Abstract

RuvAB and RuvABC complexes catalyze branch migration and resolution of Holliday junctions (HJs) respectively. In addition to their action in the last steps of homologous recombination, they process HJs made by replication fork reversal, a reaction which occurs at inactivated replication forks by the annealing of blocked leading and lagging strand ends. RuvAB was recently proposed to bind replication forks and directly catalyze their conversion into HJs. We report here the isolation and characterization of two separation-of-function ruvA mutants that resolve HJs, based on their capacity to promote conjugal recombination and recombinational repair of UV and mitomycin C lesions, but have lost the capacity to reverse forks. In vivo and in vitro evidence indicate that the ruvA mutations affect DNA binding and the stimulation of RuvB helicase activity. This work shows that RuvA’s actions at forks and at HJs can be genetically separated, and that RuvA mutants compromised for fork reversal remain fully capable of homologous recombination.

Introduction

DNA replication and recombination are two processes that are now recognized as more closely connected than originally suspected. It is well documented that replication defects induce the formation of recombination substrates, such as double-stranded DNA ends or single-stranded DNA regions (ssDNA). Depending on the nature of the replication defect, such recombinogenic DNA structures form at blocked replication forks and/or behind forks, on the newly replicated daughter chromatids ([1]; reviewed in [2–4]) (Figure 1A). In addition, replication and recombination can be directly coupled by enzymes that recognize two different targets, one specifically produced during replication and the other during recombination. The best-documented example is the bacterial PriA protein, which promotes replication restart (i) independently of recombination by its virtue of recognizing replication forks and (ii) during double-stranded DNA end recombinational repair by its virtue of recognizing D-loop structures (reviewed in [5]). Another example is the RuvAB complex, originally identified for its activity on Holliday junctions (HJs), four-DNA arm recombination intermediates (reviewed in [6,7]), and recently proposed to also act on inactivated replication forks [8] (Figure 1).

RuvA and RuvB are nearly ubiquitous bacterial proteins, with a well-conserved structure and function in distantly related species [9–11]. During homologous recombination, a RuvA tetramer binds a HJ formed by RecA-catalyzed strand exchange and two RuvB hexamers assemble on two opposite arms of the HJ to form the tripartite RuvAB-HJ complex. RuvB belongs to the AAA+ (ATPase Associated with various cellular Activities) family of enzymes and acts as a molecular motor for branch migration. Binding of the dimeric endonuclease RuvC leads to the formation of a RuvABC complex that resolves HJs to produce recombinant molecules. Band shift experiments and structural studies of RuvA complexes with synthetic HJs indicate that two tetramers can eventually assemble to sandwich a HJ and form an octameric RuvA complex [12–15]. RuvABC are essential for recombinational repair of DNA lesions in bacteria, and the ruvA ruvB operon is induced by DNA damage, via the SOS response [16].

In addition to its crucial role in processing HJs during homologous recombination, RuvAB binds fork structures in vitro [17–19], and was recently proposed to act at certain inactivated replication forks in vivo [8]. Indeed, inactivated replication forks that occur in several replication mutants are converted into HJs by the annealing of newly synthesized leading and lagging strand ends, a reaction called replication fork reversal (RFR) [20]; reviewed in [3,4] (Figure 1A). HJs formed by RFR, as those formed by homologous recombination, are resolved by RuvABC. Notably, RuvAB was shown to be essential for the formation of HJs at blocked forks in some replication mutants, including the dnaEts mutant affected for the catalytic subunit of the main E. coli DNA polymerase Pol III. We proposed that RuvAB binds to certain inactivated replication forks and catalyzes their conversion into HJs [8] (Figure 1B).

As the two functions of RuvAB in E. coli, resolution of HJs and RFR, involve interactions with two different target molecules, we searched for mutants that have lost only one of these functions. We
Author Summary

DNA replication is the process by which DNA strands are copied to ensure the transmission of the genetic material to daughter cells. Chromosome replication is not a continuous process but is subjected to accidental arrests, owing to the encounter of obstacles or to the dysfunctioning of a replication protein. In bacteria, inactivated replication forks restart but they are most often remodeled before restarting. Interestingly, enzymes involved in homologous recombination, the process that rearranges chromosomes, are also involved in fork-remodeling reactions. The subject of the present study is RuvAB, a highly conserved bacterial complex used as the model enzyme for resolution of recombination intermediates, which we found to also act at blocked forks. We describe here the isolation and characterization of two ruvA mutants that have specifically lost the capability to act at inactivated replication forks, although they remain fully capable of homologous recombination. The existence of such ruvA mutants, their properties and those of the purified RuvA mutant proteins, indicate that the action of RuvAB at replication forks is more demanding that its action at recombination intermediates, but have nevertheless been preserved during evolution.

Results

Selection of UV<sup>R</sup> ruvA Mutants Defective in RFR

The ruvA100::Cm<sup>R</sup> mutant is sensitive to UV irradiation, and UV resistance is restored in the presence of pGB-RuvA<sup>R</sup> while the pGB2 vector has no effect (Table 1). The UV sensitivity of the ruvA, ruvB and ruvC mutants results from the lack of resolution of recombination intermediates, therefore reflects the recombination defect of these mutants [2,21]. The products of a ruvA mutagenic PCR were cloned in pGB2, used to transform the ruvA100 mutant, and the UV sensitivity of cells carrying recombining plasmids was monitored. Seventeen clones were tested, nine remained UV sensitive, therefore containing a plasmid unable to complement the UV repair defect of the ruvA mutant. The remaining eight recombining plasmids that carry a ruvA allele functional for UV repair were isolated and tested for their capacity to promote RFR in a dnaE<sup>ts</sup> mutant (dnaE<sup>4066s</sup>, Table S1).

The dnaE<sup>4066s</sup> mutant is completely defective at 42°C, and partially affected at 37°C for the main E. coli DNA polymerase, Pol III. Because its slight growth defect at 37°C is suppressed by preventing SOS induction [22], recF derivatives of dnaE<sup>ts</sup> were used for the screening of RFR deficient ruvA mutants. RFR takes place at dnaE<sup>ts</sup>-blocked forks and renders RecB essential for viability. Consequently, growth of a dnaE<sup>ts</sup> recB mutant at 37°C is prevented by recB inactivation [23]. However, because RFR requires RuvAB, inactivation of ruvA or ruvB restores the growth of dnaE<sup>ts</sup> recB recF mutants and introduction of a functional ruvA gene in a dnaE<sup>ts</sup> recF recB ruvA100 mutant is lethal [8] (Table 1). Three of the plasmids conferring UV<sup>R</sup> to a ruvA100 mutant were lethal in dnaE<sup>ts</sup> recF recB ruvA100 cells at 37°C, therefore presumably carried a wild-type ruvA gene. The other five plasmids allowed variable levels of viability and therefore expressed candidate RFR-defective RuvA<sup>R</sup>. To ascertain whether the ruvA alleles in these plasmids were deficient for RFR, fork breakage was measured directly.

In dnaE<sup>ts</sup> recB mutants, resolution of HJs formed by RFR leads to an increase in the level of linear DNA in vivo, which can be quantified by pulse field gel electrophoresis (PFGE), as only linear DNA can enter PFGE [20]. Because RuvAB promotes fork reversal and RuvABC resolves the resulting HJ, the level of linear DNA resulting from fork breakage is high in dnaE<sup>ts</sup> recF recB cells (~60%) and low in the dnaE<sup>ts</sup> recF recB ruvA100 mutants (~10%) [8] (Table 1). As expected, fork breakage was increased in dnaE<sup>ts</sup> recF recB ruvA100 cells by the presence of pGB-RuvA<sup>R</sup> (Table 1). Fork breakage remained low in the presence of 4 candidate plasmids: 12–16% for pGB-nucA<sup>26</sup> and pGB-nucA<sup>80</sup>, 32–38% for pGB-nucA<sup>26</sup> and pGB-nucA<sup>87</sup> (Table 1). These ruvA alleles can promote HJ resolution, since they fully complement the UV sensitivity of a ruvA null mutant. Therefore, the defect in fork breakage suggests that they are affected for fork reversal.

Sequenceing of ruvA on pGB-nucA<sup>26</sup> and pGB-nucA<sup>87</sup> showed that these were double mutants (Es0G H136R and N79D N100D, respectively). pGB-nucA<sup>26</sup> and pGB-nucA<sup>80</sup> carried 7 mutations each, 6 of which were identical (Table 1). This result was not surprising since all plasmids derived from the same PCR cloning experiment. In order to identify the mutations in nucA<sup>26</sup> which are necessary and sufficient to abolish RFR, the 7 mutations were introduced individually or in combination on a pGB-nucA plasmid (see Supplementary Material). The capacity of the ruvA mutant alleles to promote homologous recombination was monitored by measuring the UV resistance that they confer to ruvA100 cells.

The ruvA Mutations Prevent RFR Only When ruvA is Expressed in Limiting Amounts

Although ruvA and ruvB genes form an operon, ruvB is expressed in the dnaE<sup>ts</sup> recB<sup>R</sup> mutant, as only wild-type RuvA protein is required for suppression of the recombination defects (Table 1). In dnaE<sup>ts</sup> recB ruvA<sup>100</sup> [pGB-nucA<sup>mut</sup>], ruvB is expressed from the chromosomal locus downstream of the ruvA<sup>100</sup>::Cm<sup>R</sup> insertion, whereas ruvA is expressed from its own promoter on the plasmid which has about 10 copies per cell. The imbalance between ruvA and ruvB expression could play a role in the RFR defect conferred by ruvA<sup>100</sup> and ruvB<sup>mut</sup> mutations. To test this possibility, we cloned ruvB downstream of these ruvA alleles on pGB-nucA<sup>26</sup> and pGB-nucA<sup>87</sup> plasmids. Co-expression of ruvB restored a high level of breakage in dnaE<sup>ts</sup> recB ruvA<sup>100</sup> cells expressing ruvA<sup>26</sup> or ruvA<sup>87</sup> (Table 3). In addition, a high level of breakage was observed when the ruvA<sup>26</sup> allele was inserted into the chromosome (Table 3). These observations indicate that the mutant RuvA::Cm<sup>R</sup> complexes are defective for RFR only if the ruvB gene is expressed from a single chromosomal copy downstream of the ruvA<sup>100</sup>::Cm<sup>R</sup> mutation. The insertion of the Cm<sup>R</sup> gene in ruvA most likely reduces the amount of RuvB protein synthesized.
ruvAz3 and ruvAz87 Mutants Catalyze Homologous Recombination in Various Contexts

The capacity of ruvAz alleles to catalyze homologous recombination was analyzed by different assays. Mitomycin C is a DNA damaging agent that causes various DNA lesions and mitomycin C treatment prevents growth of a ruvA null mutant, defective for recombinational repair [24] (Figure 3A). Introduction of pGB-ruvAz3 or -ruvAz87 plasmids in the ruvA100 mutant restored the same level of resistance to mitomycin C treatment as pGB-RuvA⁺ (Figure 3A), indicating that these mutant ruvA alleles promote recombinational repair of mitomycin C lesions. Inactivation of ruvA decreased conjugational recombination about 3–5 fold [25] (Figure 3B); this defect was also suppressed by the ruvAz3 or ruvAz87 alleles (Figure 3B, RecG⁺).

Full suppression of the UV sensitivity of single ruvA100 mutants by pGB-ruvAz3 and -ruvAz87 plasmids was observed at a wide range of UV doses (Figure 3C), and at 42°C, the temperature used for fork-breakage measurements (data not shown). The UV resistance conferred by these alleles was also tested in different mutant backgrounds. The ruvA100 mutation decreases the survival of UV-irradiated recR mutants deficient for the recombinational repair of gaps (Figure 3D). Introducing pGB-ruvAz3 or -ruvAz87 plasmids fully suppressed the UV-repair defect caused by the ruvA100 mutation in a ruvA100 recR double mutant (Figure 3D). recG inactivation affects the viability of ruvA, ruvB or recC mutants and renders them extremely deficient for homologous recombination [25] (Figure 3F). It was proposed that RecG provides an alternative way of resolving HJs in vivo [26]. Expression of ruvAz3 or ruvAz87 in a ruvA100 recG double mutant suppressed the viability defect (not shown) and the sensitivity to UV irradiation (Figure 3E).

Accordingly, conjugational recombination was not significantly different in ruvA100 recG mutants carrying pGB-RuvA⁺, -ruvAz3 or -ruvAz87 (Figure 3B, RecG⁺). These findings indicate that the mutant Ruv proteins promote HJ resolution in a recG context.

ruvAz3 and ruvAz87 Mutants are Affected for HJ Binding in Vivo

RusA is a HJ resolvase that is only expressed in E. coli when the ruvAz ORF is activated by the insertion of an upstream IS element (rus-1 mutant, [27]). RusA resolves HJs in vitro but is devoid of detectable branch migration activity [28]. By allowing RusA resolvase synthesis, the rus-1 mutation suppresses the recombination defects of ruvAz mutations in vivo. However, suppression is partial in ruvAz mutants in which RuvA protects HJs from RusA action [27]. As shown in Figure 3F, RuvAB rus-1 cells were resistant to UV irradiation as expected [HJs are resolved by RusA], and expression of wild-type RuvA from pGB2-RuvA⁺ made them UV sensitive (RusA-catalyzed resolution is prevented by RuvA binding to HJs). In contrast with pGB-RuvA⁺, plasmids carrying the ruvAz3 or ruvAz87 allele did not compromise the survival of ruvA100 rus-1 UV-irradiated cells, suggesting that these mutant RuvA proteins are not capable of protecting recombination intermediates from resolution by RusA (Figure 3F). Co-expression of ruvB and ruvAz87 only slightly prevented RusA action, suggesting that the HJ-binding defect of the RuvA/87 protein is mainly independent of the amount of RuvB. In contrast, co-expression of ruvB and ruvAz3 fully prevented RusA action (Figure 3F). This observation indicates that the HJ-binding defect of RuvA/3 can be suppressed.
by increasing the cellular level of RuvB, suggesting a defect in
RuvAz3-RuvB protein interactions.

Expression of RusA allows HJ resolution in dnaEts recB ruvA100
rus-1; but, because RuvA is required for RFR, the level of linear
DNA remains significantly lower in the absence of RuvA than in
its presence (compare JJC4196 containing pGB2 and pGB-RuvA,
Table 3). This observation confirms that the fork
breakage defect in the presence of RuvAz3 or RuvAz87 does not
result from a defect in HJ resolution, but rather from a defect in
HJ formation. A slight increase in the percentage of DNA entering
PFG is observed upon RusA expression (compare JJC3723 and
JJC4196 containing pGB2, Table 3). This may result, at least in
part, from RusA-resolution of HJs made behind replication forks
by recombination at gaps, which would preventing linear DNA
migration if left unresolved [8,29].

In Vitro Properties of Purified RuvA-z3 and RuvAz87
Proteins

Wild-type RuvA and mutant RuvAz3 and RuvAz87 proteins
were over-expressed in E. coli and purified. Both mutants behaved

**Separation-of-Function ruvA Mutants**

---
as wild type at all chromatographic steps during purification. The oligomeric states of the mutant RuvA proteins were analyzed by SDS-PAGE without boiling the protein samples [30]. Both RuvAz3 and RuvAz87 showed a tetramer band under denaturing gel conditions (data not shown), which indicates that the structural organization of the RuvA mutants was not affected by the mutations. Binding to a substrate that mimics a Holliday junction (X12) was measured by electrophoretic mobility shift assays (EMSA). In the presence of EDTA, wild-type RuvA formed two complexes: complex I, which contains one bound RuvA tetramer per HJ and complex II, in which the junction is sandwiched between two tetramers [31,32] (Figure 4A). The proportion of DNA bound by RuvAz3 and RuvAz87 proteins was only slightly lower than that with the control wild-type RuvA protein. However, both mutant RuvA proteins could only form complex I (Figure 4A). In the presence of Mg²⁺, where only octameric complexes can be observed [31], RuvAz3 was partially and RuvAz87 totally unable to promote band-shifts (Figure 4B). Therefore, both proteins are slightly affected for binding to HJ DNA, and strongly affected for the formation and/or the stability of octamers on the junction.

The mutant RuvA proteins were tested for branch migration of X12 in the presence of wild-type RuvB protein (Figure 4C). Both mutants were able to support branch migration of X12 but at significantly higher concentrations than wild type RuvA. RuvAz87 exhibited a relatively high branch migration activity with RuvB, while RuvAz3 was more defective in branch migration. Therefore RuvB compensates for the binding defect of RuvAz87 but only partially for that of RuvAz3. These results indicate that whereas RuvAz87 is more affected than RuvAz3 for HJ binding, RuvAz3 is more affected for RuvB binding and/or activation.

To confirm this idea, RuvB helicase activity was compared in the presence of wild-type and mutant RuvA proteins using the property of RuvA to stimulate RuvB in a classical helicase assay, in which RuvB displaces an oligonucleotide annealed to a ssDNA circular molecule (Figure 5). Both RuvA mutant proteins were capable of RuvB stimulation, but whereas 100 nM RuvA were required for RuvB to unwind 50% of the annealed oligonucleotide, 150 nM of RuvAz87 and 250 nM of RuvAz3 were required. Therefore, RuvAz3 was more deficient than RuvAz87 for the stimulation of the RuvB helicase activity.

To test the binding of the mutants to DNA substrates that mimic replication forks, band shift experiments were performed with an entirely double-stranded fork (F2) or a partially single-stranded fork (F1). Both RuvA mutant proteins were completely defective for fork binding, both in EDTA and in Mg²⁺ buffer.
The single-strand binding protein SSB, which covers ssDNA regions at replication forks in vivo, did not stimulate binding of either wild-type or mutant RuvA proteins to forked DNA with an appropriate length of ssDNA regions (not shown). Although it did not act on F1, RuvB unwound F2 in the presence of RuvA (Figure 6C). This reaction was very

Table 3. Increasing the amount of RuvB restores RFR in ruvAz mutants.

Figure 4. RuvAz3 and RuvAz87 proteins are deficient for octamerisation on HJs and slightly affected for HJ branch migration. (A) binding assay: Fluorescence-labeled junction ×12 (∼4 ng) was incubated in the presence of 5 mM EDTA with varying amounts of wild-type (wt) RuvA, RuvAz3 or RuvAz87, as indicated. Binding curves were obtained by quantification using Li-cor Biosciences ODYSSEY infrared imaging system. Squares: RuvA, circles: RuvAz3, triangles: RuvAz87. (B) as in A but in the presence of 3 mM Mg²⁺ (in the absence of EDTA). (C) branch migration assay: Reaction mixtures containing ∼4 ng labeled synthetic ×12 junctions were incubated with 250 nM RuvB and various amounts of wild-type or mutant RuvA, as indicated. Lane 2 is the substrate only. Gels were quantified as in A. Symbols are as in A. doi:10.1371/journal.pgen.1000012.g004

Figure 5. RuvAz3 is more deficient for the stimulation of RuvB helicase activity than RuvAz87. DNA helicase substrate consisting of fluorescence-labeled 52mer oligonucleotide annealed to øX174 single-stranded DNA (4 ng) was incubated with 250 nM RuvB and various amounts of wild-type or mutant RuvA, as indicated. Gels were quantified as in Figure 4. Symbols are as in Figure 4. doi:10.1371/journal.pgen.1000012.g005
Hfr conjugation, while they do not reverse forks at recombination after UV irradiation, mitomycin C treatment and that are fully capable of resolving HJs made by homologous RuvAz87 is weakly, and RuvAz3 more strongly affected for RuvB experiments indicate that both mutated proteins are particularly deficient for fork binding and allow only a weak RuvB action on fork structures. Altogether, these in vitro experiments indicate that both mutated proteins are particularly deficient for binding to forked DNA substrates. In addition, RuvAz3 is weakly, and RuvAz3 more strongly affected for RuvB activation.

Discussion

In this work, we isolated and characterized two ruvA mutants that are fully capable of resolving HJs made by homologous recombination after UV irradiation, mitomycin C treatment and Hfr conjugation, while they do not reverse forks at dnaEts-blocked forks. In agreement with the mutant strains RecE phenotype, purified mutant proteins bind HJs nearly as efficiently as wild-type protein. The in vitro RFR defect mainly correlates with in vitro defects in RuvA octamer formation on HJs and binding to forks. In addition, RuvAz3 is affected for RuvB helicase activation in vitro, which could be a major cause of the ruvAz3 mutant defects in vivo, as these defects can be suppressed by over-producing RuvB.

The RuvA polypeptide consists of three distinct domains, I, II and III. The major core domains, I (residues 1-64) and II (residues 65-140), form the central part of the RuvA tetramer and provide a platform for DNA binding. Domain III (residues 156-203), which is linked to domain II by a flexible linker, is involved in RuvB contact and branch migration [10,15,33,34]. Both mutations in ruvAz3 are in domain II and are very likely to affect primarily DNA binding: N100D lies between two helix-hairpin-helix structures that contact DNA and N79D is within the first of these structures [10,15] (Figure 2). Mutations in ruvAz3 affect the three domains (Figure 2), H29R lies within domain I, in a region thought to be involved in RuvA interactions within the tetramer and in DNA binding [33]. K129E is at the end of the second helix-hairpin-helix in domain II, in a region involved in the association of two tetramers to form RuvA octamers [14,18]. Finally, F140S is the last residue before the flexible linker and may affect the positioning of domain III within the RuvAB complex [35].

Previous studies of RuvA mutants indicated that a combination of three mutations at residues 122, 127 and 130, which disrupt RuvA tetramer-tetramer interface, inactivated recombinational repair in vivo [18]. Although the purified proteins do not form octamers on HJs in vitro, both ruvAz3 and ruvAz87 mutants remain capable of recombinational repair, which suggests that either these mutant proteins form octamers in vivo, or octamer formation is not a pre-requisite for homologous recombination. It should be noted that the defect in RuvAz3 and RuvAz87 octamer formation in vitro may be responsible for the lack of protection of recombination intermediates from RuvA, and may play a role in the RFR defect.

In the complex with a HJ, a RuvA tetramer contacts four double-stranded DNA arms and two RuvB hexamers [34]. In the model that we propose, when RuvAB binds to a replication fork to initiate RFR only three RuvA polypeptides in the tetramer are engaged in DNA contacts, including one with single-stranded DNA, and only one RuvB hexamer is present [8] (Figure 1B). Such a complex might be intrinsically unstable, so that mutant proteins with a decreased DNA affinity would, as the RuvAz mutants described here, retain the ability to bind HJs but lose fork binding. A second RuvA tetramer sandwiching the junction could strengthen interactions with both the fork and the RuvB hexamer. In this case, the defects in octamer formation, fork binding and RuvB activation observed in vitro would all contribute to the RFR defect in vivo. One of the forces driving the evolution of RuvA, among others such as recombination between diverged sequences or recombination with small DNA fragments, might be to promote RFR. Consequently, RuvA could have acquired a capacity to bind DNA and interact with RuvB exceeding the needs of conjugal recombinational and lesion recombinational repair. Our observation that mutations that affect RuvA activity do not necessarily inactivate homologous recombination may explain why, when a collection of 40 ruvA mutants was made by alanine replacement of conserved residues, 34 mutants conferred a normal level of UV resistance and 6 only showed a recombinational repair defect [33].

Although RuvAB are among the best-conserved recombination proteins in prokaryotes [9], they do not have close homologues in eukaryotes. The nature of the enzymes that catalyze HJ branch migration and/or resolution in eukaryotes is a subject of debate, possibly because different activities can be involved, depending on
the organism and on whether meiotic or mitotic recombination is considered. Rad51 is the functional and structural homologue of RecA in eukaryotes and two mammalian Rad51 orthologues, named Rad51C and XRCC3, were identified as components required for coupled HJ branch migration and resolution in cell extracts [36,37]. In addition, several purified proteins could catalyze HJ branch migration in vitro: the RecQ helicase family members BLM and WRN [39–40] and Rad54 [41]. In yeast, the Mus81-Eme1 complex from Schizosaccharomyces pombe catalyzes the resolution of synthetic HJs in vitro and is thought to resolve meiotic recombination intermediates ([42], and references therein). Interestingly, proteins that act on Holliday junctions are most often able to target alternative structures, at least in vitro. Mus81, which cleaves nicked HJs, also cleaves fork and D-loop structures (reviewed in [43]). BLM and WRN helicases, which displace HJs, also unwind fork and D-loop structures ([44]; reviewed in [45]). Similarly, the E. coli RecG protein promotes HJ branch migration and unwinds D-loops, R-loops and forks [46–48]. Recently, the yeast Rad5 protein was shown to promote fork reversal in vitro and this reaction may account for the physiological role of Rad5 during post-replicative repair of UV lesions [49]. Fork reversal by Rad5 did not require RPA and did not involve a single-stranded DNA intermediate, which may well be the case with RuvAB. The mammalian BLM and WRN proteins and the bacterial RecG protein were also shown to be able to convert fork structures into HJs in vitro [50–53]. However, when and where exactly these reactions take place in vivo remains to be determined.

It is tempting to speculate that RFR in E. coli replication mutants involves interactions of RuvA or RuvB with replication fork-associated proteins. Indeed, several proteins that act at replication forks were shown to interact with fork-associated proteins such as SSB [54] or the polymerase clamp (reviewed in [55]). In addition, RuvB is closely related to clamp-loader subunits, i.e., the DNA Pol III δ subunit and the replication factor C in eukaryotes [11,56], and also homologous to RarA (Mgs1 in yeast), a universally conserved protein associated with replication forks [29,57,58].

In conclusion, this work shows that it is possible to genetically separate the two functions of the RuvAB complex, RFR and branch migration/resolution of homologous recombination intermediates. Mutations that weaken the function of RuvA inactivate only RFR, possibly because this reaction is more demanding than HJ branch migration.

Material and Methods

Strains and Plasmids

Strains were constructed by classical P1 transduction [59] and are described in Table S1. Details of constructions are described in supporting information material. Sequencing of rnu genes in plasmids and chromosome was performed using “Genetic Analyzer” 3100 (Applied Biosystem) automatic sequencer. Oligonucleotides used for sequencing are shown in the supplementary material.

Plasmid constructions are described in supplementary material. For the construction of the mutagenic pGB-ruvAm pool, a protocol derived from Fromant et al, was used [60]. rnuAm was amplified using a mutagenic PCR reaction containing 10 mM dGTP, 10 mM dCTP, 10 mM dTTP, 2 mM dATP, 5 mM MnCl2 and ExTaq (Takara) polymerase. A first denaturation step at 94°C for 10 min was followed by 25 cycles of denaturation at 94°C for 30 s, annealing at 55°C for 30 s, elongation 72°C for 3 min 30 s. The PCR product was purified using Qiagen PCR purification kit and cloned in pGB2 as described. Separations of mutations in pGB-ruvAz60 were done as described in supplementary material.

Protein Purification

Wild-type RuvA and RuvB proteins were purified as described in previous studies [18]. Some steps were modified or added for the purification of the mutant RuvA proteins, as described in supplementary material. The concentration of RuvB was determined by absorbance at 280-nm wavelength using an extinction coefficient of OD280,native = 16,900 M⁻¹ cm⁻¹ [61]. All of the other protein concentrations were determined by the Bradford method using the protein assay reagent from Bio-Rad with BSA as a standard.

DNA Substrates

5’ IRD700-labelled and unlabelled oligonucleotides were purchased from MWG. Oligonucleotide sequences and oligonucleotide assembly are shown in Table S2. Annealing reactions and substrate purification were performed as described [62], using 2 μg of unlabelled and 1 μg of labeled oligonucleotides in each reaction. The helicase substrate was obtained by annealing 10 pmol of IRD-700-labelled 52-mer ET300 to 10 pmol φX174 virion ssDNA (NEB) in 10 mM Tris-HCl pH 7.5, 10 mM MgCl2, 50 mM NaCl [63]. The mixture was denatured at 100°C for 3 min, incubated at 68°C for 30 min and slowly cooled down at room temperature. Purification was performed on a 5–20% sucrose gradient and fractions collected after centrifugation at 4°C, 45000 rpm for 3 h. Substrates were visualized and quantified using the Li-cor Biosciences ODYSSEY infrared imaging system.

Electrophoretic Mobility Shift Assay

Binding reactions in conditions without magnesium were performed as described [18] and analysed by PAGE in 0.5× Tris-borate EDTA buffer. For binding assays in the presence of magnesium, 3 mM MgCl2 was added to the reaction buffer, which did not contain EDTA. Electrophoresis was performed in 0.5× Tris-borate buffer supplemented with 200 μM MgCl2 and using buffer recirculation. Reaction products were analyzed using the Li-cor Biosciences ODYSSEY infrared imaging system.

Branch Migration Assay

Branch migration reactions (20 μl final volume) were performed in 20 mM Tris-HCl pH 7.5, 2 mM ATP, 2 mM DTT, 100 μg/ml BSA, 1.5 mM MgCl2. The reactions contained ~5 ng labeled synthetic junction with 250 nM RuvB and various concentrations of RuvA protein. Proteins were diluted in 20 mM Tris HCl pH 7.5, 1 mM EDTA, 0.5 mM DTT, 100 μg/ml BSA, 150 mM NaCl, 10% glycerol. Branch migration reactions were performed as described [18] and visualized as described above.

DNA Helicase Assay

DNA helicase reactions were performed under the same conditions as branch migration assays described above. Reaction products were analyzed by electrophoresis in 1.2% agarose gel in 1× TAE buffer and visualized as described above.

UV and Mitomycin C Resistance Tests

UV irradiation was performed as described [8]. For mitomycin C treatment, cells were grown at 37°C in LB to an OD600 = 0.5 C. Mitomycin C was added to the culture at a final concentration of 2 μg/ml and incubation continued at 37°C for 90 minutes. An untreated culture was used as control. Appropriate dilutions were
plated on LB plates and incubated overnight at 37°C. Ratios of cfu of mitomycin C treated over cfu of untreated cells were calculated.

Conjugation

Conjugations were performed as described using JJC145 as Hfr donor [29], donor and recipient cells were mixed for 25 min. Selective medium was M9 minimal medium supplemented with leucine, proline, threonine and arginine (2% final concentration each) and 10 μg/mL Cm.

Measure of Linear DNA by PFGE

Quantification of pulsed field gels was performed using in vivo 3H-thymidine labeled chromosomes as previously described [20].
