Airway tight junctions as targets of viral infections

Tight Junctions and Viral Infections

ABSTRACT
The apical junctional complexes (AJCs) of airway epithelial cells are a key component of the innate immune system by creating barriers to pathogens, inhaled allergens, and environmental particles. AJCs form between adjacent cells and consist of tight junctions (TJs) and adherens junctions (AJs). Respiratory viruses have been shown to target various components of the AJCs, leading to airway epithelial barrier dysfunction by different mechanisms. Virus-induced epithelial permeability may allow for allergens and bacterial pathogens to subsequently invade. In this review, we discuss the pathophysiologic mechanisms leading to disruption of AJCs and the potential ensuing ramifications. We focus on the following viruses that affect the pulmonary system: respiratory syncytial virus, rhinovirus, influenza viruses, immunodeficiency virus, and other viruses such as coxsackievirus, adenovirus, coronaviruses, measles, parainfluenza virus, bocavirus, and vaccinia virus. Understanding the mechanisms by which viruses target the AJC and impair barrier function may help design therapeutic innovations to treat these infections.

Introduction
The human airway is in direct contact with the outside world, and therefore, is an integral member of the innate immune system and maintaining inner homeostasis. The airway acts as a barrier, comprised of surface liquids, mucus, and epithelium with its apical junctional complexes (AJCs). AJCs form between adjacent cells and consist of tight junctions (TJs) and adherens junctions (AJs), maintaining cell polarity and attachment between neighboring cells. Likewise, AJCs control molecule, microorganism, and particle trafficking throughout the paracellular space in a semipermeable manner (Figure 1). The apical TJ is a dynamic structure and undergoes continuous turnover. It includes three main subsets of proteins: 1. The claudin family, comprising claudin-1 through 27 in mouse and human; 2. The tight junction-associated Marvel domain-containing (TAMPs) family, containing occludin, tricellulin, and MARVEL domain-containing protein 3 (MARVELD3); and 3. The immunoglobulin family, consisting of Junctional Adhesion Molecule-A (JAM-A), JAM-B, JAM-C, and the Coxsackie and Adenovirus Receptor (CAR). Immunohistological experiments have shown that claudins differ in their intracellular localization. Claudin-3, –5, and –8 have been detected exclusively in TJ complexes, while claudin-1 and –4 localized throughout the lateral membranes and the apico-lateral TJ complexes. The localization patterns have implications for viral targeting of these proteins, as discussed in subsequent sections.

The AJ is located more basally than the TJ and contains proteins within the Cadherin family, most notably E-cadherin, and the nectin sub-family. They maintain and stabilize cell-cell adhesions and regulate the actin cytoskeleton. Moreover, E-cadherin binds to α- and β-catenin, which are involved in gene expression, intracellular signaling, and transcriptional regulation. Cytosolic plaque proteins and polarity proteins both interact with TJ proteins and play crucial parts in maintaining TJ function. TJ proteins bind to zonula occludens
(ZO) family plaque proteins, which link the TJ with actin-binding proteins. Together, these proteins regulate paracellular transport of ions and small molecules, as well as maintain cellular structure by interacting with the actin cytoskeleton. Polarity proteins play a vital role in the maintenance of apical and basolateral polarization. Some major polarity proteins include Crumbs complex, comprised of Crumbs, Proteins Associated with Lin Seven 1 (PALS1), PALS1-Associated Tight Junction protein (PATJ), and the Scribble complex, containing scribble, Dlg, and Lgl. 

**Figure 1. Structure of the airway epithelial cell apical junction complexes.** The human airway comprises epithelium, surface mucus layers, and underlying immune cells, such as dendritic cells (DC). AJC form between neighboring cells and comprise TJ and AJ, which are associated with an underlying perijunctional actin cytoskeleton. Respiratory viruses can lead to AJC disassembly and disruption. Subsequently, virus-induced epithelial permeability may allow for allergens, environmental insults, like pollution and cigarette smoke, and bacterial pathogens to invade. An immune response, represented here with DC, is activated to combat the viral infection and reestablish the AJC and eliminate the bacterial pathogens and allergens that gained access to the internal system. Multiple pathways have been implicated in restoring the AJC barrier. Following RSV infection, cyclic adenosine cAMP and PKD-inhibitors have reduced viral replication and attenuated AJC disruption to restore the epithelial barrier. This image was created with BioRender.com.

**Abbreviations used in the image:** AJC (apical junctional complex), AJ (adherens junction), TJ (tight junction), ZO (zonula occludens), DC (dendritic cell), cAMP (cyclic adenosine monophosphate), PKD (protein kinase D), RSV (respiratory syncytial virus), HRV (human rhinovirus), COVID-19 (coronavirus disease 2019, also known as SARS-CoV-2), SARS-CoV (severe acute respiratory syndrome coronavirus), HIV (human immunodeficiency virus), MeV (measles virus), IAV (influenza A virus), EV (enterovirus), CV (coxsackievirus), Adv (adenovirus), H1N1 (2009 pandemic Influenza A/H1N1pdm09 strain), HPIV (human parainfluenza virus), HBoV (human bocavirus), VV (vaccinia virus), CAR (coxsackie and adenovirus receptor).
Viruses are obligate intracellular parasites and require the use of living cellular machinery for survival. This means that viruses have to enter cells, transport their genome to the cytosol or nucleus, and then replicate and produce their progeny. Viral infections enter epithelial cells either via binding to specific AJC targets as receptors for subsequent internalization or by causing disassembly of distinct AJC proteins through regulating the expression or localization of the protein, thus obtaining unencumbered access to the underlying tissue. Many viruses bind to receptors on the apical side of the epithelial cells. Others, however, target basolateral receptors, which are ordinarily inaccessible due to the TJ barrier. These viruses have developed mechanisms to cause TJ disassembly, typically either through regulation of protein expression or localization, in order to reach their receptors. While some viral infections lead to barrier dysfunction by direct cytotoxicity, others cause AJC disruption without inhibiting cell viability, which may represent an evolutionary strategy that facilitates viral replication. Not only does AJC dysfunction allow for viral infectivity, but virus-induced epithelial permeability may allow for allergens and bacterial pathogens to subsequently invade. In this review, we discuss the pathophysiologic mechanisms of viral entry resulting in disruption of the AJC, subsequent ramifications, and restoration of the epithelial barrier. We focus on the following viruses that affect the pulmonary system: respiratory syncytial virus (RSV), human rhinovirus (HRV), influenza viruses, human immunodeficiency virus (HIV), and multiple other viruses such as...
coxsackievirus (CV), adenovirus (AdV), coronavirus family, measles virus (MeV), human parainfluenza virus (HPIV), human bocavirus (HBoV), and vaccinia virus (VV). Uncovering the mechanisms by which viruses impact the AJC and impair barrier function will help design therapeutic innovations to treat these infections.

**Viral disruption of tight junctions**

Emerging evidence has shown that different viruses cause AJC dysfunction by targeting several TJ and AJ proteins (Table 1). The majority of these studies have been conducted on transformed airway epithelial cell lines, which form polarized, tight barriers, while others have utilized primary airway epithelial cells (AECs) and murine models. Below, we discuss recent studies that have investigated the impact of viral infection on airway epithelial barrier integrity.

**Respiratory Syncytial Virus (RSV)**

The family Pneumoviridae was recently reclassified as a family with two genera, orthopneumovirus and metapneumovirus. Human RSV is a representative member of the orthopneumovirus family, and human metapneumovirus (hMPV) is an example within the metapneumovirus family. These viruses are large, enveloped, negative-sense, single-stranded, RNA viruses. There are multiple reports of the effect of RSV on the airway epithelial barrier, while the effect of hMPV has not been studied. RSV primarily infects airway epithelial cells and is the leading cause of lower respiratory tract infections (LRTI) among young children and a significant cause of morbidity and mortality among the elderly and immunocompromised individuals. It is transmitted by either direct or indirect contact with respiratory droplets. Multiple studies have shown a strong association between RSV infection, persistent wheezing, and childhood asthma. Environmental exposures are considered to be major driving factors for exacerbations of viral infection and may increase the susceptibility of the airway epithelial barrier to RSV infection.

Our group previously showed that RSV infection of both 16HBE14o – human bronchial epithelial (16HBE) cell lines and primary AECs led to disassembly and disruption of TJ and AJ proteins, such as ZO-1, occludin E-cadherin, β-catenin, and claudin-1 and 4 independent of cell death and necrosis. Moreover, RSV infection did not affect the expression and total quantity of AJC proteins, indicating that the changes in the assembly of the AJC could be explained by rearrangements and internalization of the TJs, a process called endocytosis. These results were consistent with other studies that showed RSV induced a decrease in epithelial resistance and increased permeability of the monolayers. While these studies in 16HBE and AECs cells obtained from lower airways showed marked disruption of claudin-4, studies done in nasal epithelial cells showed an induction of claudin-4, which is possibly explained by the differences in cellular and anatomic properties between nasal and bronchial epithelial cells.

Protein kinase D (PKD) is involved in regulating cell motility, polarity, and shape by controlling the phosphorylation of cortactin. Cortactin is a ubiquitously expressed actin-binding protein that regulates F-actin dynamics between polymerization and depolymerization states during plasma membrane remodeling. Studies showed that PKD colocalizes with E-cadherin, indicating a close role in AJC. Other investigators showed that activation of PKD could decrease the expression of claudin-1 in bronchial epithelial cells. Our group showed that in both 16HBE and AECs, RSV infection triggered PKD-dependent TJ disassembly. In another study, we showed similar effect of double-stranded RNA (dsRNA) mimic, poly(I:C), induced barrier dysfunction, which was also prevented by PKD antagonists. TJ and AJ are associated with cortical F-actin bundles, which are essential for their stabilization in steady-state epithelial cell monolayers. Taken together, RSV-induced AJC disorganization and dysfunction is likely a result of cortical F-actin cytoskeletal remodeling, which is regulated by PKD phosphorylation of cortactin. Likewise, RSV-induced relocalization of cortactin was significantly reduced by pretreatment of epithelial cell monolayers with cyclic adenosine monophosphate (cAMP) analogs. Cyclic cAMP is an essential second messenger required for many critical homeostatic cellular functions such as hormonal regulation, cell differentiation and proliferation, and gene expression. Elevated cAMP levels in epithelial cells modified RSV-
induced airway barrier disruption and reduced viral replication.\textsuperscript{15} Interestingly, this study showed a barrier-protective role for cAMP even when added up to 24 h after viral inoculation.\textsuperscript{15}

In wild-type C57BL/6 mice, RSV infection induced downregulation of ZO-1, occludin, and claudin-1 proteins.\textsuperscript{18} Another study using wild-type BALB/c mouse also found that RSV infection led to decreased mRNA expression of claudin-1 and occludin in lung samples.\textsuperscript{66} There is evidence that ZO-1 and occludin act as positive regulators of epithelial barrier integrity, and therefore, these changes likely contribute to the leakiness of the airway epithelial barrier following infection. The loss of ZO-1 has been shown to be associated with increases in paracellular permeability to ions and large uncharged molecules.\textsuperscript{19,20} Similarly, decreased occludin attenuated the formation of barrier structure in vitro,\textsuperscript{67} and downregulation of claudin-1 was associated with increased permeability of airway epithelial monolayers.\textsuperscript{54} There was an increase in inhaled fluorescent dextran uptake and evidence of increased flux of substances across the respiratory membranes in the mice, thus suggesting the important role of ZO-1, occludin, and claudin-1 in barrier integrity. Intriguingly, RSV infection induced marked upregulation of claudin-2 expression.\textsuperscript{18,21} Claudin-2 belongs to a subset of TJ proteins called pore-forming TJ that prevent epithelial barrier formation, and claudin-2-deficient mice showed decreased permeability in renal proximal tubules.\textsuperscript{68} Likewise, upregulation of claudin-2 by proinflammatory cytokines was shown to increase the permeability of epithelial barriers.\textsuperscript{69}

**Human rhinovirus**

HRV is a member of the *Enterovirus* genus and family *Picornaviridae* and is a non-enveloped, positive-sense, single-stranded RNA virus.\textsuperscript{70,71} HRVs are divided into three distinct groups: HRV A, HRV B, and HRV C.\textsuperscript{72,73} Transmission of HRV occurs through either direct contact or through small aerosol droplets. It is the leading cause of the common cold and upper respiratory tract infections.\textsuperscript{74} Previous studies have revealed that infection of AECs and 16HBE with HRV causes a decrease in trans-epithelial electrical resistance (TEER) and an increase in paracellular permeability. In both *in vivo* and *in vitro* studies, HRV caused disassembly of ZO-1. Some studies have found a dose-dependent increase in apoptosis,\textsuperscript{69} while others have found no evidence of cell death.\textsuperscript{22,74} Looi et al. observed a decrease in claudin-1, occludin, and ZO-1 protein expression in AECs obtained from asthmatic children compared to non-asthmatic.\textsuperscript{23} Interestingly, there was sustained barrier dysfunction in the AECs of asthmatic children, suggesting a continued compromise of the airway. In addition to the same AJC changes that Looi et al. detected, Faris et al. observed a reduction in expression of claudin-4, E-cadherin, and Crumbs3 in polarized, undifferentiated AECs from healthy nonsmokers.\textsuperscript{74} Similarly, in primary human nasal epithelial cells, HRV decreased ZO-1, occludin, claudin-1, and E-cadherin expression, thereby increasing permeability for viral entry.\textsuperscript{21,24}

Understanding the underlying mechanism is crucial in determining possible therapeutic targets. HRV-induced epithelial cell dysfunction was not modified by neutralizing chemokines, such as tumor necrosis factor (TNF)-α, IFN-γ, and IL-1β, suggesting a cytokine-independent process.\textsuperscript{22} NADPH oxidase (NOX), a multunit enzyme that mediates the release of reactive oxygen species (ROS), called the oxidative burst, during viral and bacterial infections,\textsuperscript{75} has been shown to contribute to the inflammatory pathway and barrier disruption in multiple viruses, such as RSV, influenza, and Hepatitis C.\textsuperscript{76–78} Comstock et al. showed, in 16HBE, that HRV-induced ZO-1 and occludin dissociation from the cell periphery was due to the generation of ROS by Rac1-dependent NOX1 activity.\textsuperscript{79} Rac1 is a GTPase protein that regulates many cellular processes, such as cell-cell adhesion and motility.\textsuperscript{80} These effects were also replicated by using poly(I:C), which suggests that HRV exerts its barrier disrupting effects through the generation of dsRNA. Inhibitors of Rac1 attenuated HRV – and poly(I:C) – induced disruptions of barrier function. In nonpolarized AECs, HRV was shown to still stimulate ROS generation, but instead through activation of xanthine oxidase.\textsuperscript{79} Further studies are warranted to understand the role of antioxidants in viral clearance and bacterial superinfection prevention.
Coxsackievirus (CV) and other enteroviruses

CV and other enteroviruses are also members of the Enterovirus genus and family Picornaviridae. These viruses cause a range of diseases, like poliomylitis, hepatitis A, hand, foot, and mouth disease, and the common cold, and can also trigger severe respiratory infections.\textsuperscript{81,82} Transmission usually happens through the respiratory droplets, but can also occur through fecal-oral contamination.\textsuperscript{25,26,81,83,84} The effect of enterovirus-A71 (EV-A71) and coxsackievirus-A16 (CV-A16) on airway barrier have been studied. Epithelial permeability increased in 16HBE cells infected with either EV-A71 and CV-A16 infections, suggesting a disruption in TJ assembly.\textsuperscript{25} There was decreased claudin-4, E-cadherin, and ZO-1 levels due to a decrease in the poliovirus receptor related protein 1 (PVRL1).\textsuperscript{25} PVRL1, also known as nectin1, serves as a cell adhesion molecule (CAM) at the AJ level. This epithelial barrier breakdown allows exposure of the CAR, a member of the immunoglobulin TJ family, as it is located more basolateral within the TJ.\textsuperscript{25–27} As a result, these viruses bind to CAR, leading to infection of the epithelial cell and spread to neighboring cells. In addition, coxsackie B internalization is coupled with the endocytosis of occludin, and studies have shown their co-localization in vesicles inside cells.\textsuperscript{14,28} Occludin enters the cell via macropinocytosis, while coxsackie enters through caveolin-mediated endocytosis. Despite this difference, drugs that impair the macropinocytosis of occludin also impair virus internalization, and vice versa.

Adenovirus

AdVs are members of the Adenoviridae family, which are non-enveloped, double-stranded, DNA viruses.\textsuperscript{85–88} Human AdVs are common causes of upper and lower respiratory tract infections, as well as conjunctival and gastrointestinal tract infections.\textsuperscript{86–88} Transmission usually occurs through aerosol droplets, either by direct contact or surface contact.\textsuperscript{87,88} Like many EVs and CVs, AdVs also bind to CAR for viral entry, and therefore, similarly, TJ disruption is required in order for AdVs to reach the receptor. AdV 9 E4-ORF, as a representative example, binds to PATJ and ZO-2 proteins, which causes a disruption in the TJ and cell polarity without comprising the AJ.\textsuperscript{14} This allows for AdV binding of CAR, and subsequent binding of more basolateral molecules called integrins in order to enter the cell. Recent studies have hypothesized a different mechanism in which AdV enters cells. A splice isofrom of CAR, CAR\textsuperscript{EXS}, localizes to the apical surface of polarized epithelial cells and thus allows for AdV entry.\textsuperscript{14} Further investigation is needed to determine which mechanisms AdV employs to gain access into the cells.

Influenza viruses

Influenza viruses are members of the Orthomyxoviridae family and are enveloped, negative-sense, single-stranded, RNA viruses.\textsuperscript{29,89,90} Influenza virus is mainly transmitted by droplets or respiratory secretions of infected persons.\textsuperscript{29,91} It causes upper respiratory infections, which present with fever, runny nose, cough and sore throat. It may progress to the lower respiratory system and present with shortness of breath, pneumonia, and respiratory distress. Acute respiratory distress syndrome (ARDS) and multi-organ failure are uncommon but potentially fatal developments of influenza.\textsuperscript{92,93} Secondary bacterial pneumonia is a frequent complication of influenza infection, particularly in patients with chronic diseases, which may result in sepsis and significant morbidity and mortality. Influenza viruses are divided into two major categories: A (IAV) and B.\textsuperscript{94,95} The IAV viruses are further classified to different subtypes and strains based on their hemagglutinin (H) and neuraminidase (N) surface proteins. Influenza H1N1 virus caused a pandemic in the summer of 2009.

Influenza viruses primarily infect the airway epithelium and are known to damage the AJC by altering the cytoskeleton of AECs.\textsuperscript{30,96,97} Short et al. used an in vitro co-culture model of human epithelial cells and endothelial cells infected with IAV (H1N1 and H5N1 subtypes). They demonstrated that the infection induced disruption of the epithelial cell barrier, leading to a significant decrease in TEER and increase in permeability. There was loss of claudin-4, but no changes in ZO-1, β-catenin and E-cadherin.\textsuperscript{29,30} The barrier disruption was not due to cell death, which is in contrast with previous studies showing cell death in influenza
infected cells. Interestingly, infection was only detected inside epithelial cells, and not endothelial cells, suggesting that epithelial cells may be more permissive to IAV infection. Pro-inflammatory cytokines were upregulated by endothelial cells but did not play a role in epithelial barrier dysfunction.

In another study, differentiated AECs cells were infected with 2009 pandemic Influenza A/ H1N1pdm09 strain. There was evidence of a decline in barrier function, with a marked decrease in TEER and increase in permeability. They showed a decrease of ZO-1 and the F-actin cytoskeleton, as well as cell death following viral infection and barrier dysfunction. Many cytokines and chemokines were secreted in infected cells, with a significant increase in IL-6, TNF-α, and IL-8, suggesting activation of anti-viral inflammatory responses. Further research is needed to determine if the increased cytokine production is independent of or a result of AJC disruption. Another study used two strains of H1N1pdm09 viruses, A/California04/09 (CA04), and A/ New York/1682/09 (NY1682), to infect human alveolar type II epithelial cells. The study, similarly, found a disruption of the airway barrier with a decrease in TEER and increase in permeability. NY1682 had a higher infectivity rate compared to CA04 and resulted in significantly more epithelial barrier injury, but it stimulated less cytokine production.

**Human Immunodeficiency Virus (HIV)**

HIV is a member of the *Retroviridae* family and an enveloped, positive-sense, single-stranded, RNA virus that, upon entry into the target cell, undergoes reverse transcription and converts to double-stranded DNA. In 2019, there were approximately 38 million people worldwide living with HIV. The virus is primarily transmitted through sexual contact, infected blood, and perinatally. Pulmonary infection remains the leading reason for hospitalization among individuals with HIV, and multiple previous studies have also identified noninfectious pulmonary complications, such as chronic obstructive pulmonary diseases (COPD) and poor lung function. HIV infects the airway epithelium and induces secretions of mucus and pro-inflammatory cytokines. Brune et al. studied the role of HIV on primary AECs monolayers by infecting the cells with two different HIV strains, X4 tropic and R5 tropic. Cells exposed to HIV X4 tropic strain increased paracellular permeability within 24 hours, compared to control cells or HIV R5 tropic cells. This was not due to cell death or apoptosis. There was a statistically significant decrease in E-cadherin mRNA, and protein levels following exposure to the X4 tropic virus. Furthermore, lysosomal inhibitors attenuated E-cadherin degradation following virus exposure. Therefore, this reduction in E-cadherin protein levels was a result of both decreased transcription and lysosomal degradation. Interestingly, AECs cells exposed to HIV R5 tropic showed no changes in E-cadherin. X4 tropic virus uses the CXCR4 co-receptor for cell entry, while R5 tropic virus uses the CCR5 co-receptor. Due to the differences in co-receptors, the X4 tropic virus was internalized by AECs, but R5 virus was not. This perhaps explains the differences in E-cadherin degradation between these two strains.

Nuclear factor erythroid 2 (Nrf2) activates antioxidant response elements, thereby protecting cells from oxidative stress. Fan et al. obtained primary AECs from HIV-1 transgenic and wild-type Fischer 344 rats to study the role of Nrf2-mediated antioxidants on the TJ. They found that inhibiting Nrf2 expression triggered a significant decrease in TEER and an increase in paracellular permeability. This was due to decreased expression of ZO-1, occludin and claudin-18. Furthermore, the overexpression of Nrf2 had a more robust effect on enhancing the barrier structure and function in cells isolated from HIV-1 transgenic rats than wild-type. Lassiter et al. showed an increase in oxidative stress in the lung lavage fluids of HIV transgenic rats, in comparison to wild-type rats. This was correlated with the relocation of ZO-1 and occludin into the cytoplasm of cells, as well as overall decreases in protein expression levels, leading to decreased TEER and increased paracellular permeability. Next, alveolar epithelial monolayers from wild type rats were exposed to gp120 and Tat, HIV-related proteins, which, similar to the HIV transgenic rats, led to decreased ZO-1 and occludin protein levels at the TJ. Taken together, this...
suggests that gp120 and Tat produce oxidative stress, disrupting ZO-1 and occludin and resulting in barrier dysfunction. Alcohol consumption can exacerbate HIV-induced oxidative stress. It has been shown that the combination of alcohol and HIV decreased ZO-1 and occludin drastically, making alveolar epithelial cells more susceptible toward the virus.\(^{35,36}\)

**Coronavirus family**

The *Coronaviridae* family are enveloped, positivesense, single-stranded, RNA viruses.\(^{102,103}\) Coronaviruses are enteric and respiratory tract pathogens, which usually cause a mild disease. However, the Middle East respiratory syndrome (MERS-CoV), severe acute respiratory syndrome coronavirus (SARS-CoV), and SARS-CoV-2, known as Coronavirus disease 2019 (COVID-19), are well-recognized members of the *Coronaviridae* family that cause severe respiratory and systemic diseases. MERS and SARS-CoV caused large outbreaks in 2002–2003 and 2012, respectively, while COVID-19, which was first discovered in Wuhan city, Hubei province in China in December 2019, has caused a massive global pandemic, infecting more than 95 million people and resulting in more than two million deaths worldwide to date.\(^{104}\) Pulmonary symptoms associated with these viruses include dry cough, dyspnea, hypoxemia, pneumonia, and ARDS, and have led to serious complications such as rapid, progressive respiratory failure and mortality.\(^{105,106}\) To date, there are two vaccines available for coronavirus prophylaxis, Pfizer-BioNTech and Moderna COVID-19 Vaccine, which the Food and Drug Administration (FDA) granted authorization of emergency use (EUA). Both of these vaccines use mRNA technology and require two doses. The mRNA is taken up by cells and provides the instructions to produce a spike protein, which is then displayed on the cell’s surface. Because of the spike protein, the immune system recognizes that there is a threat and initiates an immune response by making antibodies.\(^{107}\) Additionally, many other vaccines candidates against COVID-19 are in pre-clinical, early, and late phases of development.

The pathophysiology of these viruses causing inflammation, especially their effect on AECs, is not well understood. Presently, only a few studies have investigated the impact of these viruses on the AEC barrier. A study investigating SARS-CoV in Madin-Darby Canine Kidney II (MDCKII) epithelial cells showed that binding of SARS-CoV’s envelope (E) protein to PALS1 PDZ domain caused a rearrangement of PALS1, leading to disruption of TJ proteins, such as ZO-1 and E-cadherin, loss of barrier function, an increase in paracellular permeability, and further infiltration of SARS-CoV virions into the subepithelial space.\(^{37}\) Similarly, De Maio et al. highlighted that binding of the E protein to PALS1 could play a role in the pathogenesis of COVID-19.\(^{38}\) Zhu et al. showed that COVID-19 is able to replicate in human airway epithelium, leading to cytopathic effects. However, the effect of the virus on the airway barrier was not studied.\(^{108}\) Robinol et al. published a preliminary, non-peer-reviewed study that showed evidence of COVID-19 affecting the tight junction. The study revealed that COVID-19 decreased TEER, increased paracellular permeability, and induced disruption of ZO-1 in primary AECs.\(^{39}\) Infected cells were forced out from the apical side, indicating a role for apoptosis.\(^{39}\) As this novel virus is rapidly spreading across the world, further investigation is needed to understand its pathogenesis, especially the impact on tight junction barriers in both cell cultures and animal models.

**Measles virus (MeV)**

MeV is a member of the *Paramyxoviridae* family and is an enveloped, non-segmented, single-stranded, negative-sense RNA virus.\(^{40}\) MeV is highly contagious, as it is transmitted through respiratory aerosols and continues to affect individuals worldwide.\(^{40,109,110}\) MeV’s target is commonly lymphoid organs, but epithelial tissues of different organs are susceptible to infection. MV infects macrophages and dendritic cells in the airway to then gain access to the lymphatic organs, where it replicates. The virus then crosses back into the airway in order to be expelled and infect the next host. Until recently, the mechanism of MeV infection of epithelial cells was unknown, as there was a limited number of cell lines that support the virus, and MeV usually infects AECs from the
basolateral surface, which makes the study design more challenging.\textsuperscript{109,110} Muhlebach et al. used primary AECs grown in air-liquid interface and showed that MeV needs nectin-4, an AJ protein of the immunoglobulin family, in order to infect and spread basolaterally.\textsuperscript{41} They found that strongly nectin-4 positive cells were located immediately adjacent to infectious centers. However, nectin-4 was downregulated within infected epithelial cells.\textsuperscript{41} Therefore, it is believed that nectin-4 is the epithelial cell receptor for MeV within the airway epithelium. The downregulation of nectin-4 allowed MeV to exit into the airway and be released into the air through coughing and sneezing, thereby leading to infection of the next host.\textsuperscript{41} Other AJC proteins may be involved in MeV pathogenesis, but further research is warranted to confirm this. In one study, well-differentiated primary AECs were infected with MeV and there was disassembly of the F-actin filaments on day three of infection.\textsuperscript{40} Ludlow et al. found no changes in ZO-1, with ZO-1 remaining intact at the cell membrane, in both \textit{in vitro} and \textit{in vivo} models, suggesting that barrier breakdown is not necessary for MeV spread to the adjacent cells.\textsuperscript{111}

**Human parainfluenza virus (HPIV)**

HPIV is another member of the \textit{Paramyxoviridae} family and is an enveloped, non-segmented, negative-strand, RNA virus.\textsuperscript{42} The virus is subdivided into HPIV 1–5. They are common respiratory tract pathogens and are known to cause bronchiolitis, croup, pneumonia, and tracheobronchitis in children.\textsuperscript{42–44} Transmission occurs through direct or indirect contact with infectious fluids, either through contaminated fomites on surfaces or through inhalation of airborne droplets.\textsuperscript{112} A limited number of studies have investigated the role of tight junction integrity on HPIV infectivity. Both HPIV3 and HPIV5 caused a decrease in TEER and increased permeability in AECs, indicating disruption of the epithelial barrier.\textsuperscript{42} However, this study did not investigate which AJC proteins were disrupted. In another study, human alveolar epithelial cells (A549 cells) were infected with HPIV2. There was an upregulation of claudin-1 mRNA expression but no changes in claudin-3, claudin-4, claudin-7, ZO-1, ZO-2, and occludin levels.\textsuperscript{43} In order to further investigate the importance of claudin-1 upregulation, the researchers used A549 cell lines that overexpress claudin-1. They found decreased HPIV2 growth and protein expression following viral infection in these cells and, therefore, that HPIV2 cell-to-cell spread is inhibited by claudin-1. It is thought that claudin-1 mRNA and protein expression following HPIV infection is induced by multiple cytokines, such as TNFα and IL-1β.\textsuperscript{43} HPIV has developed mechanisms in order to decrease claudin-1 expression, thereby promoting its own spread throughout the body. One of HPIV’s viral proteins, the V protein, reduced claudin-1 expression during infection, allowing for both viral entry and dissemination through cell-to-cell spread.\textsuperscript{43} It is proposed that the V protein suppresses the production of IL-1β, thereby inhibiting claudin-1 expression. There is currently no vaccine or antiviral treatments that can eliminate HPIV from the body.\textsuperscript{113} Understanding the mechanisms of viral spread can aid in developing treatment options.

**Human Bocavirus (HBoV)**

HBoV is a member of the \textit{Paroviridae} family and is a non-enveloped, positive-sense, single-stranded DNA virus.\textsuperscript{45,46} It is categorized into HBoV 1–4 and is a common respiratory virus that causes acute respiratory infections and wheezing in young children.\textsuperscript{45,46} The transmission mechanism of HBoV is still unknown. However, other viruses in this family are transmitted through inhalation or contact with infectious surfaces.\textsuperscript{114} In primary human AECs infected with human bocavirus type 1 (HBoV1), TEER slowly started to decrease after 4 days’ post infection and continued to do so even after 48 days, which is consistent with the persistent virus’s release kinetics.\textsuperscript{45} Multiple studies have shown that HBoV1 causes airway epithelial damage through disassembly of ZO-1 proteins.\textsuperscript{45,46} Furthermore, there is a decrease in β-tubulin IV, a marker for cilia following viral infection.\textsuperscript{45,46} In another study, A549 cells were infected with human bocavirus VP1 unique region (HBoV-VP1u), which resulted in a significant decrease in TEER and increase in permeability in these cells.\textsuperscript{47} The same study found an increase in claudin-1
and a decrease in occludin. Secretory phospholipases A2 (sPLA2) are a family of enzymes that play an important role in lung inflammation and tissue damage, and it was shown that VP1u exhibits sPLA2-like activity, which could explain the impact of the virus on epithelial barrier injury.\textsuperscript{47}

**Vaccinia virus (VV)**

VV is a member of the *Poxviridae* family and is an enveloped, double-stranded DNA virus.\textsuperscript{115} VV is known to cause smallpox, but there is limited knowledge of how it is spread.\textsuperscript{116} Infection of AECs showed that this virus primarily infects through the basolateral rather than the apical surface, which is accessible near the edges of the cell monolayers. In AECs, VV had no effect on TEER or ZO-1 localization. This is in contrast to studies done on HeLa and Vero cultured cell lines that have shown rapid cell death, decrease TEER, and changes in ZO-1 expression.\textsuperscript{46} More research is needed to delineate VV’s impact on the airway epithelial TJ.

**Immune response following viral infection and tight junction restoration**

Following viral infection, two simultaneous mechanisms need to occur: repairing the tight junction barrier in order to prevent further viral infectivity and inciting an immune response to combat the virus. The restoration of tight junction morphology following a viral infection is crucial to establish a barrier between our internal system and the outside world. Virus-induced tight junction disassembly and dysfunction contribute to producing an immune response. The immune system has generated multiple mechanisms in response to viral infection to reestablish the AJC and fight the viral infection. Viruses induce the upregulation of various cytokines and chemokines. While some cytokines, such as interleukin (IL) –4 and IL-13, have been shown to provoke barrier disruption in 16HBE cells and air-liquid interface cultivated paranasal sinus mucosa cells, others play a vital role in protecting injured cells.

In human bronchial epithelial cells, IL-4 and IL-13 act via the Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathway. Studies have shown that these cytokines lead to the disassembly of ZO-1, occludin, E-cadherin, and β-catenin.\textsuperscript{117} There were no significant changes in claudin-1, −2, or −3. In a mouse model, lung IL-13 reduced claudin-18, while it increased claudin-4 expression.\textsuperscript{7}

IL-22, a member of the IL-10 cytokine family, provides stability to injured cells and is produced by natural killer (NK) and natural killer T (NKT) cells following many viral infections, in particular influenza infection.\textsuperscript{118} No studies have looked at IL-22 activation following former coronaviruses such as SARS-CoV or MERS.\textsuperscript{119} However, recent research suggests that IL-22 may be activated by COVID-19 infection, which signifies the need for further investigation to elucidate a causal relationship between this virus and IL-22 signaling.\textsuperscript{119} In vivo studies in wild-type C57BL/6 mice and in vitro studies in AECs suggest that increased IL-22 protects the epithelial barrier by promoting increased levels of claudin-4, ZO-1, and ZO-2.\textsuperscript{118} As mentioned in the previous section, influenza viruses cause dysfunction of claudin-4, and influenza H1N1, specifically, has also been shown to decrease levels of ZO-1.\textsuperscript{29,98} Therefore, IL-22 repair of these tight junctions following viral infection allows for proper functioning.

IL-22 helps restore the tight junction barrier, which protects against secondary bacterial infection. Continuous dysfunction of the AJC can lead to bacterial infection superimposed on the viral infection. *Streptococcus pneumoniae* and *Staphylococcus aureus* are the leading causes of secondary bacterial pneumonia following influenza infection, and both have been shown to activate IL-22.\textsuperscript{119} IL-22 has also been shown to be stimulated following *Klebsiella pneumonia* and *Pseudomonas aeruginosa* bacterial infections. Increases in IL-22 expression following bacterial superinfection allows for continued repair of the viral-induced disassembled TJ proteins.\textsuperscript{119} IL-22BP is a soluble binding protein that acts as a competitive inhibitor of IL-22. In one study, both wild-type C57BL/6 and IL-22BP–/– mice (i.e., mice without IL-22BP) were infected with influenza A for 6 days prior to *S. aureus* infection.\textsuperscript{120} IL-22BP–/– mice were protected against *S. aureus* infection in comparison to the wild-type mice. The researchers then conducted a similar experiment with *S. pneumoniae* infection.
following influenza A disease, and similar results were observed.\textsuperscript{120} After 48 hours, there was complete clearance of \textit{S. pneumoniae} in IL-22BP/- mice, while the bacterial load in wild-type mice remained high. Further studies showed that claudin-1, claudin-4, claudin-5, and claudin-8 gene expression was increased in IL-22BP/- mice following \textit{S. aureus} superinfection, despite similar expression during influenza infection alone.\textsuperscript{120} These results suggest that IL-22 may exert its effect on tight junction function similar to what occurred in IL-22BP/- mice. TJ impairment can lead to an increased likelihood of bacterial superinfection and disease severity, and IL-22 helps mitigate these effects through increased expression of ZO-1, ZO-2, claudin-1, claudin-4, claudin-5, and claudin-8.\textsuperscript{118,120}

HRV may be responsible for up to half of all viral-associated COPD and asthma exacerbations.\textsuperscript{22,121} Betamethasone, a steroid typically used to treat skin diseases, allergic conditions, and some rheumatic disorders, has shown promising outcomes in restoring the AJC barrier following HRV infection. Inhaled corticosteroids, such as fluticasone propionate (FP) and budesonide (BUD) are used in managing of COPD. They may also aid in protecting against epithelial barrier dysfunction in response to viral infection and environmental insults, like cigarette smoking.

Cigarette smoke leads to TJ disorganization, directly through the cleavage of occludin and claudin and indirectly through oxidative stress, which leads to the production of cytokines, most notably interleukins IL-6 and IL-8, which results in airway inflammation. There is a decrease in TEER following cigarette smoke extract (CSE) exposure in 16HBE cells.\textsuperscript{122} In one study, primary nasal epithelial cells and 16HBE cells were exposed to both CSE and HRV infection, and this resulted in an exaggerated decrease in barrier function in both systems.\textsuperscript{123} Interestingly, a single dose of betamethasone, the same amount used in commercially-available nose drops, showed significant protection of the barrier.\textsuperscript{123} CSE and poly(I:C) led to the secretion of IL-8, which was efficiently suppressed by both fluticasone propionate (FP) and budesonide (BUD).\textsuperscript{122} BUD and FP also attenuated ZO-1 disruption following CSE exposure alone. It is hypothesized that BUD interferes with epidermal growth factor (EGF) receptor activation, thus helping maintain the AJC barrier. Following poly(I:C) infection, there was a significant reduction in TEER, which was attenuated following BUD and FP exposure.\textsuperscript{122} Further research is warranted to determine the role of betamethasone, BUD, and FP in the treatment of HRV-induced asthma and COPD.

As mentioned above, HRV is a significant cause of asthma exacerbations.\textsuperscript{121} Azithromycin, a macrolide antibiotic used to treat many pulmonary bacterial infections, has been shown to reduce the severity of an acute asthma exacerbation by inhibiting Intercellular Adhesion Molecule 1 (ICAM-1), a receptor for HRV.\textsuperscript{124} It may help in reestablishing the AJC barrier following infection. In primary AECs, azithromycin induced intracellular localization of claudin-1 and –4, occludin, and JAM-A.\textsuperscript{125} There were no effects on E-cadherin. Of note, improved TEER following azithromycin administration suggests that this processing of TJ proteins helps decrease permeability and increase cell integrity, thereby potentially preventing entry of viral infections.\textsuperscript{124,125} Further studies are warranted to elucidate its mechanism in therapeutic strategies and its effect on the tight junction barrier.

The coinfection of viruses and bacteria have been documented in multiple respiratory conditions, like pneumonia, cystic fibrosis, and COPD. \textit{H. influenzae} is an opportunistic pathogen among patients with COPD, and coinfection with HRV is common. In 16HBE monolayers, HRV promotes paracellular migration of non-typeable \textit{H. influenzae} from the apical to basolateral surface strictly in the cells with disrupted ZO-1, thereby suggesting that it is the ZO-1 disassembly that allows \textit{H. influenzae} superinfection.\textsuperscript{22} This phenomenon was not observed in either RSV or influenza A.

In addition to repairing the tight junction barrier to prevent further viral or bacterial infection, the immune system must fight against the virus at hand. Tight junction disassembly helps trigger the immune system response. A limited number of studies have investigated this, and further research is essential to help understand the role of tight junctions in immune responses. In 16HBE cells, downregulation of E-cadherin leads to epidermal growth factor receptor-dependent increases in the
thymus – and activation-regulated chemokine (TARC), a chemokine that plays an important role in activating Th2 immune responses. Multiple viruses, like RSV, SARS-CoV, COVID-19, Enterovirus, and Coxsackievirus, decrease E-cadherin expression, thereby potentiating a Th2 immune response.

Conclusion

Airway epithelial barrier integrity is crucial for internal homeostasis and has been recognized to play an essential role in health and disease. In addition to homeostasis maintenance, epithelial cells constitute the first line of defense from the environment. Epithelial cells possess AJCs comprised of multiple TJ and AJ proteins that regulate the passage of allergens, pollutants, viruses, and other pathogens into and out of the airways. TJ proteins are involved in key regulatory cell functions such as differentiation, proliferation, and migration by recruiting signaling proteins in response to extracellular stimuli, while AJ proteins are necessary for regulating the actin cytoskeleton and stabilizing cell-cell connections.

Extensive research has shown that many respiratory viruses enter the body through the airway epithelia and disrupt this barrier through dysregulation of the AJC. Recent studies highlighted in this review discuss the disruption mechanisms in which viruses enter these cells, causing infection and initiation of their cytopathic actions. ZO-1 is the most highly implicated protein in respiratory viral targeting. Some viruses lead to decreased levels of ZO-1, while others caused ZO-1 disassembly and internalization without reducing levels of ZO-1. Other TJ proteins involved in viral entry into the epithelia include occludin, E-cadherin, β-catenin, and numerous proteins in the claudin family. Understanding the interaction between the airway epithelial barrier and viral pathogens is of great significance. Identifying mechanisms of viral-induced epithelial pathology will help in understanding the role of the airway epithelial barrier in diseases such as ARDS, asthma, COPD, and cystic fibrosis, as well as in the design of anti-viral strategies.
