Dated: June 12, 2017

We construct closed-form gravitational waveforms (GWs) with tidal effects for the coalescence and merger of binary neutron stars. The method relies on a new set of eccentricity-reduced and high-resolution numerical relativity (NR) simulations and is composed of three steps. First, tidal contributions to the GW phase are extracted from the time-domain NR data. Second, those contributions are employed to fix high-order coefficients in an effective and resummed post-Newtonian expression. Third, frequency-domain tidal approximants are built using the stationary phase approximation. Our tidal approximants are valid from the low frequencies to the strong-field regime and up to merger. They can be analytically added to any binary black hole GW model to obtain a binary neutron star waveform, either in the time or in the frequency domain. This work provides simple, flexible, and accurate models ready to be used in both searches and parameter estimation of binary neutron star events.

PACS numbers: 04.25.D-, 04.30.Db, 95.30.Sf, 95.30.Lz, 97.60.Jd

The 2015 detections of gravitational waves (GWs) of merging binary black holes (BBHs) [1, 2] have initiated a new observational era in astronomy and fundamental physics. In the coming years, ground-based advanced interferometers will reach design sensitivity and observe the coalescence and merger of binary neutron stars (BNSs) [3]. These observations will have a unique potential to probe the fundamental physics of NSs and to connect high-energy astrophysical phenomena with their strong-gravity engines. Main examples are the possibility to constrain the equation of state (EOS) of the cold ultradense matter in NS interiors, e.g. [4], and the possibility to show the unequivocal connection between electromagnetic signals, e.g. short gamma ray bursts [5] or kilonovae [6], with the collision of two compact objects.

A key open problem for GW astronomy with BNS sources is the availability of faithful waveform models that capture the strong-gravity and tidally-dominated regime of the late-inspiral and merger. State-of-art tidal waveform models have been developed in [7, 8] and are based on the effective-one-body (EOB) description of the general-relativistic two body problem [9, 10]. That approach proved to be very powerful but has also limitations. EOB waveforms cannot be efficiently evaluated, hence they cannot be directly used for GW searches or parameter estimation. To that purpose one must build other representations [11] that require extra efforts and introduce further uncertainties. Additionally, current published tidal EOB models neither include spin effects nor are tested against spinning NR simulations [12]. Recent work also showed that the current EOB models are not uniformly accurate on the binary parameter space that has been simulated in Ref. [13]. Thus, modeling techniques complementary to EOB, see e.g. [14, 15], are needed especially because post-Newtonian (PN) approximants fail towards merger and introduce systematic uncertainties in GW parameter estimation [16, 17].

In this work we construct for the first time closed-form (analytical) approximants to the tidal GW phase directly employing numerical relativity (NR) simulations. Simple time and frequency domain approximants are build from a set of error-controlled BNS merger simulations. Our method is inspired by some ideas used in the modeling of BBH’s GWs. In particular, it makes direct use of NR data as in the Phenom approach [19] and employs resummed PN expressions as in the EOB approach.

Eccentricity-reduced and high-resolution NR simulations

For this work we simulated nine BNS configurations in general relativity. We simulated equal-masses BNSs both irrotational and with spins (anti-) aligned to the orbital angular momentum. Three different parameterized EOSs (MS1b, H4, SLy) [20] are employed to span a large range of tidal parameters (see below). The binary gravitational mass is \( M = M_A + M_B \sim 2.7 \), where \( A, B \) label the NSs and \( M_A \) is the mass of star \( A \) in isolation. Spin magnitudes are in the range \( \chi_A = \chi_B \sim [-0.1, +0.15] \), where \( \chi_A = S_A/M_A^2 \) is the mass-rescaled dimensionless spin. We use the numerical methods implemented in the pseudospectral initial data SPH code [21] and in the 3+1 adaptive-mesh-refinement evolution RAB code [22]. Key technical points are the use of the Z4c formulation of general relativity and of an high-order scheme for the hydrodynamics [23, 24]. See [25] for further details. Note that we employ geometric units \( G = c = M_\odot = 1 \).
These new simulations significantly improve the waveform’s quality over previous ones. Low-eccentricity initial data were generated following Ref. [20]; our BNSs have $e \sim 10^{-3}$. Each BNS is evolved using four to five grid resolutions making a total of 37 runs. The NSs are resolved with smallest grid spacings in the range $h = 0.291 - 0.059$ in each direction. These are the largest BNS simulations performed with the BAM code so far and utilized $\sim 25$ million CPU hours on various high-performance-computing clusters. Numerical uncertainties are estimated from convergence tests and a detailed error budget has been computed. Our waveforms have maximal errors at merger, accumulated over $\sim 12$ orbits, of $\sim 0.5 - 1.5$ radians, depending on the particular configuration [25].

Extraction of tidal contributions. Spin and tidal effects in the phase of the complex GW $h(t) = A(t)e^{-i\phi(t)}$ are parametrized to leading PN order respectively by the effective spin

$$\chi_{\text{eff}} = X_A \chi_A + X_B \chi_B - \frac{38}{113} X_A X_B (\chi_A + \chi_B)$$

(1)
descrating the spin-orbit (SO) interaction [27], and by the tidal coupling constant [10]

$$k_T^2 = 2 \left[ \frac{X_A}{X_B} \left( \frac{X_A}{C_A} \right)^5 k_b^2 + \frac{X_B}{X_A} \left( \frac{X_B}{C_B} \right)^5 k_b^2 \right]$$

(2)

where $k_b^A$ is the quadrupolar Love number describing the static quadrupolar deformation of one body in the gravitoelectric field of the companion, $X_A = M_A/M$, and $C_A$ is the compactness of star $A$. We work with the phase as a function of the dimensionless GW frequency $\hat{\omega} = M \hat{\omega}_0 \phi(t)$ and use the ansatz

$$\phi(\hat{\omega}) \approx \phi_0(\hat{\omega}) + \phi_{\text{SO}}(\hat{\omega}) + \phi_T(\hat{\omega})$$

(3)

where $\phi_0$ denotes the nonspinning black hole (or point particle) phase evolution. The next-to-leading order PN expression of the tidal contribution (TaylorT2 approximant) [18] reads

$$\phi_T^{T2} = -\kappa_T^2 \frac{c_{\text{Newt}} x^{5/2}}{X_A X_B} \left( 1 + c_1 x \right)$$

(4)

with $x(\hat{\omega}) = (\hat{\omega}/2)^{2/3}$, where $\hat{\omega}/2$ is the orbital frequency, and $c_{\text{Newt}} = -13/8$, $c_1 = 1817/364$ (value for equal mass case). Similarly, the SO contribution is $\phi_{\text{SO}} \propto \chi_{\text{eff}}$ at leading PN order. Using Eq. (3) the nonperturbative SO and tidal contributions can be extracted by linear combinations of simulation data with different parameters, as detailed in [12, 25]. For simplicity, we neglect spin-spin interactions: they are subdominant contributions and poorly resolved in our simulations [25]. We find that the spin and tidal terms in Eq. (3) are decoupled to the level of the NR uncertainties, Fig. 1. This

FIG. 1. Phase as a function of the GW frequency from NR simulations. The simulations are labeled as EOSX/A. Top: Total phase / number of cycles accumulated within frequency interval $\hat{\omega} \in [0.04, 0.17]$ for different BNSs. Markers indicate the merger (peak of the GW’s amplitude) of the particular simulation for the highest resolved simulation. Bottom: Tidal phase contribution $\phi_T / k_T^2$ computed by subtracting pairs of datasets; note it is independent on the spin.

fact allows us to construct spinning BNSs using binary black hole baseline waveforms and adding the tidal contribution. Further, Fig. 1 indicates that the TaylorT2 approximant does not capture the phase evolution in the strong field region, failing for $\hat{\omega} \gtrsim 0.06$, cf. [10].

Time-domain tidal approximant. A closed-form expression for $\phi_T$ is obtained using the fitting formula

$$\phi_T = -\kappa_T^2 \frac{c_{\text{Newt}} x^{5/2}}{X_A X_B} \left( 1 + c_1 x \right) \times \frac{1 + n_1 x + n_2 x^2 + n_3 x^3}{1 + d_1 x + d_2 x^3}$$

(5)

Demanding that Eq. (5) reproduces Eq. (4) in a low frequency expansion, we set $d_1 = (n_1 - c_1)$. The other coefficients are fit to NR data. Note that for simplicity Eq. (5) does not contain tidal terms corresponding to higher multipoles [29], and the dependency from $X_{A,B}$ of the higher effective PN terms is ignored. This is justified since we seek an effective expression of the phase; the coefficients of the latter could be further improved using more simulations with various mass ratios.

The fit is performed on a dataset spanning the interval $\hat{\omega} \in [0, 0.17]$. Eq. (4) is used for $\hat{\omega} \leq 0.0074$, while the tidal EOB waveforms of [7] are used for $\hat{\omega} \geq 0.0074, 0.04$. The datasets are connected such that phase differences near the interval boundaries are minimal. We interpolate the data on a grid consisting of 10000, 5000, 500 points in the three intervals, respec-
In most cases our new waveforms are compatible with the NR data within the estimated uncertainties. The proposed tidal approximant remains accurate also for longer waveforms. Phase differences with respect to hybrid tidal EOB-NR waveforms and accumulated over the last 300 orbits before merger are of the order of $\sim 1$ rad, see [23]. In the nonspinning cases, our results can be directly compared to the tidal EOB waveforms of [21, 8] [see green lines in Fig. 2]; comparable performances are observed in spite of the simplicity of our model.

Although the fit has been derived with an equal mass ansatz, it gives a good prediction also for the unequal mass case. That is partly due to the leading-order dependence on the mass ratio contained in the tidal coupling constants, Eq. (2). Also, while we use NR data up to $\hat{\omega} = 0.17$, the model remains accurate also for BNSs with smaller $\kappa_2^T$ that merge at higher frequencies. Let us stress that the model performances are independent of the BBH baseline, provided the latter is a faithful representation of BBH waveforms.

**Frequency-domain tidal approximant.** In the frequency domain $h(f) = f^{-7/6} A(f) e^{-\Psi(f)}$. The expression of the tidal phase is computed using the stationary phase approximation (SPA) [29]

$$d^2 \Psi_T^{SPA} / d\omega_f^2 = \frac{Q_2(\omega_f)}{\omega_f^2},$$

where $\omega_f$ is the Fourier domain circular frequency $\omega_f = 2\pi M f$, and $Q_2(\omega) = d\phi / d\log \omega$. The integration of Eq. (6) with (5) is performed numerically; the constants of integration are fixed by demanding continuity with the TaylorF2PN in the limit $f \to 0$. The resulting expression $\Psi_T^{NR}$ can be approximated by a Padé function:

$$\Psi_T^{NR} = -\kappa_2^T \tilde{\chi}_{Newt}^{1/2} \times$$

$$\frac{1 + \tilde{n}_1 x + \tilde{n}_3 x^3/2 + \tilde{n}_5 x^4/2 + \tilde{n}_7 x^5/2}{1 + \tilde{d}_1 x + \tilde{d}_3 x^3/2}$$

with $\tilde{\chi}_{Newt} = 39/16$ and $\tilde{d}_1 = \tilde{n}_1 - 3115/1248$, the other parameters read: $\tilde{n} = (-17.428, 31.867, -26.414, 26.414, 26.414)$ and $\tilde{d}_3/2 = 36.089$.

Figure 3 compares the obtained tidal approximants $\Psi_T^{NR}$ with the TaylorF2PN and the 2.5PN approximants given in [23] (TaylorF2_{2.5PN}). Because of the construction of Eq. (7) the low frequency behavior of TaylorF2 is recovered. At higher frequencies PN expressions predict smaller tidal effects than $\Psi_T^{NR}$. Considering the accuracy of $\Psi_T^{NR}$, the Padé fit recovers $\Psi_T^{NR}$ with fractional errors $\lesssim 1\%$.

To further test the performance of the proposed frequency-domain model we compute the unfaithfulness $(\tilde{F} = 1 - F$, one minus faithfulness) which is the mismatch for the fixed intrinsic binary parameters with respect to tidal EOB waveforms starting at $\sim 25\text{Hz}$ and
hybridized with NR simulations [25]. The unfaithfulness quantifies the loss in the signal-to-noise ratio (squared) due to the inaccuracies in the signal modeling. The typical maximum value used in the GW searches is $F \lesssim 0.03$, which roughly corresponds to $\lesssim 10\%$ loss in the number of events (assuming that they are uniformly distributed).

Figure 4 shows $F$ for different approximants and varying the minimum frequency in the overlap interval from $Mf_{\text{min}} \sim [0.0022, 0.04]/2\pi$, i.e. from $\sim 27$ Hz to the NR regime ($\sim 480$ Hz). Tidal approximants have significant mismatches with respect to BBH ones already for $Mf_{\text{min}} \sim 0.01/2\pi$. The unfaithfulness computed from $Mf_{\text{min}} \sim 0.0022/2\pi$ up to the merger is only weakly dependent on the particular tidal approximant. However, tidal effects become significant at higher frequencies, and if the $F$ computations are restricted to higher frequencies significant differences amongst the approximants emerge. $\Psi_T^{\text{NRP}}$ has the smallest unfaithfulness. For MS1b$_{0.00}^{1.35}$ (top panel), in particular, the proposed tidal approximant has an unfaithfulness about one order of magnitude smaller than TaylorF2. For SLy$_{0.00}^{1.35}$ (bottom panel) the unfaithfulness is $F < 0.03$ for all tidal approximants, indicating that the largest contribution due to tidal effects comes from the strong-field–NR regime.

Conclusion. The tidal approximants, which we propose, can be efficiently used for both GW searches and parameter estimation of BNS events. For data-analysis applications it is trivial to re-parametrize the tidal coupling constant $\kappa_2^A$ in terms of the mass ratio and (combinations of) the dimensionless tidal parameters that are shown to be optimal for those purposes [17, 18]. The cutting frequency for the phase approximants is given by the NR results of [33] that characterize the merger frequency of any BNS in terms of $k_2^A$. Tidal corrections to the amplitude can be also added following [29]. Further work could also aim at improving the approximants using more NR data by including precession effects [34, 35].

Although we focused on BNSs, by setting $k_2^A = 0$ and with the appropriate choice of the resulting $k_2^T$ one could construct waveforms for black-hole–neutron star binaries.

SUPPLEMENTARY MATERIAL

Simulations overview

The physical parameters of the BNS configurations and the grid configurations used in the simulations are summarized in Tab. I. The configurations consist of equal mass ($M_A = M_B$) binaries with aligned or anti-aligned spins ($\chi_A = \chi_B$). In total, nine (37) new configurations (simulations) have been performed for the scope of this paper. BNS configurations are indicated by the EOS, the masses (subscript), and the spin (superscript), i.e. $E0S^{\chi_A}_{M_A}$. We also use non-spinning data from the simulations described in [13] with the notation (EOS$_{M_A+M_B}^{\chi_A}$).

Our initial configurations are constructed with the pseudospectral SGRID code [26, 36–38], which makes use of the constant rotational velocity approach [21, 39] to construct constraint solved spinning BNS configurations in hydrodynamical equilibrium. Eccentricity reduced initial data are constructed following [26, 40] by applying an the constant rotational velocity approach [21, 39] to construct constraint solved spinning BNS configurations in hydrodynamical equilibrium. Eccentricity reduced initial data are constructed following [26, 40] by applying an

Evolutions are performed with the BAM code [22, 24, 41, 42]. We use 7 mesh refinement levels labeled with $l = 0, \ldots, 6$ with grid spacing $h_l = h_0/2^l$ for $l > 0$ and number of points per direction $n_l$. Different grid resolutions named R1, R2, etc. have been employed; the NS diameter is typically covered with $n_6 = 64, 96, 128, 192, 256$ points for respectively R1 to R5 (Table I). The numerical fluxes for the general relativistic hydrodynamics are computed as in [24] based on a flux-splitting approach with the local Lax-Friedrich flux and after reconstruction of the characteristic fields [43, 44]. This method guarantees clear convergence and a robust error assessment of the numerical simulations, see below.

Simulations accuracy

**Eccentricity**

We construct eccentricity reduced initial data by means of an iterative procedure that monitors and varies the binary’s initial radial velocity and the eccentricity parameter, see Eq. (2.37) and (2.39) of [26]. As an initial guess, quasi-equilibrium configurations in the usual quasi-circular orbit are employed for which residual eccentricities are in the range of $e \sim 10^{-2}$. The steps of the iterative procedure are then, (i) evolve the data for $\sim 3$ orbits, (ii) measure the eccentricity $e$, for which we use the proper distance as described in [26], and (iii) re-compute the initial data with adjusted parameters. As an exemplary case, the iteration procedure for the SLy$^{0.00}_{1,37}$ case is presented in Fig. 5. Target residual eccentricities $e \sim 10^{-3}$ are usually achieved within three iterations [26].
FIG. 5. Proper distance along the connection line between the two NSs centers for SLy\textsuperscript{0,00} \textsubscript{1.35}.

FIG. 6. Phase difference for setup SLy\textsuperscript{0,00} \textsubscript{1.35} (solid lines). Dashed lines are rescaled phase differences assuming second order convergence, which is achieved for resolution R2 and above. Straight vertical lines mark the moment of merger, i.e. the peak in the GW amplitude.

Waveform’s error-budget

The GW metric multipoles

\[ r h_{\ell m}(t) = A_{\ell m}(t) e^{-i\phi_{\ell m}(t)} \]  

are constructed from the curvature multipoles using frequency domain integration of Ref. [45]. In this work only the dominant (2,2)-mode is considered and indices are dropped in the following. The retarded time is defined as \( u = t - r_* \), where \( r_*(M) \) is the tortoise coordinate of the Schwarzschild spacetime of mass \( M \) computed from the coordinate (isotropic) radius at which GWs are extracted (see below).

Uncertainties due to truncation errors are estimated following [24]. As an exemplary case we present the phase difference between different resolutions for SLy\textsuperscript{0,00} \textsubscript{1.35} in Fig. 6. Second order convergence (dashed lines) is achieved for resolutions R2 and higher. For a better approximation of the waveform we follow the description of [46] and apply a Richardson extrapolation for the phase using the highest three available resolutions for each dataset.

GWs are extracted at finite radii, where we pick \( r = 1000 \) for our analysis. The numerical error introduced by finite radii extraction of the GW is obtained by comparing finite radii waveforms with second order polynomial extrapolated waveform (similar results are obtained by including next-to-leading order terms, see [24, 47]).

Time-domain approximants

Time-domain fit

To obtain the time-domain fit, we split the interval \( \tilde{\omega} \in I = [0, 0.17] \) into three different intervals: \( I_{T2} = [0, 0.0074] \), \( I_{EOB} = [0.0074, 0.04] \), \( I_{NR} = [0.04, 0.17] \). In \( I_{T2} \) we evaluate Eq. (4) at 10000 equally spaced points. For interval \( I_{EOB} \) we compute three tidal EOB waveforms [7] corresponding to the three irrotational runs of Tab. I and with starting frequency \( \tilde{\omega}(0) = 0.0065 \). We compute \( \Delta \phi_T / \kappa_T^2 \) by taking the difference of \( \phi(\tilde{\omega}) \) for different BNS configurations. From the obtained curves we compute the average and interpolate on an equally spaced grid with a total of 5000 grid points in \( I_{EOB} \). A phase shift is applied to the EOB data by minimizing the phase difference between the T2 and EOB data in the interval \( \tilde{\omega} \in [0.00715, 0.00765] \). For the interval \( I_{NR} \) we compute \( \phi_T / \kappa_T^2 \) by taking the difference between the irrotational NR data [as for the EOB waveforms]; we then take the average of all obtained results, interpolate on an equally spaced grid with 500 grid points, and fix the initial phase by minimizing the phase difference in \( [0.04, 0.044] \).

The obtained data on \( I = I_{T2} \cup I_{EOB} \cup I_{NR} \) are fitted as a function of \( x \), after factoring out the leading order Newtonian term. The result is given in Eq. (5); the high frequency part of the fit is shown in the bottom panel of Fig. 7.
Waveform comparison

In addition to the exemplary cases in the main text, we further test the performances of the proposed model comparing to

- Waveforms from all the simulations listed in Tab. I [See Fig. 7 for examples].
- Equal and unequal mass NR waveforms of Ref. [13] [see Fig. 8 in which we also include tidal EOB waveforms].
- Hybrid EOB-NR waveforms with a starting frequency of 75 Hz. The hybrid waveforms are constructed by combining tidal EOB waveforms of [7] with the highest resolution irrotational data presented in Tab. I [See Fig. 9 for the results].

We find that our time-domain approximant is robust for a variation of the binary parameters and the waveform length. In particular, spurious effects due to time-domain waveform alignment do not influence significantly our results.

Frequency-domain approximants

The 2.5PN TaylorF2 expression of Damour et al. [29] (DNV) with which we compare reads for equal mass BNSs:

$$\Psi_T^{2.5\text{PN}} = \kappa^2_{\text{Newt}} \frac{x^5}{5} \left( 1 + \tilde{c}_1 x + \frac{\tilde{c}_3}{2} x^3 + \frac{\tilde{c}_5}{2} x^5 \right),$$

(9)

where

$$\tilde{c}_{\text{Newt}} = -\frac{39}{4}, \quad \tilde{c}_1 = \frac{3115}{1248}, \quad \tilde{c}_3/2 = -\pi, \quad \tilde{c}_2 = \frac{23073805}{3302208} + \frac{20}{81} \tilde{\alpha}_2^2 + \frac{20}{351} \beta_2^{22}, \quad \tilde{c}_5/2 = -\pi \frac{4283}{1092}.$$

(10)

For equal masses $\tilde{\alpha}_2^2 = 85/14$. The expression above includes tail terms up to 2.5PN order and the 2PN is computed up to an unknown (not yet calculated) coefficient which we set $\beta_2^{22} = 0$. 

FIG. 7. GWs for different setups, see Tab. I. We compare our waveform model with full NR simulations. For each configuration we show the real part obtained with Eq. (5) (orange) and the real part of the comparison waveform (gray). The dephasing between the model and the comparison waveform $\phi - \phi_{\text{NR}}$ is shown blue and $\log_{100} |\phi - \phi_{\text{NR}}|$ is shown red. The numerical uncertainty is shown as a blue shaded region and the alignment region as a gray shaded interval.
FIG. 8. Comparison of the proposed waveform model with NR simulations of [13]. For each configuration we show the real part obtained with (5) (orange) and the real part of the NR waveform (gray). The dephasing between the model and the NR data $\phi - \phi_{NR}$ is shown blue and $\log_{100}|\phi - \phi_{NR}|$ is shown red. We also include the phase between the NR data with respect to the EOB models of [9] (green dashed) and [17] (green dot-dashed). The numerical uncertainty is shown as a blue shaded region and the alignment region as a gray shaded interval. Considered configurations are: an equal mass setup for the MS1b with masses $M_A = M_B = 1.375$ (upper left); an unequal mass setup setup with $M_A = 1.65, M_B = 1.10$ for MS1b (upper right), and unequal mass setups with $M_A = 1.50, M_B = 1.00$ for MS1b (lower left) and SLy (lower right) (bottom row).

To validate the frequency approximant we compute the mismatch (or unfaithfulness)

$$\bar{F} = 1 - \max_{\phi_c, t_c} \frac{(h_1(\phi_c, t_c), h_2)}{\sqrt{(h_1, h_1), (h_2, h_2)}}$$

with $\phi_c, t_c$ an arbitrary phase and time shift, and the noise-weighted overlap defined as

$$(h_1, h_2) = 4R \int_{f_{\text{min}}}^{f_{\text{max}}} \frac{\tilde{h}_1(f)\tilde{h}_2(f)}{S_n(f)} \, df.$$ (12)

Above, $S_n(f)$ is the one-sided power spectral density of the detector noise, where we use the ZERO_DET_highP noise curve of [48]. The value of $\bar{F}$ indicates the loss in signal-to-noise ratio (squared) when the waveforms are aligned in time and phase. Template banks are constructed so that the maximum value is $\max(\bar{F}) = 0.03$. Such mismatch corresponds to a maximum loss in event-rate of $\sim 0.09$. 

$$\bar{F} = 1 - \max_{\phi_c, t_c} \frac{(h_1(\phi_c, t_c), h_2)}{\sqrt{(h_1, h_1), (h_2, h_2)}}$$

FIG. 9. We compare our waveform model with hybrid NR-tidal EOB waveforms. For each configuration we show the real part obtained with (orange) and the real part of the hybrid waveform (gray). The dephasing between the model and the hybrid $\phi - \phi_{\text{NR}}$ is shown blue and $\log_{100} |\phi - \phi_{\text{NR}}|$ is shown red. The alignment region is marked as a gray shaded interval. The simulations cover about 300 orbits before the merger.
