C_a = (a^2/6)I \) when all the four scales are equal.
to a. As a result, the best approximation of the isotropic Gaussian with variance $\sigma^2$ was obtained by setting each scale to $\sqrt{6}\sigma$. As for the anisotropic setting, a simple algorithm for uniquely determining the scales for a given size, elongation, and orientation (equivalently, for a given covariance) was provided in [3]. The algorithm took the covariance $C$ as input and returned the box spline that had the minimum kurtosis among all box splines with covariance $C$.

1.2 Problem description

There are, however, two bottlenecks with the above approach. The first is that one cannot control the accuracy of the Gaussian approximation in case of the space-variant filtering. We note that this problem can be addressed for the more simple setting of convolution filtering simply using higher-order box splines (see Figure 1). In effect, this amounts to repeated filtering of the image with the four-directional box spline. However, this cannot be done in the space-variant setting, where the kernel changes from point-to-point. The only possibility is to adapt the algorithm for the higher-order box splines. This, however, turns out to be of limited practical use since the size of the finite-difference mesh grows as $2^N$ with the order $N$ (two points per box distribution).

The other problem is the control on the elongation of the anisotropic box splines. This problem is intimately related to the geometry of the Cartesian grid $\mathbb{Z}^2$. Note that the axes $L_\theta$ of the box distribution in the continuous setting corresponds to the discrete points $L_\theta = \{(m, n) \in \mathbb{Z}^2 : m \cos \theta_k - n \sin \theta_k = 0\}$ on the grid. As a result, one requires $\tan \theta_k$ to be a rational number to avoid interpolating the off-grid samples. It is, however, easily seen that, for $N > 4$, one cannot find lines $L_{\theta_1}, \ldots, L_{\theta_N}$ with the requirement that $\theta_1, \ldots, \theta_N$ are uniformly distributed. This restricted us to the four-directional box spline $\beta_a(x, y)$. This restriction on the number of directions resulted in a ceiling on the maximum achievable elongation. In particular, while $\beta_a(x, y)$ could arbitrarily elongated in the neighborhood of its four axes, it was difficult to achieve large elongations in the neighborhood of the mid-axes, i.e., along $\pi/8, 3\pi/8, 5\pi/8$, and $7\pi/8$. It was found that, for every orientation $0 \leq \phi < \pi$, there is a bound $e(\phi)$ on the elongation achievable by $\beta_a(x, y)$ given by

$$e(\phi) = \frac{1 + t + \sqrt{1 + t^2}}{1 + t - \sqrt{1 + t^2}},$$

(6)

where $t = |\tan \phi - \cot \phi|/2$. This meant that $\rho_a$ could be made at most
as large as $e(\phi)$ under the constraint that $\theta_a = \phi$, where $\rho_a$ and $\theta_a$ are as defined in (5). The smallest value of $e(\phi)$ as $\phi$ varied over the half-circle was found to be roughly 5.8, and this was reached along the mid-axes where one had the least control.

2 Improved accuracy and elongation

We now address the above mentioned problems for the four-directional box-spline. Our interest is mainly in the space-variant setting, where the filter varies from point-to-point in the image.

2.1 Improved accuracy

As remarked earlier, the Gaussian approximation can be improved by convolving the box spline with itself. All that needs to be guaranteed is that the covariance remains equal to that of the target Gaussian after the convolution. In fact, when the functions involved have some structure, one can exactly predict how the covariance changes with smoothing.

**Proposition 2.1 (Covariance of convolutions).** Let $f(x,y)$ and $g(x,y)$ be two functions which are symmetric around the origin, and which have unit mass. Then the covariance of $(f * g)(x,y)$ is the sum of the covariances of $f(x,y)$ and $g(x,y)$.

Note that $\beta_a(x,y)$ automatically satisfies the conditions in the proposition. Our next observation is that we can get a higher-order space-variant filter from a lower-order space-variant filter by applying a global convolution. We note that the space-variant filtering of $f(x,y)$ can generally be written as

$$\mathcal{F}(x,y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x-u,y-v)h(x,y;u,v) \, du \, dv,$$

where $h(x,y;u,v)$ is the space-variant kernel that is indexed by the spatial coordinates $(x,y)$.

**Proposition 2.2 (Filter decomposition).** Let $h_1(x,y;u,v)$ be a space-variant kernel, and let $h_2(x,y)$ be a convolution kernel. Then the convolution of $f(x,y)$ with $h_2(x,y)$, followed by the space-variant filtering with $h_1(x,y;u,v)$, can be expressed as a single space-variant filtering:

$$\mathcal{F}(x,y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x-u,y-v)h(x,y;u,v) \, du \, dv,$$
where

\[ h(x, y; u, v) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} h_1(x, y; u', v') h_2(u - u', v - v') \, du' \, dv'. \]

Propositions 2.1 and 2.2 together suggest a simple means of improving the Gaussian approximation for space-variant filtering. Suppose that \( C \) is the covariance of the target Gaussian. We split this into two parts, namely,

\[ C = \sigma^2 I + \Delta C. \tag{7} \]

Note that \( C \) and \( \Delta C \) have the same orientations, that is, \( \sigma^2 I \) possibly alters the elongation, but not the orientation. This is confirmed by the fact that \( C \) and \( \Delta C \) have the same set of eigenvectors.

**Algorithm 1** Space-variant \( O(1) \) Gaussian filtering (better accuracy)

**Input:** Image \( f(m, n) \), covariance map \( C(m, n) \).
1. Set \( \sigma^2 \) to be half the bound in (9).
2. Set \( a_1 = \cdots = a_4 = \sqrt{6} \sigma \).
3. Pass \( a_1, \ldots, a_4 \) and \( f(m, n) \) to the **BoxFilter** algorithm, which return \( g(m, n) \).
4. At each pixel, compute \( a(m, n) \) from \( C(m, n) - \sigma^2 I \).
5. Pass \( a(m, n) \) and \( g(m, n) \) to **BoxFilter** algorithm, which returns \( f(x, y) \).

**Return:** Filtered image \( f(x, y) \).

The idea is we first convolve the image \( f(x, y) \) with an isotropic \( \beta(x, y) \) of covariance \( \sigma^2 I \) (each \( a_k \) is \( \sqrt{6} \sigma \)). This is done using the \( O(1) \) algorithm described earlier. We then calculate the residual \( \Delta C \) at each point in the image. This is used to fix \( a \) of the anisotropic \( \beta_a(x, y) \). The scale assignments are then used for the space-variant filtering, again using the \( O(1) \) algorithm. The main steps are given in Algorithm 1. It is clear that the overall algorithm requires \( O(1) \) operations per pixel.

There is a technical point that must be addressed at this point. Namely, \( \sigma \) must be so chosen that \( \Delta C \) is again a valid covariance matrix, that is, \( \Delta C \) be positive definite. Now, note that \( \Delta C \) can be written as \( Q^T (\Lambda - \sigma^2 I) Q \), where \( Q^T \Lambda Q \) is the eigen decomposition of \( C \). It follows that a necessary and sufficient condition for \( \Delta C \) to be a valid covariance matrix is that \( \sigma^2 \) must be smaller than the minimum eigenvalue of \( C \), that is,

\[ \sigma^2 < \frac{1}{2} \left( C_{11} + C_{22} - \sqrt{(C_{11} - C_{22})^2 + 4C_{12}^2} \right). \tag{8} \]
Figure 2: This show the steps involved in improving the accuracy of the Gaussian approximation. The isotropic ones are shown on the top panel, while the bottom panel shows the anisotropic ones. In either case, (a) is the four-directional box spline with covariance $\sigma^2 I$, and (b) is the four-directional box spline with covariance $C - \sigma^2 I$, where $C$ is the covariance of the target Gaussian. The resulting box spline approximation is shown in (c), which indeed looks more Gaussian-like than the ones in (b) and (c). See Figure 3 for a comparison of the approximations.
The other consideration comes from the bound in (6) (this concerns only the anisotropic case), which requires that the ratio of the eigenvalues of \( \Delta C \) must be with \( e(\phi) \), where \( \phi \) is the orientation of the target Gaussian. A simple calculation shows that this is equivalent to

\[
\sigma^2 < \frac{1}{2} \left( C_{11} + C_{22} - \frac{e(\phi) + 1}{e(\phi) - 1} \sqrt{(C_{11} - C_{22})^2 + 4C_{12}^2} \right). \tag{9}
\]

Since \( e(\phi) > 1 \), this bound is clearly smaller than the one in (8), so it suffices to guarantee that (9) holds.

We have empirically observed that, while it is the order of the box splines that dictates the final smoothness, it is the size of \( \sigma \) that controls the level of approximation. In practice, we have observed that the best approximations are obtained when \( \sigma^2 \) is roughly 50% of the bound in (9). We will discuss this in detail in the sequel.

### 2.2 Improved elongation

We now address the elongation problem. The elongations achievable by the box spline is minimum exactly mid-way between the axes of the box distributions, namely along 22.5°, 67.5°, 112.5°, and 157.5°. An intuitive solution to this is to place box distributions along these angles. As mentioned earlier, the problem is that the tangents of these angles are not rational. The best we can do in this situation is to approximate the tangents by rational numbers. In other words, for an given angle \( \theta \), the problem reduces to one of finding integers \( p \) and \( q \) such that \( p/q \approx \tan \theta \). Of course, we would also like to keep \( p \) and \( q \) as small as possible. Also, for every \( \theta \) with \( \tan \theta = p/q \), we balance it with the orthogonal angle \( \theta + 90^\circ \). This is easily done by setting the tangent of the orthogonal angle to \(-q/p\). For example, if we set \( p = 1 \) and \( q = 2 \), then we get two orthogonal directions at roughly 26.6° and 116.6°. The other two directions are obtained by setting \( p = 2 \) and \( q = 1 \) which gives the orthogonal directions at roughly 63.4° and 153.4°. Though these are not distributed uniformly over the half-circle, they are off the mark by only about 4°. To the best of our knowledge, this is the best we can do keeping \( p \) and \( q \) as small as possible.

This gives us eight directions on the Cartesian grid that are “almost” uniformly distributed over the half-circle and whose tangents are rational. The idea then is to place box distributions along all or some of these directions. The higher the number of directions, the better is the Gaussian approximation. Unfortunately, as mentioned in the introduction, there are practical difficulties in simultaneously using the eight directions. Keeping in mind that we
already have a solution to improve the accuracy, we instead propose the following trick. The idea is to use a pair of four-directional box splines, \( \beta_a(x, y) \) with angles \( \Theta = \{0^\circ, 45^\circ, 90^\circ, 135^\circ\} \), and \( \beta'_a(x, y) \) with angles \( \Theta' = \{26.6^\circ, 63.4^\circ, 116.6^\circ, 153.4^\circ\} \). We next divide the half-circle into two disjoint sectors \( S \) and \( S' \), where \( S \) consists the neighborhood of the former angles, and \( S' \) consists of the neighborhood of the latter angles. To approximate a Gaussian with orientation \( \phi \), we use \( \beta_a(x, y) \) if \( \phi \) is in \( S \), and \( \beta'_a(x, y) \) if \( \phi \) is in \( S' \). This allows us to achieve better elongations than what \( \beta_a(x, y) \) or \( \beta'_a(x, y) \) could achieve by themselves. Of course, we will now require two sets of running sums, one corresponding to each of the box splines. The overall algorithm for space-variant filtering is summarized in Algorithm 2. We note that, as proposed in Section 2.1, we could smooth the four-directional box splines with a isotropic box spline, if higher accuracy is desired.

**Algorithm 2** Space-variant \( O(1) \) Gaussian filtering (improved elongation)

1. **Input:** Image \( f(m, n) \) and covariance map \( C(m, n) \) on \( \mathbb{Z}^2 \).
2. Perform running sums on \( f(m, n) \) along \( \Theta \) to get \( g(m, n) \).
3. Perform running sums on \( f(m, n) \) along \( \Theta' \) to get \( g'(m, n) \).
4. At each \((m, n)\) do
   (a) Compute the orientation \( \phi \) from \( C(m, n) \).
   (b) if \( \phi \in S \), then
       (b1) Compute \( a \) for \( \beta_a(x, y) \), and the finite-difference parameters.
       (b2) Apply finite-difference on \( g(m, n) \) to get \( \tilde{f}(m, n) \).
   else \( (\phi \in S') \)
       (b1) Compute \( a \) for \( \beta'_a(x, y) \), and the finite-difference parameters.
       (b2) Apply finite-difference on \( g'(m, n) \) to get \( \tilde{f}(m, n) \).
5. Return: Filtered image \( \tilde{f}(m, n) \).

2.3 Filtering algorithm for \( \beta'_a(x, y) \)

We note that the algorithm for space-variant filtering using \( \beta'_a(x, y) \) is identical to the one for \( \beta_a(x, y) \). For completeness, we describe this in Algorithm 3. Here \( x_0, \ldots, x_{15} \) and \( y_0, \ldots, y_{15} \) are the coordinates of the finite-difference mesh, and \( w_0, \ldots, w_{15} \) are the corresponding weights. The exact values are given in table 1. The shifts \( \tau_1 \) and \( \tau_2 \) along the image coordinates are given by

\[
\tau_1 = \frac{1}{2\sqrt{5}}(2a_1+a_2-a_3-2a_4) \text{ and } \tau_2 = \frac{1}{2\sqrt{5}}(a_1+2a_2+2a_3+a_4-6\sqrt{5}).
\]
whose area can be determined by inspection. This can also be found using the square \([\sqrt{5}, \sqrt{5}, \sqrt{5}, \sqrt{5}]\). The box spline \(\beta^*_b(x, y)\) is supported within the square \([-3, 3]^2\), and this is why we have a finite sum in (11). This can be seen as an interpolation step, where we interpolate the running-sum using the samples of the box spline.

### 2.4 Analytical formulas for \(\beta^*_b(x, y)\)

The exact formula for the box spline \(\beta^*_b(x, y)\) in (11) can be computed analytically. To do so, we note that this box spline can be expressed as the convolution of two rescaled and rotated box functions. In particular, \(\beta^*_b(u, v)\) is given by the area of overlap between a box function of width \(\sqrt{5}\) and height \(1/\sqrt{5}\) that is centered at the origin and rotated by \(\phi_1\), and a second box function of same width and height that is centered at \((u, v)\) and rotated by \(\phi_2\), where \(\tan \phi_1 = 1/2\) and \(\tan \phi_2 = 2\). The overlapping region is a polygon, whose area can be determined by inspection. This can also be found using symbolic computation. For example, this can be done in Mathematica by
We defined the size, elongation and orientation as in (5). The final expressions are respectively

\[
\beta(x, y) = \frac{1}{60} \left( 4a_1^2 + a_2^2 + a_3^2 + 4a_4^2 - 2(a_1^2 + a_2^2 - a_3^2 - a_4^2) \right).
\]

and then invoking the command Convolve\{ f[u,v], g[u,v], \{u,v\}, \{x,y\}\}. The function returned is a piecewise polynomial of second degree that is compactly supported on an octagonal domain. The equation for each patch is stored in a look-up table.

**Algorithm 3** Space-variant \(O(1)\) filtering using \(\beta_a'(x, y)\)

1. **Input:** Image \(f(m, n)\) and scale map \(a(m, n)\) on \(Z^2\).
2. Use recursion to compute the following:
   (a) \(g_1(m, n) = \sqrt{5}f(m, n) + g_1(m-1, n-2)\).
   (b) \(g_2(m, n) = \sqrt{5}g_1(m, n) + g_2(m-2, n-1)\).
   (c) \(g_3(m, n) = \sqrt{5}g_2(m, n) + g_3(m+1, n-2)\).
   (d) \(g_4(m, n) = \sqrt{5}g_3(m, n) + g_4(m+2, n-1)\).
3. **At each** \((m, n)\) **do**
   (a) Set up \(w_i, x_i, y_i(i = 0, 1, \ldots, 15)\) using table [1] and \(\tau_1, \tau_2\) using [10].
   (b) Compute \(F_i = F(m+\tau_1-x, n+\tau_2-y)\) for \(i = 0, 1, \ldots, 15\) using [11].
   (c) Set \(\bar{f}(m, n) = w_0F_0 + \cdots + w_{15}F_{15}\).
4. **Return:** Filtered image \(\bar{f}(m, n)\).

Similar to \(\beta_a(x, y)\), we can control the covariance (size, elongation, and orientation) of \(\beta_a'(x, y)\) using its scale vector. We computed the covariance of \(\beta_a'(x, y)\) to be

\[
\frac{1}{60} \left( \frac{4a_1^2 + a_2^2 + a_3^2 + 4a_4^2 - 2(a_1^2 + a_2^2 - a_3^2 - a_4^2)}{2(a_1^2 + a_2^2 - a_3^2 - a_4^2)} \right).
\]

We defined the size, elongation and orientation as in (5). The final expressions are respectively

\[
\frac{r}{60} = \frac{r + \sqrt{p^2 + q^2}}{r - \sqrt{p^2 + q^2}}, \quad \text{and} \quad \tan^{-1} \left[ \frac{-p + \sqrt{p^2 + q^2}}{q} \right],
\]

where \(p = 3(a_1^2 - a_2^2 - a_3^2 + a_4^2)\), \(q = 4(a_1^2 + a_2^2 - a_3^2 - a_4^2)\), and \(r = 5(a_1^2 + a_2^2 + a_3^2 + a_4^2)\).

We note that \(a_1, \ldots, a_4\) cannot be uniquely determined from the above three constraints. As proposed in our earlier paper, we select the box spline
that has the minimum kurtosis of all box splines with a given covariance. This turns out to be a one-dimensional optimization problem and can be solved efficiently using a root-finding algorithm. The kurtosis of $\beta_\alpha(x, y)$ using the definition in [13] turns out to be

$$
\frac{\kappa}{5} \left( 4a_1^4 + a_2^4 + a_3^4 + 4a_4^4 + 2(a_1^4 + a_2^4 - a_3^4 - a_4^4) \right),
$$

where $\kappa$ is the kurtosis of the box function $\text{Box}_1(t)$. To get a number from this matrix, we simply take its Frobenius norm, which is then optimized to get the scale vector. The steps of the derivation are identical to the one described in [3], and therefore we skip the details.

### 3 Experiments

We now present some results that confirm the improvements suggested in the previous section. First, we try to see the improvement in the accuracy of the Gaussian approximation. To do so, we consider an isotropic Gaussian with $C = I$, and an anisotropic Gaussian with size 1, elongation 3, and orientation $30^\circ$. In either case, we split the covariance as $C = \sigma^2 I + \Delta C$. The steps in the construction are shown in Figure (2), and the final box splines are compared in Figure (3). In either case, we have used the four-directional box spline to approximate the Gaussian with covariance $\sigma^2 I$, where the four scales were set to $\sqrt{6}\sigma$. To approximate the Gaussian with covariance $\Delta C$, we used a four-directional box spline, but now with unequal scales. The four scales were computed by minimizing the kurtosis of the box spline as explained earlier. It is seen from the figures that the final box splines are indeed very good approximations of the target Gaussian. In particular, the maximum pointwise error was within 1% of the peak value for the isotropic one, while it was within 2% for the anisotropic ones. Note in figure (3) how the convolution helps in “rounding” the sharp corners of the four-directional box spline.

To get a better understanding of the improvement in the accuracy, we compare the approximation error between the target Gaussian and the two box splines. We do this for various sizes, elongations, and orientations of the target Gaussian $g(x, y)$. We use the ratio $\|f - g\|_2/\|g\|_2$ as the normalized error between the approximating box spline $f(x, y)$ and $g(x, y)$, where $\|f\|_2$ is the $L_2$ norm of a function. We computed the error from the analytical formulas of the Gaussian and the box splines using numerical integration. The results are reported in table 2. In the first two instances (isotropic setting),
Figure 3: In this figure, we compare the target Gaussian (c) with the box
spline approximation (a) proposed in [3] and the one (c) proposed in this
work. The isotropic Gaussian has covariance $I$, while the anisotropic one has
elongation 3 and orientation $30^\circ$. The maximum pointwise error is within
1% of the peak value for the former and within 2% for the later. A visual
comparison confirms the improvement in the accuracy – it is indeed hard to
distinguish (b) from (c).

Table 2: Improvement in Gaussian approximation using Algorithm 1. The
table shows the normalized errors for the BoxFilter in [3] (second row)
and the filter proposed in the paper (third row). This is done for certain
representative size ($s$), elongation ($\rho$), and orientation ($\theta$) of the target
Gaussian.

| $(s, \rho, \theta)$ | (1,1,0) | (5,1,0) | (1,4,0) | (5,4,0) | (5,3,$\pi$/8) | (5,8,$\pi$/3) | (5,5,$\pi$/2) |
|------------------|--------|--------|--------|--------|-------------|-------------|-------------|
| Error (%) in [3] | 10.8   | 10.8   | 19.1   | 18.7   | 23.9        | 19.2        | 17.2        |
| Present error (%)| 4.9    | 4.9    | 15.3   | 14.6   | 20.8        | 15.8        | 12.6        |
| Improvement (%)  | **54.8**| **54.8**| **21.6**| **18.32**| **12.7** | **17.7** | **26.7** |
note that there is almost a 40% improvement in the approximation (this is the case for any size). The improvement is less dramatic, but nonetheless appreciable, for the remaining five instances (anisotropic setting). We found that this is between 10% – 30% for the anisotropic box splines in general. The improvement is on the higher side when the orientation is close to one of the four axes of the box spline.

We now discuss the choice of $\sigma$ in (7) used in the above experiments. As noted earlier, we have observed that the best results are obtained when $\sigma^2$ for the isotropic box spline is roughly 50% of the bound in (9). The variation in the approximation accuracy is shown in table 3 for a particular Gaussian. Exhaustive experiments across various settings have shown that this happens consistently across different size, elongation, and orientation. The explanation for this is that very little smoothing takes place when $\sigma$ is small, which explains the marginal improvement in accuracy. On the other hand, large values of $\sigma$ result in over-smoothing, where the isotropic box spline dominates the overall anisotropy – the contribution from the anisotropic part is less significant. Following these observations, we set $\sigma^2$ to be 50% of the bound in (9).

Table 3: Effect of $\sigma$ in (7) on the Gaussian approximation. The table shows the difference between (a) the approximation error between a fixed Gaussian $(s = 5, \rho = 3, \theta = \pi/4)$ and the BoxFilter, and (b) the error between the same Gaussian and the present filter. The best results are obtained when $\sigma^2$ is roughly 50% of the bound in (9).

| % of the bound in (9) | 10 | 20 | 30 | 40 | 50 | 60 | 70 | 80 |
|----------------------|----|----|----|----|----|----|----|----|
| Improvement (%)      | 3.5 | 12.1 | 22.3 | 29.9 | 33.3 | 33.13 | 30.9 | 28.8 |

We now study the improvement in elongation obtained using Algorithm 2. While there is an explicit formula for the bound of $\beta_a(x, y)$, we computed the bound of $\beta'_a(x, y)$ empirically. Table 4 gives a comparison of the maximum elongations achievable using $\beta_a(x, y)$ and $\beta'_a(x, y)$ as against that achievable using only $\beta_a(x, y)$. In the table, we give the bounds on the elongation for orientations in the sector $[0^\circ, 45^\circ]$, spanned between two neighboring axes of $\beta_a(x, y)$. While large elongations are achievable using $\beta_a(x, y)$ in the the caps $[0^\circ, 5^\circ]$ and $[40, 45^\circ]$, the bound falls off quickly outside these caps. In particular, the bound falls to a minimum of 5.8 at 22.5°. The second box spline $\beta'_a(x, y)$, with its axis along 26.6°, helps us improve the elongation over $[5^\circ, 40^\circ]$. For example, the bound at 22.5° has now increased to 10.8, and remains fairly high in the cap $[20^\circ, 40^\circ]$. However, a minimum of 8.2 is
reached at 13.3°, exactly midway between the axes of $\beta_a(x, y)$ and $\beta'_a(x, y)$. This is nevertheless better than the previous low of 5.8. We have evidence that the use of a third box spline with axes close to 13.3° can improve the minimum bound to 15.2. We note that the use of multiple box splines increases the run time of the BoxFilter by only 10% – 15%. The added computations are required only from the running sums, which is the fastest part of the algorithm. The finite-difference part of the algorithm remains the same. For every orientation, one simply has to choose the correct running sum and the associated finite-difference.

Table 4: Comparison of the elongations achievable in [3] and using Algorithm 2. The table shows the bounds on the elongation at different orientations using a single box spline filter (second row) and a pair of box spline (third row). The new bound is the maximum of the bounds of the two box splines.

| Orientation | 0°  | 5°  | 13.3° | 20°  | 22.5° | 25°  | 26.6° | 30°  | 40°  | 45°  |
|-------------|-----|-----|-------|------|-------|------|-------|------|------|------|
| Previous bound | ∞   | 13.6 | 6.8   | 5.9  | 5.8   | 5.9  | 6.0   | 6.1  | 13.6 | ∞    |
| New bound   | ∞   | 13.6 | 8.2   | 9.5  | 10.8  | 30.1 | 28.8  | 13.6 | ∞    |

We have implemented a basic version of Algorithm 1 as an ImageJ plugin. The Java code can be found at www.math.princeton.edu/~kchaudhu/code.html. Some of the results in this paper can be reproduced using this plugin. The typical run time on a 256 × 256 image (Intel quad-core 2.83 GHz processor) was around 300 milliseconds. As expected, the run time was approximately the same for filters of different shape and size. On the other hand, we have tested the formulas for the box spline $\beta_a(x, y)$ by implementing Algorithms 2 in Matlab. The typical run time was around 600 milliseconds on a 256 × 256 image. The results obtained on a impulse image are shown in Figure 4. In the future, we plan to improve the run time by implementing the algorithms in Java.

4 Discussion

In this work, we showed that the performance of the box spline filters in [3] can be improved, while preserving the $O(1)$ complexity of the original algorithm. In particular, we showed how the accuracy of the Gaussian approximation can be improved by pre-filtering the image with an isotropic Gaussian of appropriate size. This idea is in fact quite generic, and can be used to improve the performance of any algorithm for space-variant filtering. We also showed that better elongations can be achieved using a pair of
Figure 4: This shows the Gaussian-like blobs obtained by applying Algorithm 3 to an impulse image. (a) is the isotropic response obtained using equal scales. (b) and (c) are the anisotropic responses obtained using unequal scales. The latter are oriented along 45° and 135°, and have elongation 3.

four-directional box splines instead of one. The present work suggests that both the accuracy and the elongation can be dramatically improved, at a small extra cost, by using a bank of four-directional box splines (ideally, three or four) whose axes are evenly distributed over the half-circle. We will investigate this possibility in the future.
