The cortisol stress response and the molecular programming of the corticoid axis were characterized for the first time during early ontogeny in a Mediterranean marine teleost, the European sea bass (*Dicentrarchus labrax*). Sea bass embryos, pre-larvae and larvae at specific points of development were exposed to acute stressors and the temporal patterns of cortisol whole body concentrations and the expression of genes involved in corticosteroid biosynthesis, degradation and signaling were determined. Expression of genes (*gr1, gr2, mr, crf*) involved into the corticoid response regulation combined with histological data indicated that, although a cortisol stress response is evident for the first time around first feeding, a pattern becomes established in larvae at flexion until the formation of all fins. Moreover, mRNA transcript levels of 11\(\beta\)-hydroxylase and 11\(\beta\)-hsd2 showed a strong correlation with the whole body cortisol concentrations.

Concluding, our data reveal the presence of an adaptive mechanism in European sea bass at early ontogeny enabling to cope with external stressful stimuli and provide a better insight into the onset and regulation of the stress response in this species.
metabolism in order to accomplish their metamorphosis into juvenile fish. Throughout this period, cortisol regulates osmoregulatory function\textsuperscript{21,22} and is implicated in the metamorphosis from larvae to juveniles\textsuperscript{23,24}.

Studies conducted in European sea bass, \textit{Dicentrarchus labrax}, and other species showed the presence of maternal cortisol in embryos and that \textit{de novo} cortisol synthesis starts shortly after hatching but a significant elevation in whole body cortisol in response to a stressor becomes obvious days to weeks later, depending on the species\textsuperscript{25–30}.

However, our knowledge on the development of the hypothalamic–pituitary–interrenal (HPI) axis of European sea bass and its response to stressors during early ontogeny or the molecular mechanisms involved is scarce. To this end, we examined the temporal patterns of cortisol and genes related to the corticosteroid signaling (\textit{gr1, gr2, mr, crf}), corticosteroid synthesis (11\textbeta-hydroxylase) and cortisol metabolism or inactivation (11\textbeta-\hsd2) at various stages during early ontogeny in order to assess the ontogenesis of the corticosteroid-signaling pathway. Moreover, we subjected European sea bass embryos, pre-larvae and larvae to an acute stressor in order to determine any differences in the timing or magnitude of the activation of the corticosteroid stress axis and the molecular response at each developmental point/stage.

Results

Ontogeny of the HPI axis in European sea bass. Histology data revealed that the brain of sea bass was evident at hatching (Figure 1a) while a morphological differentiation of the pituitary was possible at day 5 post hatching (dph) (Figures 1b, 1d). At this day the first thyroid follicles appear and they increase in number and size as fish grow (Figure 1f). Pituitary gland is clearly visible and differentiated at 30 dph when neurohypophysis and adenohypophysis are distinct (Figure 1e, 1f). Interrenal and chromaffin tissues are both located in head kidney adjacent to the cardinal vein. The kidney was present at 3 dph and it was characterized by the presence of kidney tubules with a distinct morphology (Figure 1c). However, morphological differentiation of the interrenal and chromaffin tissues was difficult at early stages of development using routine histology, and only at 28 dph, i.e. around flexion the respective endocrine cells were simultaneously evident.

Temporal patterns of cortisol content and gene expression at early ontogeny. European sea bass embryos had low basal cortisol content (2 \pm 0.7 ng g\textsuperscript{-1}) that had declined at hatching (0.6 \pm 0.3 ng g\textsuperscript{-1}) and subsequently slightly increased at mouth opening (1.5 \pm 0.2 ng g\textsuperscript{-1}), but the differences were not statistically significant. The first peak (\textit{P}, 0.001) was observed at first feeding (6.8 \pm 1.3 ng g\textsuperscript{-1}), after which whole-body cortisol mean concentrations dropped gradually from flexion (4.1 \pm 1.2 ng g\textsuperscript{-1}; \textit{P} < 0.001) onwards to the formation of all fins (1.9 \pm 0.5 ng g\textsuperscript{-1}) (Figure 2a). All genes assessed in the current study were expressed in all developmental stages examined. Transcripts of \textit{gr1} (Figure 2b) showed a gradual increase throughout early development, with lowest mRNA abundance recorded in embryos.
Figure 2 | Temporal patterns of cortisol content and gene expression at early ontogeny. Changes in resting (0 h) whole body cortisol levels and mRNA transcript levels of gr1, gr2, mr, cfr, 11β-ḥsd2 and 11β-hydroxylase during the different developmental points/stages (embryos-EM, hatch-HAT, mouth opening-MO, first feeding-FF, flexion-FLX, formation of all fins-FINS). Values are means ± standard error (n=3). Means with different letters differ significantly from one another (P < 0.05).
Ontogeny of the cortisol stress response and molecular onset of genes related to the HPI axis. Figures 3 shows the cortisol response and Figures 4–6 the expression profile of the different stress–related genes prior to (0 h) and after (0.5 h, 1 h, 2 h and 24 h) the application of the stressor during early ontogeny (embryos, hatch, mouth opening, first feeding, flexion and formation of all fins). There was no statistically significant effect of stress on cortisol levels of embryos at 0.5 h, 1 h and 2 h post-stress, while there was a significant (P < 0.001) increase at 24 h after the application of the stressor, i.e. approximately 48 h following fertilization. An identical pattern of changes was observed after stress at hatching and mouth opening. A statistically significant (P < 0.05) effect of the stressor on whole-body cortisol concentrations soon after the application of the acute stressors was observed for the first time at first feeding, where whole body cortisol increased from the 0 h basal values (6.8 ± 1.3 ng g⁻¹) to a maximum at 0.5 h (10.8 ± 1.0 ng g⁻¹) and 1 h (9.6 ± 0.5 ng g⁻¹) to return to basal values at 24 h (3.5 ± 0.5 ng g⁻¹). At flexion, a prolonged peak was observed with basal cortisol values at 0 h (4.1 ± 1.2 ng g⁻¹) and peak values (P < 0.05) at 0.5 h (17.1 ± 1.7 ng g⁻¹), 1 h (19.9 ± 6.5 ng g⁻¹) and 2 h (23.4 ± 3.1 ng g⁻¹) post stress. In addition, the magnitude of the stress response was higher (P < 0.001) than the respective at first feeding. Finally, at the formation of all fins, cortisol content at 0 h (1.9 ± 0.5 ng g⁻¹) sharply increased at 0.5 h (17.1 ± 1.6 ng g⁻¹) to reach a maximum at 2 h (33.7 ± 2.7 ng g⁻¹) after stress and return to basal values at 24 h (3.3 ± 1.4 ng g⁻¹). The magnitude of the stress response was statistically significant higher (P < 0.001) than the respective in first feeding and flexion. Transcripts of gr1 (Figure 4a) showed no statistically significant changes following exposure to the stressors at hatching and mouth opening. However, in first feeding and flexion there was a 1.9- and 1.8-fold upregulation (P < 0.001) at 24 h, respectively, while at the formation of all fins a significant 1.4-fold downregulation (P < 0.05) compared to controls was observed at 2 h post-stress. A similar pattern of expression was observed in gr2 transcripts (Figure 4b), with stable mRNA abundance during hatching and mouth opening and an upregulation (P < 0.05) at 24 h at first feeding and flexion. In the formation of all fins, gr2 reaches a maximum at 0.5 h after stress and then mRNA levels fall down to a minimum at 2 h. Transcript levels of mr (Figure 5a) showed no statistically significant changes between the different time points, apart at first feeding were a decrease is observed from 0.5 h till 2 h after stress. Exposure to stressors did not affect cfr abundance around hatching, mouth opening and first feeding, however, in flexion there was an upregulation (P < 0.001) at 2 h and 24 h post-stress. In all fins, cfr transcripts peaked, as whole-body cortisol concentrations, at 0.5 h post stress followed by a gradual decrease to the basal levels of control at 24 h (Figure 5b).

11β-hydroxylase expression pattern showed statistically significant temporal differences at all points/stages of development. In particular, at hatching there was a significant increase (P < 0.001) at 24 h (i.e. hatching 100% completed) post-stress, while at mouth opening and first feeding there was a peak at 1 h and 2 h post-stress respectively. In flexion, 11β-hydroxylase abundance remained at high levels from 0 h till 1 h post stress after which there was a statistically significant decrease (P < 0.05) at 2 h. In all fins, the pattern of changes resembled that of cortisol, with low transcripts at 0 h, 1.6 to 1.4-fold upregulation at 0.5 and 1 h followed by a sharp down-regulation at 2 h (Figure 6a). 11β-hsd2 levels did not show significant changes around hatching and mouth opening. However, in first feeding there was a gradual decrease in mRNA transcripts from high values at 0 h to a minimum at 2 h post-stress. In flexion, 11β-hsd2 abundance was constant except for a sharp increase at 24 h. However, if we exclude the values at 24 h, there was a statistically significant increase at 1 h post stress, which is no longer “masked” by the high values at 24 h. As in the case of 11β-hydroxylase, at the formation of all fins the pattern of 11β-hsd2 changes are similar to that of cortisol, with peak values at 0.5 and 1 h post-stress followed by a drop to the basal values at 2 h and 24 h (Figure 6b).

Discussion

The temporal changes of whole-body cortisol levels during the early developmental stages of teleosts show that the initial maternal deposit of cortisol is depleted during embryogenesis and reaches a minimum around the time of hatch and then the larva begins to synthesize cortisol de novo, a pattern which is observed in a similar way across a number of species. These results are in agreement with results obtained in this study as well as in studies in Japanese flounder19, tilapia16, rainbow trout13, Asian sea bass17, common carp15, gilthead sea bream27, Atlantic salmon18, zebrasfish40, and in previous work in E. sea bass30.

Gr1 is present in the embryos with very low transcript levels but soon after hatch its expression follows a continuous elevation during development. Gr2 abundance in embryos is higher than gr1, and its expression pattern is characterized by an initial elevation in hatch and a second in first feeding followed by a relatively steady expression, thereafter. Previous immunohistochemical and in situ hybridization data also verify the presence of gr2 mRNA transcripts and of the glucocorticoid receptor early in development with increasing expression towards the juvenile stage41. In addition we show, for the first time, the expression profile of mr, cfr, 11β-hydroxylase and 11β-hsd2 during the early stages of development. Mr is present in embryos in very low copies and its expression increases as development proceeds, following a pattern similar to that obtained for mr expression during embryogenesis in zebrafish40.

Cfr expression is detected in embryos in very small quantities; however, there is a peak in mRNA transcripts at hatch that decline in mouth opening and then gradually increase from first feeding to the formation of all fins, indicating a maturation of the HPI axis. The expression of 11β-hydroxylase is upregulated immediately before the rise in larval cortisol levels which occurs in first feeding, pointing to the activation of the steroidogenic pathway around that time. 11β-hsd2 mRNA transcripts follow a transient pattern as they appear at high levels in embryos, drop in hatch, reach a maximum in first feeding and then drop again at the following developmental stages. The high amounts in embryos may be associated with the maternal cortisol deposit that needs to be metabolized and the second peak which appears in first feeding coincides with the first peak of cortisol during early development of sea bass, and may reflect the immediate response of the corticoid system to the sudden accumulation of cortisol. Apart from embryos where the mRNA abundance of 11β-hsd2 and 11β-hydroxylase is high, the expression patterns of these genes are quite similar to the respective patterns obtained from zebrafish40.
The acute stress challenge tests didn’t result in a cortisol response in embryos, hatch and mouth opening stages, apart from a maximum at 24 h post stress. However, further research is needed to clarify whether this maximum is a result of a delayed stress response or reflects differences in the developmental point/stage. Histological data showed that the first appearance of a distinct hypothalamo-hypophysial-interrenal axis is observed at first feeding, where a peak in whole body cortisol levels was observed at 0.5 h post stress, followed by a protracted decrease until at 24 h when it reached resting levels. These results, in accordance with the molecular data, imply

Figure 3 | Ontogeny of the cortisol stress response. The cortisol response prior to (0 h) and after (0.5 h, 1 h, 2 h and 24 h) the application of the stressor during early ontogeny. Values are means ± standard error (n=3). Means with different letters differ significantly from one another (P < 0.05).
Figure 4 | Expression of gr1 and gr2 after application of a stressor during early ontogeny. (a) Expression profile of gr1 prior to (0 h) and after (0.5 h, 1 h, 2 h and 24 h) the application of the stressor at the different developmental points/stages. (b) Expression profile of gr2 prior to (0 h) and after (0.5 h, 1 h, 2 h and 24 h) the application of the stressor at the different developmental points/stages. Values are means ± standard error (n = 3 pools of ca. 30 mg for embryos, hatched eggs and larvae samples, apart from juveniles where pools of 1–2 fish were used). Means with different letters differ significantly from one another (P < 0.05).

that as early as at first feeding sea bass individuals are capable of responding to external noxious stimuli. In addition the first peak observed in whole-body cortisol concentrations at first feeding reflects the essential role of cortisol to carbohydrate and protein metabolism towards transition to exogenous feeding. As development proceeds, the magnitude and duration of the response is higher and a pattern seems to be established from flexion until the formation of all fins where cortisol values reach a maximum at 2 h. This is further supported by the histological data showing that while the kidney tubules with a distinct morphology were present at hatching, a clear morphological differentiation of the interrenal and chromaffin tissues was possible only at 28 days post hatch (i.e. at flexion) using routine histology. Similar results were found in cichlid fishes where the head kidney from 12 to 30 days after fertilization is functionally mixed, with the nephron and developing hemopoietic and endocrine (chromaffin and interrenal tissue)19. These results indicate that even at the stage of first feeding fish are capable of a stress-induced stimulation of cortisol and that the HPI axis becomes gradually established until the development of all fins. This is in accordance with previous work conducted in European sea bass20,21, rainbow trout22, the yellow perch23 and the zebrafish24. However, this is the first time that the exact pattern of cortisol response following exposure to acute husbandry stressors is revealed at early developmental stages.

With the aim to shed light on the molecular mechanisms related to the onset of the cortisol stress response, we carried out qPCR experiments in order to measure the mRNA transcript levels of genes related to the HPI axis, gr1 and gr2, mr and cf, and genes related to the biosynthesis and degradation of cortisol, 11β-hsd2 and 11β-hydroxylase. During HPI axis activation, gr1, gr2 and mr are the mediators of the transcriptional effects of circulating cortisol on target tissues and cf produced in the hypothalamic preoptic area (POA), stimulates the pituitary corticotropes to secrete adrenocorticotropic hormone (ACTH)25,26, which in turn stimulates synthesis and secretion of cortisol into the circulation27. Gr1 expression levels after application of an acute stressor were not altered in any developmental stage apart from all fins, where a down-regulation was observed at 2 h post stress. The same is the case of the mRNA levels of gr2, as the only response to the stress was detected at the stage of all fins, where an increase was observed at 0.5 h post stress followed by a down-regulation at 2 h. The down-regulation of gr1 and gr2 is in accordance with data from other studies carried out in sea bass exposed to very high stocking densities28, in coho salmon29, in Atlantic salmon30, in common carp31, in the hippocampus of rats exposed to increasing corticosteroid levels32, in mouse pups with high corticosteroid levels due to 24-h maternal deprivation33. The statistically significant increase of the expression levels of both gr1 and gr2 observed at 24 h post stress in first feeding may be related, as with the case of cortisol, to a delayed stress response or to the role of cortisol in metabolism and neural development for the passage of fish to exogenous feeding. The mRNA abundance of mr was not altered at any of the developmental stages examined apart from first feeding where the expression levels decreased from 0.5 h to 2 h post stress. However, as this is not repeated in the later stages and especially at all fins where the HPI axis is expected to be more mature, this alteration may not reflect a response to stress but rather a suppression related to the needs of the developmental stage. Csf expression pattern at all fins follows an increase at 1 h and a gradual decrease until 24 h post stress, which is in accordance with the pattern observed for cortisol at this stage, where the peak of cortisol levels is at 2 h post stress. In flexion, there is a statistically significant increase at 2 h that remains at high values still at 24 h, indicating that at this stage the cfr system is being established, but the prolonged expression and the delayed response compared to the pattern of cortisol at the same stage, reveals that it is not mature yet.

During fish ontogenesis cortisol is a critical hormone when changes occur at the metabolic demands of the larvae34,35 and it is also implicated in neural development and in the induction metamorphosis36,37. The inability of the stress response system to respond to the stress-elevated cortisol levels via the cfr and the grs at these stages until only at all fins, might be of critical importance for the survival of the larvae and the normal progress of the development. There are very limited data available about the role of gr and mr in fish development. The major mineralocorticosteroid in mammals and non-mammalian vertebrates is aldosterone. However, in fish, deoxycorticosterone (DOC) is considered to be a mr ligand instead of aldosterone, as the latter is not detected in fish, but also cortisol is a high-affinity ligand for mr. A recent study carried out in zebrafish showed that both GR and MR are present during embryogenesis and suggested that gr plays a more important role after hatching in zebrafish, whereas mr is suggested to be important at the earlier stages of development, and that after hatching a ligand other than cortisol, perhaps DOC, may be responsible for mr signaling38. Studies in mice showed that mice lacking a functional gr survive until birth but die shortly thereafter due to impaired lung development39 and that there is no abnormal embryonic development detected in a mutant zebrafish line that does not develop corticotrophic pituitary cells40. Other studies demonstrated that knocking down maternal gr leads to developmental defects in mesoderm formation in zebrafish41 and that gr signaling is essential for zebrafish muscle development42. In the present study, mr expression profiles during the stress response in first feeding seems to give mr a more important role at this stage than that of grs, which at the later stages of development is inverted. This is in accordance with the results obtained from the other studies mentioned above.

We tested the hypothesis that the molecular events related to the appearance of the cortisol synthesis pathway are tightly linked to the enzymes which take part in cortisol biosynthesis and degradation. Therefore, we quantified the temporal expression of 11β-hydroxylase that generates cortisol from 11-deoxycortisol44 and 11β-hsd2, an enzyme that converts the biologically active cortisol to the inactive cortisone. After the acute stress application the transcript levels of 11β-hydroxylase appear statistically significant altered at hatch and mouth opening but these changes may not reflect a stress response, but these changes could represent the role of this enzyme in gonad differentiation, as 11β-hydroxylase appears to be a key transducer in the mechanism of sex determination in fish45. However, in first feeding appears a strong relation between 11β-hydroxylase transcripts and cortisol increase. This pattern continues also in the later stages of development, where mRNA expression of 11β-hydroxylase is upregulated along with cortisol levels. This is in accordance with data obtained for rainbow trout, where mRNA abundance of 11β-hydroxylase also increases in response to an acute stressor46. In first feeding, where the first response is observed, 11β-hsd2 mRNA transcripts are at high amounts in the larvae and gradually decline to a minimum at 2 h post stress; if compared with the cortisol pattern, it becomes clear that the mRNA levels of this enzyme are correlated with the amount of cortisol present. At the following developmental stages this becomes more obvious as the maximum mRNA levels of this gene are observed at 1 h post stress, just prior to the cortisol peaks (at 2 h), and at 2 h the transcript levels drop again to the resting values.

The cortisol stress response and the regulation of genes related to the corticoid axis in combination with histological analysis were studied for the first time during early ontogeny in European sea bass, Dicentrarchus labrax. Sea bass embryos, pre-larvae and larvae were exposed to acute stressors and the temporal patterns of cortisol whole body concentrations and the expression of genes involved in corticosteroid biosynthesis (11β-hydroxylase), degradation (11β-hsd2) and signaling (gr1, gr2, mr and cf) were determined. Histological data showed that although the kidney was present at hatching, morphological differentiation of the interrenal and chromaffin tissues was difficult at early stages of development using routine histology, and only around flexion the respective endocrine cells were simulta-
neously evident. Whole body cortisol concentrations showed a decline from embryos to hatching, remained at low levels at mouth opening and peaked at first feeding. In addition, around first feeding an effect of stress was evident for the first time on post-stress cortisol concentrations. As development proceeds, a pattern with a higher magnitude and longer duration of the cortisol stress response was established from flexion until the formation of all fins. Expression data of genes related to the regulation of the corticoid response (gr1, gr2, mr and crf) indicated that, although a cortisol stress response is evident at first feeding, the HPI axis seems to be fully mature only at the stage of all fins. Moreover, the mRNA transcript levels of 11β-hydroxylase and 11β-hsdl2 showed a strong correlation with the whole body cortisol concentrations. Overall, the data indicate that fish do respond to external noxious stimuli as early as at first feeding but the cortisol stress response becomes fully functional and mature until only at the stage of all fins. In addition, several changes occurred in early development (embryos, hatching and mouth opening) may resemble, apart from an adaptive to stress role of cortisol, its implication in other important aspects of development and metabolism. In conclusion, our data reveal the presence of an adaptive mechanism in European sea bass at early ontogeny enabling to cope with external stressful stimuli and provide a better insight into the onset and regulation of the stress response in this species.

Methods

Animals and husbandry conditions. Batches of fertilized European sea bass eggs were obtained from a private fish farm (DIAS S.A.) and transferred to the installations of the Institute of Aquaculture, Hellenic Center for Marine Research (Heraklion, Crete). Larval rearing was performed applying the pseudogreen-water technique in 500 L cylindro-conical tanks, with an initial density of 100 eggs L⁻¹ in which both hatching and rearing took place. Tanks were initially filled with filtered seawater from a deep well. Aeration was provided by means of a wooden diffuser located in the tank center at a rate of 1,000–1,500 ml min⁻¹ in which both hatching and rearing took place. Tanks were coupled to a biological filter and were initially filled with filtered seawater from a deep well. Aeration was provided by means of a wooden diffuser located in the tank center at a rate of 150–200 ml min⁻¹. Aeration was provided by means of a wooden diffuser located in the tank center at a rate of 150–200 ml min⁻¹. Aeration was provided by means of a wooden diffuser located in the tank center at a rate of 150–200 ml min⁻¹. Aeration was provided by means of a wooden diffuser located in the tank center at a rate of 150–200 ml min⁻¹.

Figure 7 | Sampling design. Ontogeny of the neuroendocrine stress response in European sea bass (DPH: Days Post Hatch). An acute stress test was applied in all developmental points/stages.

| Development | Description | DPH | Total Length (mm) |
|-------------|-------------|-----|-------------------|
| Embryos     | 70% of embryos in 50% epiboly stage | 0   | -2                |
| Hatching    | 70% of embryos are hatched | 6   | 4.71 ± 0.09       |
| Mouth opening | Mouth opens, complete yolk sac absorption | 9   | 5.25 ± 0.19       |
| First feeding | First day of exogenous feeding | 29  | 11.1 ± 0.44       |
| Flexion     | 65% completed the notochord flexion | 44  | 15.48 ± 0.21      |
| Fins        | All fins have been developed |     |                   |

Historical analysis. Sea bass larvae were killed with an overdose of anesthetic (ethylene glycol monophenyl ether, Merck, 807291) and fixed in buffered formalin. Samples were dehydrated in a 70–95% ethanol series and embedded in glycol methacrylate resin (Technovit 7100, Heraeus Kulzer, Germany). Serial sections were obtained at a thickness of 3–5 µm on a microtome (Leica RM2245, Germany) using disposable blades. After drying, slides were stained with methylene blue/azure II/basic fuchsin and examined under a light microscope in order to record the first appearance of the tissues comprising the HPI axis and to describe the relevant organs/tissues.
Whole body cortisol. Samples were homogenized according to Stouthart et al. All wells except the 'non-specifics' received 100 µl cortisol antibody (Cortisol Antibody [x2m210] monoclonal and IgG purified) and were incubated overnight at 4°C. Subsequently, the plates were washed three times with 200 µl wash buffer and 100 µl blocking buffer was added to each well in order to block the non-specific sites. Plates were then washed three times with wash buffer and after the final wash step, all wells received 200 µl of 'Optiphase hisa-3 scintillation liquid' (PerkinElmer, USA). Beta-emission was quantified by a 3 min count per well using a Microbeta Plus (Wallac/PerkinElmer, USA).

RNA purification and cDNA synthesis. Samples of embryos, pre-larvae and larvae were let to thaw on ice, disrupted and homogenized using the TissueRuptor (Qiagen, Hilden, Germany) for 20 s in 600 µl RLT Plus buffer (RNeasy Plus Mini Kit Qiagen, Valencia, USA). Total RNA was isolated with the RNeasy Plus Mini Kit (Qiagen, Valencia, USA). RNA yield and purity was determined by measuring the absorbance at 260 and 280 nm using the Nanodrop® ND-1000 UV–Vis spectrophotometer (Peqlab, Erlangen, Germany), and its integrity was tested by electrophoresis in 1% agarose gels. Reverse transcription (RT) was carried out using 1 µg RNA with QuantiTect Reverse transcription kit (Qiagen).

Primer design. Primers for Glucocorticoid Receptor 1 (gr1), Glucocorticoid Receptor 2 (gr2), Mineralocorticoid Receptor (mr), Corticotropin Releasing Factor (crf), eukaryotic Elongation Factor 1 (eEF1a), 18S Ribosomal protein S30 (18S), and ribosomal 18S RNA (18S) were obtained by a previous work of our group. Primer design for steroid 11β-hydroxylase (11β-hydroxylase) was based on the available sequence with accession number AF449173.2. Forward and reverse primers for 11β-Hydroxysteroid Dehydrogenase type II (11β-hsd2) were designed based on the conserved regions as revealed by multiple sequence alignments of other teleost fish.

In the case of 11β-hydroxylase, the forward primer (11β-Fwd) was a 21-mer with the sequence 5’-GAGGAGCATGCTGACACAGG-3’ and the reverse primer (11β_Rev) an 19-mer primer with the sequence 5’-AGAGGACGACACGCTGAGA-3’. For 11β-hsd2, the sequence of the forward primer (hsd_Fwd) was 5’-CACCCTGACACACTGCTG-3’ and the reverse primer (hsd_Rev) had the sequence 5’-ACAAGGGCCACACAGGAC-3’. The products of each primer pair were further checked with sequencing in order to confirm that they amplified the desired genes.

Quantitative real-time PCR (qPCR). The mRNA expression of genes encoding for gr1, gr2, mr, crf, 11β-hydroxylase and 11β-hsd2 was determined with quantitative polymerase chain reaction (qPCR) assays using the KAPA SYBR Fast qPCR Kit (Kapa Biosystems). Reactions were cycled and the resulting fluorescence was detected with M Mini Thermal Cycler (Bio-Rad) under the following cycling parameters: 95°C for 3 min (HotStartTag DNA Polymerase activation step), 94°C for 15 s (denaturation step), 60°C for 30 s (annealing step), 72°C for 20 s (extension step), 40 cycles (1 step). Levels of gr1, gr2, mr, crf, 11β-hydroxylase and 11β-hsd2 mRNA were normalized based on the reference genes 18S, eEF1a and Fau. A relative standard curve was constructed for each gene, using 4 serial dilutions (1:5) of a pool of all cDNA samples. We also performed geNORM analysis in order to validate which are the most suitable reference genes to serve as an internal control and we concluded to eEF1a and 18S.

Statistical analysis. All statistical analyses were performed with SigmaPlot 11.0 (Jandel Scientific). All data are presented as means ± standard error of the mean (SEM). Data were initially screened for normality and homogeneity. Statistical comparisons of temporal patterns of cortisol and gene expression of unstressed specimens (0 h) vs. reared in conditions with different developmental stages were made using one-way ANOVA. Statistical comparisons of cortisol content and gene expression between the different time points following exposure to a stressor and the various developmental stages/stages tested were made using two-way ANOVA. Holm-Sidak's honestly significant difference test for multiple comparisons was used to determine significant differences among groups. The significant level used was P < 0.05.

Acknowledgments
The research received funding from the European Union Seventh Framework Programme (FP7/2010-2014) under grant agreement n° 265957. We would like to thank Mr. N. Mitriazakis for his valuable assistance in larvae rearing and Mrs. Cassandra Koumaki for technical assistance in the histological work.

Author contributions
A.T. and M. P. wrote the main manuscript. A.T. and N.P. carried out larvae rearing and sampling. M.G. and G.F. made cortisol measurements. P.K. carried out histology experiments and prepared figure 1. A.T. prepared figures 2–7. All authors reviewed the manuscript.
