Abstract
We review the present status for the determinations of the light and heavy quark masses, the light quark chiral condensate and the decay constants of light and heavy-light (pseudo)scalar mesons from QCD spectral sum rules (QSSR). Bounds on the light quark running masses at 2 GeV are found to be (see Tables 1 and 2): 6 MeV < (m_d + m_u)(2) < 11 MeV and 71 MeV < m_s(2) < 148 MeV. The agreement of the ratio m_s/(m_u + m_d) = 24.2 in Eq. (57) from pseudoscalar sum rules with the one (24.4 ± 1.5) from ChPT indicates the consistency of the pseudoscalar sum rule approach. QSSR predictions from different channels for the light quark running masses lead to (see Section 10.3): m_s(2) = (117.4 ± 23.4) MeV, (m_d + m_u)(2) = (10.1 ± 1.8) MeV, (m_d − m_u)(2) = (2.8 ± 0.6) MeV with the corresponding values of the RG invariant masses. The different QSSR predictions for the heavy quark masses lead to the running mass values: m_c(M_Z) = (1.23 ± 0.05) GeV and m_b(M_Z) = (4.24 ± 0.06) GeV (see Tables 5 and 6), from which one can extract the scale independent ratio m_b/m_s = 48.8 ± 9.8. Runned until M_Z, the b-quark mass becomes: m_b(M_Z) = (2.83 ± 0.04) GeV in good agreement with the average of direct measurements (2.82 ± 0.63) GeV from three-jet heavy quark production at LEP, and then supports the QCD running predictions based on the renormalization group equation. As a result, we have updated our old predictions of the weak decay constants f_{K^0}(1.3), f_{K^+}(1.46), f_{a_0}(0.98) and f_{K^*}(1.43) (see Eqs. (87) and (89)). We obtain from a global fit of the light (pseudo)scalar and B_s mesons, the flavour breakings of the normal ordered chiral condensate ratio: \langle \bar{s}s \rangle/\langle \bar{u}u \rangle = 0.66 ± 0.10 (see Eq. (113)). The last section is dedicated to the QSSR determinations of f_{D(\alpha)} and f_{B(\alpha)}.

This review updates and completes the reviews [1, 2] and some parts of the book [3]. It has been extracted from a chapter of the forthcoming book: QCD as a theory of hadrons: from partons to confinement [4].
1 Introduction

One of the most important parameters of the standard model and chiral symmetry is the light and heavy quark masses. Light quark masses and chiral condensates are useful for a much better understanding of the realizations of chiral symmetry breaking \[5\]–\[7\] and for some eventual explanation of the origin of quark masses in unified models of interactions \[8\]. Within some popular parametrizations of the hadronic matrix elements \[9\], the strange quark mass can also largely influence the Standard Model prediction of the \(CP\) violating parameters \(\epsilon'/\epsilon\) which have been measured recently \[10\]. However, contrary to the QED case where leptons are observed, and then the physical masses can be identified with the pole of the propagator (on-shell mass value)\[4\] the quark masses are difficult to define because of confinement which does not allow to observe free quarks. However, despite this difficulty, one can consistently treat the quark masses in perturbation theory like the QCD coupling constant. They obey a differential equation, where its boundary condition can be identified with the renormalized mass of the QCD lagrangian. The corresponding solution is the running mass, which is gauge invariant but renormalization scheme and scale dependent, and the associated renormalization group invariant mass. To our knowledge, these notions have been introduced for the first time in \[14\]. In practice, these masses are conveniently defined within the standard \(\overline{MS}\)-scheme discussed in previous chapters. In addition to the determination of the ratios of light quark masses (which are scale independent) from current algebra \[5\], and from chiral perturbation theory (ChPT), its modern version \[15\]–\[19\], a lot of effort reflected in the literature \[20\] has been put into extracting directly from the data the running quark masses using the SVZ \[21\] QCD spectral sum rules (QSSR) \[9\], LEP experiments and lattice simulations. The content of these notes is:

- a review of the light and heavy quark mass determinations from the different QCD approaches.
- a review of the direct determinations of the quark vacuum condensate using QSSR and an update of the analysis of its flavour breakings using a global fit of the meson systems.
- An update of the determinations of the light (pseudo)scalar decay constants, which, in particular, are useful for understanding the \(\bar{q}q\) contents of the light scalar mesons.
- A review of the determinations of the weak leptonic decay of the heavy-light pseudoscalar mesons \(D_{(s)}\) and \(B_{(s)}\).

This review develops and updates the review papers \[1, 2\] and some parts of the book \[3\]. It also updates previous results from original works.

2 Definitions of perturbative quark masses in QCD

Let’s remind the meaning of quark masses in QCD. One starts from the mass term of the QCD lagrangian:

\[
\mathcal{L}_m = m_i \bar{\psi}_i \psi_i ,
\]

where \(m_i\) and \(\psi_i\) are respectively the quark mass and field. It is convenient to introduce the dimensionless mass \(x_i(\nu) = m_i(\nu)/\nu\), where \(\nu\) is the renormalization scheme subtraction constant. The running quark mass is a solution of the differential equation:

\[
\frac{d\tilde{x}_i}{dt} = (1 + \gamma(\alpha_s))\tilde{x}_i(t) \cdot \tilde{x}_i(t = 0) = x_i(\nu) .
\]

\[2\] For a first explicit definition of the perturbative quark pole mass in the \(\overline{MS}\)-scheme, see \[1\] (renormalization-scheme invariance) and \[13\] (regularization-scheme invariance).
In the $\overline{\text{MS}}$-scheme, its solution to order $a_s^3$ ($a_s \equiv \alpha_s/\pi$) is:

$$\overline{m}_i(\nu) = \overline{m}_i(-\beta_1 a_s(\nu))^{-\gamma_1/\beta_1} \left\{ 1 + \frac{\beta_2}{\beta_1} \left( \frac{\gamma_1}{\beta_1} - \frac{\gamma_2}{\beta_2} \right) a_s(\nu) + \frac{1}{2} \left[ \frac{\beta_2}{\beta_1} \left( \frac{\gamma_1}{\beta_1} - \frac{\gamma_2}{\beta_2} \right)^2 - \frac{\beta_2^2}{\beta_1^2} \left( \frac{\gamma_1}{\beta_1} - \frac{\gamma_2}{\beta_2} \right) \right] a_s^2(\nu) + 1.95168 a_s^3 \right\},$$

(3)

where $\gamma_i$ and $\beta_i$ are the $\mathcal{O}(a_s^i)$ coefficients of the quark-mass anomalous dimension and $\beta$-function, which read for $SU(3)_c \times SU(n)_f$:

$$\gamma_1 = 2, \quad \gamma_2 = \frac{1}{6} \left( \frac{101}{2} - \frac{5n}{2} \right), \quad \gamma_3 = \frac{1}{96} \left[ 14747 - \left( \frac{160}{9} \zeta_3 - \frac{2216}{9} \right) n - \frac{140}{27} n^2 \right]$$

$$\beta_1 = -\frac{1}{2} \left( 11 - \frac{2}{3} n \right), \quad \beta_2 = -\frac{1}{4} \left( 51 - \frac{19}{3} n \right), \quad \beta_3 = -\frac{1}{64} \left( 2857 - \frac{5033}{9} n + \frac{325}{27} n^2 \right).$$

(4)

The invariant mass $\overline{m}_i$ has been introduced for the first time by [13] in connection with the analysis of the breaking of the Weinberg sum rules by the quark mass terms in QCD. For the heavy quarks, one can also define a perturbative (short distance) pole mass at the pole of the propagator. The IR finiteness of the result to order $\alpha_s^2$ has been explicitly shown in [11, 12]. The independence of $M_{\text{pole}}$ on the choice of the regularization-scheme has been demonstrated in [13]. The extension of the previous result to order $\alpha_s^3$ is: [22]:

$$M_{\text{pole}} = \overline{m}(p^2) \left[ 1 + \left( \frac{4}{3} + \ln \frac{p^2}{m^2} \right) \left( \frac{\alpha_s}{\pi} \right) + \left[ K_Q + \left( \frac{221}{24} - \frac{13}{36} n \right) \ln \frac{p^2}{m^2} + \left( \frac{15}{8} - \frac{n}{12} \right) \ln^2 \frac{p^2}{m^2} \right] \left( \frac{\alpha_s}{\pi} \right)^2 \right],$$

(5)

where in the RHS $m$ is the running mass evaluated at $p^2$ and:

$$K_Q = 17.1514 - 1.04137 n + \frac{4}{3} \sum_{i \neq Q} \Delta \left( r \equiv \frac{m_i}{M_Q} \right).$$

(6)

For $0 \leq r \leq 1$, $\Delta(r)$ can be approximated, within an accuracy of 1% by:

$$\Delta(r) \approx \frac{\pi^2}{8} r - 0.597 r^2 + 0.230 r^3.$$

(7)

It has been argued that the pole masses can be affected by nonperturbative terms induced by the resummation of the QCD perturbative series [23] and alternative definitions free from such ambiguities have been proposed (residual mass [24] and 1S mass [25]). Assuming that the QCD potential has no linear power corrections, the residual or potential-subtracted (PS) mass is related to the pole mass as:

$$M_{PS} = M_{\text{pole}} + \frac{1}{2} \int_{|\vec{q}| < \mu} \frac{d^3 \vec{q}}{(2\pi)^3} V(\vec{q}) .$$

(8)

The 1S mass is defined as half of the perturbative component to the $^3S_1$ $QQ$ ground state, which is half of its static energy $\langle 2M_{\text{pole}} + V \rangle$. The running and short distance pole mass defined at a given order of PT series will be used in the following discussions.

[3] These definitions might still be affected by a dimension–2 term advocated in [24], which might limit their accuracy. [25].
3 Ratios of light quark masses from ChPT

The ratios of light quark masses are well-determined from current algebra \[5\], and ChPT \[15\]. In this approach, the meson masses are expressed using a systematic expansion in terms of the light quark masses:

\[
\begin{align*}
M_{\pi^+}^2 &= (m_u + m_d)B + O(m^2) + ... \\
M_{K^+}^2 &= (m_u + m_s)B + O(m^2) + ... \\
M_{K^0}^2 &= (m_d + m_s)B + O(m^2) + ...
\end{align*}
\]

where \( B \equiv -\langle \bar{\psi}\psi \rangle / f_K^2 \) from the Gell-Mann, Oakes, Renner relation \[30\]:

\[
m_{\pi^+}^2 f_K^2 \simeq -(m_u + m_d)\langle \bar{\psi}\psi \rangle + O(m^2).
\]

However, only the ratio, which is scale independent can be well determined. To leading order in \( m \):

\[
\begin{align*}
\frac{m_u}{m_d} &\approx \frac{M_{\pi^+}^2 - M_{K^0}^2 + M_{K^+}^2}{M_{\pi^+}^2 + M_{K^0}^2 - M_{K^+}^2} \approx 0.66 \\
\frac{m_s}{m_d} &\approx \frac{-M_{\pi^+}^2 + M_{K^0}^2 + M_{K^+}^2}{M_{\pi^+}^2 + M_{K^0}^2 - M_{K^+}^2} \approx 20
\end{align*}
\]

Including the next order + electromagnetic corrections, the ratios of masses are constrained on the ellipse:

\[
\left(\frac{m_u}{m_d}\right)^2 + \frac{1}{Q^2} \left(\frac{m_s}{m_d}\right)^2 = 1
\]

where: \( Q^2 \simeq (m_s^2 - \hat{m}^2)/(m_d^2 - m_u^2) = 22.7 \pm 0.8 \) using the value of the \( \eta \to \pi^+\pi^-\pi^0 \) from the PDG average \[20\], though this value can well be in the range 22–26, to be compared with the Dashen’s formula \[32\] of 24.2; \( \hat{m} \equiv (1/2)(m_u + m_d) \). In the figure of \[7\] one shows the range spanned by \( R \equiv (m_s - \hat{m})/(m_d - m_u) \) and the corrections to the GMO mass formula \( \Delta_M : M_S^2 = (1/3)(4M_K^2 - m_{\pi^+}^2)(1 + \Delta_M) \). The Weinberg mass ratio \[5\] is also shown which corresponds to the Dashen’s formula and \( R \approx 43 \). At the intersection of different ranges, one deduces \[5\]:

\[
\begin{align*}
\frac{m_u}{m_d} &= 0.553 \pm 0.043, \quad \frac{m_s}{m_d} = 18.9 \pm 0.8, \\
\frac{2m_s}{(m_d + m_u)} &= 24.4 \pm 1.5.
\end{align*}
\]

The possibility to have a \( m_u = 0 \) advocated in \[33\] appears to be unlikely as it implies too strong flavour symmetry breaking and is not supported by the QSSR results from 2-point correlators of the divergences of the axial and vector currents, as will be shown in the next sections.

4 Bounds on the light quark masses

In QSSR, the estimate and lower bounds of the sum of the light quark masses from the pseudoscalar sum rule have been firstly done in \[34, 35\], while a bound on the quark mass difference has been firstly derived in \[33\]. The literature in this subject of light quark masses increases with time \[1\]. However, it is in some sense quite disappointing that in most of the published papers no noticeable progress

\[4\]

\[5\]

\[6\]
has been done since the previous pioneering works. The most impressive progress comes from the QCD side of the sum rules where new calculations have become available both on the perturbative radiative corrections known to order $\alpha_s^3$ \textsuperscript{[34, 37, 38]} and on the nonperturbative corrections \textsuperscript{[21–41]}. Another new contribution is due to the inclusion of the tachyonic gluon mass as a manifestation of the resummation of pQCD series \textsuperscript{[24, 27, 28]}. Alas, no sharp result is available on the exact size of direct instanton contributions advocated to be important in this channel \textsuperscript{[12]}, while \textsuperscript{[43]} claims the opposite. Though the instanton situation remains controversial, recent analysis \textsuperscript{[44, 45]} using the results of \textsuperscript{[46]} based on the ILM of \textsuperscript{[47]} indicates that this effect is negligible justifying the neglect of this effect in different analysis of this channel. However, it might happen that adding together the effect of the tachyonic gluon to the one of direct instanton might also lead to a double counting in a sense that they can be two alternative ways for parametrizing the nonperturbative vacuum \textsuperscript{[28]}. In absence of precise control of the origin and size of these effects, we shall consider them as new sources of errors in the sum rule analysis.

### 4.1 Bounds on the sum of light quark masses from pseudoscalar channels

Lower bounds for $(\bar{m}_u + \bar{m}_d)$ based on moments inequalities and the positivity of the spectral functions have been obtained, for the first time, in \textsuperscript{[34, 37, 38]}. These bounds have been rederived recently in \textsuperscript{[48, 49]} to order $\alpha_s$. As checked in \textsuperscript{[1]} for the lowest moment and redone in \textsuperscript{[45]} for higher moments, the inclusion of the $\alpha_s^3$ term decreases by about 10 to 15% the strength of these bounds, which is within the expected accuracy of the result.

For definiteness, we shall discuss in details the pseudoscalar two-point function in the $\bar{u}\bar{d}$ channel. The analysis in the $\bar{u}\bar{d}$ channel is equivalent. It is convenient to start from the second derivative of the two-point function which is superficially convergent:

$$\Psi''(Q^2) = \int_{t_0}^\infty dt \frac{2}{(t + Q^2)^3} \frac{1}{\pi} \text{Im}\Psi(t).$$  \tag{14}$$

The bounds follow from the restriction of the sum over all possible hadronic states which can contribute to the spectral function to the state(s) with the lowest invariant mass. The lowest hadronic state which contributes to the corresponding spectral function is the $K^-$-pole. From eq. \textsuperscript{(14)} we then have

$$\Psi''_s(Q^2) = \frac{2}{(M_K^2 + Q^2)^2} f_K M_K^4 + \int_{t_0}^\infty dt \frac{2}{(t + Q^2)^3} \frac{1}{\pi} \text{Im}\Psi_s(t),$$  \tag{15}$$

where $t_0 = (M_K + 2m_N)^2$ is the threshold of the hadronic continuum.

It is convenient to introduce the moments $\Sigma_N(Q^2)$ of the hadronic continuum integral

$$\Sigma_N(Q^2) = \int_{t_0}^\infty dt \frac{2}{(t + Q^2)^3} \times \left(\frac{t_0 + Q^2}{t + Q^2}\right)^N \frac{1}{\pi} \text{Im}\Psi_s(t).$$  \tag{16}$$

One is then confronted with a typical moment problem (see e.g. Ref. \textsuperscript{[50]}) The positivity of the continuum spectral function $\frac{1}{\pi} \text{Im}\Psi_s(t)$ constrains the moments $\Sigma_N(Q^2)$ and hence the l.h.s. of Eq. \textsuperscript{(15)} where the light quark masses appear. The most general constraints among the first three moments for $N = 0, 1, 2$ are:

$$\begin{align*}
\Sigma_0(Q^2) &\geq 0, \quad \Sigma_1(Q^2) \geq 0, \quad \Sigma_2(Q^2) \geq 0; \\
\Sigma_0(Q^2) - \Sigma_1(Q^2) &\geq 0, \quad \Sigma_1(Q^2) - \Sigma_2(Q^2) \geq 0; \\
\Sigma_0(Q^2)\Sigma_2(Q^2) - (\Sigma_1(Q^2))^2 &\geq 0.
\end{align*}$$  \tag{17–18}$$

The inequalities in Eq. \textsuperscript{(18)} are in fact trivial unless $2Q^2 < t_0$, which constrains the region in $Q^2$ to too small values for pQCD to be applicable. The other inequalities lead however to interesting bounds\footnote{See also the chapter on two-point functions where more references to original works are given.}.
which we next discuss.

The inequality \( \Sigma_0(Q^2) \geq 0 \) results in a first bound on the running masses:

\[
\left[ m_s(Q^2) + m_u(Q^2) \right]^2 \geq \frac{16\pi^2}{N_c} \frac{2f_K^2M_K^4}{Q^4} \frac{1}{\left( 1 + \frac{M_K^2}{Q^2} \right)^3} \frac{1}{\left( 1 + \frac{11\alpha_s(Q^2)}{\pi} \right)} + \ldots,
\]

(20)

where the dots represent higher order terms which have been calculated up to \( \mathcal{O}(\alpha_s^3) \), as well as non-perturbative power corrections of \( \mathcal{O}(1/Q^4) \) and strange quark mass corrections of \( \mathcal{O}(m_s^2/Q^2) \) and \( \mathcal{O}(m_u^2/Q^2) \) including \( \mathcal{O}(\alpha_s) \) terms. Notice that this bound is non-trivial in the large-\( N_c \) limit (\( f_K^2 \sim \mathcal{O}(N_c) \)) and in the chiral limit (\( m_s \sim M_K^2 \)). The bound is of course a function of the choice of the euclidean \( Q \)-value at which the r.h.s. in Eq. (20) is evaluated. For the bound to be meaningful, the choice of \( Q \) has to be made sufficiently large. In Ref. [48] it is shown that \( Q \geq 1.4 \) GeV is already a safe choice to trust the pQCD corrections as such. The lower bound which follows from Eq. (20) for \( m_u + m_s \) at a renormalization scale \( \mu^2 = 4 \) GeV results in the solid curves shown in Fig. 1 below.

Figure 1: Lower bound in MeV to order \( \alpha_s \) for \((m_s + m_u)(2)\) versus \( Q \) in GeV from Eq. (20) for \( \Lambda_3 = 290 \) MeV (upper curve) and 380 MeV (lower curve). Quark mass values below the solid curves in Fig. 1 are forbidden by the bounds.

The resulting value of the bound at \( Q = 1.4 \) GeV is:

\[
(m_s + m_u)(2) \geq 80 \text{ MeV} \quad \Rightarrow \quad (m_u + m_d)(2) \geq 6.6 \text{ MeV} ,
\]

(21)

if one uses either ChPT and the previous SR analysis for the mass ratios. Radiative corrections tend to decrease the strengths of these bounds. Their contributions to the second moment of the two-point function are (see previous part of the book):

\[
\Psi_5(q^2) = \frac{3}{8\pi^2} \left( \frac{\bar{m}_u + \bar{m}_s}{Q^2} \right)^2 \left[ 1 + \frac{11}{3} \left( \frac{\pi_s}{\pi} \right)^2 + 14.179 \left( \frac{\pi_s}{\pi} \right)^2 + 77.368 \left( \frac{\pi_s}{\pi} \right)^3 \right]
\]

(22)

At this scale, the PT series converges quite well and behaves as:

\[
\text{Parton} \left[ 1 + 0.45 + 0.22 + 0.15 \right] .
\]

(23)

Including these higher order corrections, the bounds become:

\[
(m_s + m_u)(2) > (71.4 \pm 3.7) \text{ MeV} \quad \Rightarrow \quad (m_u + m_d)(2) > (5.9 \pm 0.3) \text{ MeV} ,
\]

(24)
The bound will be saturated in the extreme limit where the continuum contribution to the spectral function is neglected.
The quadratic inequality in Eq. (19) results in improved lower bounds for the quark masses which we show in Fig. 2 below.

![Figure 2: The same as in Fig. 1 but from the quadratic inequality to order $\alpha_s$.](image)

The quadratic bound is saturated for a $\delta$–like spectral function representation of the hadronic continuum of states at an arbitrary position and with an arbitrary weight. This is certainly less restrictive than the extreme limit with the full hadronic continuum neglected, and it is therefore not surprising that the quadratic bound happens to be better than the ones from $\Sigma_N(Q^2)$ for $N = 0, 1,$ and $2$. Notice however that the quadratic bound in Fig. 2 is plotted at higher $Q$–values than the bound in Fig. 1. This is due to the fact that the coefficients of the perturbative series in $\alpha_s(Q^2)$ become larger for the higher moments. In Ref [48] it is shown that for the evaluation of the quadratic bound $Q \geq 2$ GeV is already a safe choice.

Similar bounds can be obtained for $(m_u + m_d)$ when one considers the two–point function associated with the divergence of the axial current

$$\partial_{\mu} A^\mu(x) = (m_d + m_u) \bar{d}(x)i\gamma_5 u(x).$$ (25)

The method to derive the bounds is exactly the same as the one discussed above and therefore we only show, in Fig. 3 below, the results for the corresponding lower bounds which one obtains from the quadratic inequality. At $Q = 2$ GeV, one can deduce the lower bounds from the quadratic inequality:

$$(m_s + m_u)(2) > 105 \text{ MeV}, \quad (m_u + m_d)(2) > 7 \text{ MeV}.$$ (26)

The convergence of the QCD series is less good here than in the lowest moment. It behaves as [45]:

$$\text{Parton} \left[1 + \frac{25}{3} \left(\frac{\alpha_s}{\pi}\right) + 61.79 \left(\frac{\alpha_s}{\pi}\right)^2 + 517.15 \left(\frac{\alpha_s}{\pi}\right)^3\right].$$ (27)

which numerically reads:

$$\text{Parton}\left[1 + 0.83 + 0.61 + 0.51\right].$$ (28)

This leads to the radiatively corrected lower bound to order $\alpha_s^3$:

$$(m_s + m_u)(2) > (82.7 \pm 13.3) \text{ MeV}, \quad (m_u + m_d)(2) > (6 \pm 1) \text{ MeV}.$$ (29)
Figure 3: Lower bound in MeV for \((m_d + m_u)(2)\) from the quadratic inequality to order \(\alpha_s\).

where the error is induced by the truncation of the QCD series which we have estimated to be about the contribution of the last known \(\alpha_s^3\) term of the series \(\frac{\alpha_s}{2\pi}\). From the previous analysis, and taking into account the uncertainties induced by the higher order QCD corrections, the best lower bound comes from the lowest inequality and is given in Eq. (24). The result is summarized in Table 1.

Table 1: Lower bounds on \(m_{u,d,s}(2)\) in MeV

| Observables | Sources | Authors |
|-------------|---------|---------|
| \(\bar{m}_u + \bar{m}_d\) | 6 \(\pi\) | LRT97 [48], Y97 [49] (updated here to order \(\alpha_s^3\)) |
| | 6.8 \(\langle \bar{\psi}\psi\rangle + \text{GMOR}\) | DN98 [51] (leading order) |
| \(\bar{m}_d - \bar{m}_u\) | 1.1 \(K\pi\) | Y97 [49] (updated here to order \(\alpha_s^3\)) |
| \(\bar{m}_s\) | 71.4 \(K\) | LRT97 [48] (updated here to order \(\alpha_s^3\)) |
| | 90 \(\langle \bar{\psi}\psi\rangle + \text{ChPT}\) | DN98 [51] (leading order) |

\(^8\)In Ref. [44], alternative bound has been derived using a Hölder type inequality. The lower bound obtained from this method, which is about 4.2 MeV is weaker than the one obtained previously.
4.2 Lower bound on the light quark mass-difference from the scalar sum rule

As in [36], one can extract lower bound on the light quark mass difference \( (m_u - m_d) \) and \( (m_u - m_s) \) working with the two-point function associated to the divergence of the vector current:

\[
\partial_\mu V^\mu_{uq} = (m_u - m_q) : \bar{\psi}_u(i)\psi_q : .
\]

(30)

The most recent analysis has been done in [49]. We have updated the result by including the \( \alpha^2_s \)-term. It is given in Table 1.

4.3 Bounds on the sum of light quark masses from the quark condensate and \( e^+e^- \to I = 0 \) hadrons data.

Among the different results in [51], we shall use the range of the chiral \( \langle \bar{\psi}\psi \rangle \equiv \langle \bar{u}u \rangle \simeq \langle \bar{d}d \rangle \) condensate from the vector form factor of \( D \to K^*\ell\nu \). Using three-point function sum rules, the form factor reads to leading order:

\[
V(0) = \frac{m_c(m_D + m_{K^*})}{4f_Df_{K^*}m_D^2m_{K^*}} \exp[(m_D^2 - m_c^2)\tau_1 + m_{K^*}^2\tau_2] \times \left\{ -1 + M_0^2 \left( \frac{\tau_1}{3} + \frac{m_c^2}{4}\tau_1^2 + \frac{2m_c^2 - m_c m_s}{6}\tau_1\tau_2 \right) \right. \\

The factor \( \rho \simeq 2 \sim 3 \) expresses the uncertainty in the factorization of the four quark condensate. In our numerical analysis, we start from standard values of the QCD parameters and use \( f_{K^*} = \)
The value of \( f_D \simeq (1.35 \pm 0.07) f_\pi \) is consistently determined by a two-point function sum rule including radiative corrections as we shall see in the next chapter, where the sum rule expression can, e.g., be found in \[3\]. The following parameters enter only marginally: 
\[ m_u(1 \text{ GeV}) = (0.15 \sim 0.19) \text{ GeV}, \quad s_{10} = (5 \sim 7) \text{ GeV}^2, \quad s_{20} = (1.5 \sim 2) \text{ GeV}^2. \]
Using the conservative range of the charm quark mass: 
\[ m_c(\text{pole}) \text{ between } 1.29 \text{ and } 1.55 \text{ GeV} \text{ (the lower limit comes from the estimate in } \[3\] \text{ and the upper limit is } 1/2 \text{ of the } J/\Psi \text{ mass) } \]
one can deduce the running condensate value at 1 GeV \[ \langle \bar{\psi}\psi \rangle / [-225 \text{ MeV}]^3 \leq 1.5. \]
This result has been confirmed by the lattice \[53\]. Using the GMOR relation:
\[ 2m_\pi^2 f_\pi^2 = -(m_u + m_d)\langle \bar{u}u + \bar{d}d \rangle + \mathcal{O}(m_q^2). \]
one can translate the upper bound into a lower bound on the sum of light quark masses. The lower bound on the chiral condensate can be used in conjunction with the positivity of the \( m_q^2 \) correction in order to give an upper bound to the quark mass value. In this way, one obtains:
\[ 6.8 \text{ MeV} \leq (m_u + m_d)(2 \text{ GeV}) \leq 11.4 \text{ MeV}. \]
The resulting values are quoted in Tables \[1\] and \[2\]. We expect that these bounds are satisfied within the typical 10% accuracy of the sum rule approach.

We also show in Table \[2\] the upper bound obtained in \[52\] by using the positivity of the spectral function from the analysis of the \( e^+e^- \rightarrow I = 0 \) hadrons data where the determination will be discussed in the next section.

## 5 Sum of light quark masses from pseudoscalar sum rules

### 5.1 The (pseudo)scalar Laplace sum rules

The Laplace sum rule for the (pseudo) scalar two-point correlator reads (see e.g. \[34\]–\[41\]):
\[
\int_{t_c}^\infty dt \exp(-t\tau) \frac{1}{2\pi} \text{Im} \Psi_5(t) \simeq (\overline{m_u} \pm \overline{m_d})^2 \frac{3}{8\pi^2}\tau^{-2} \left[ (1 - \rho_1) \left( 1 + \delta_{\pm}^{(0)} \right) + \sum_{n=2}^{6} \delta_{\pm}^{(n)} \right],
\] (36)
where the indices 5 and + refer to the pseudoscalar current. Here, \( \tau \) is the Laplace sum rule variable, \( t_c \) is the QCD continuum threshold and \( \overline{m}_i \) is the running mass to three loops,
\[ \rho_1 \equiv (1 + t_c\tau) \exp(-t_c\tau). \]
(37)
Using the results compiled in previous Chapter , the perturbative QCD corrections read for \( n \) flavours:
\[
\delta_{\pm}^{(0)} = \left( \frac{\alpha_s}{\pi} \right) \left[ 11 \frac{3}{3} - \gamma_1 \gamma_E \right]
+ \left( \frac{\alpha_s}{\pi} \right)^2 \left[ 10801 \frac{1}{144} - 39 \frac{3}{2} \zeta(3) - \left( \frac{65}{24} - \frac{2}{3} \zeta(3) \right) n \right]
- \frac{1}{2} \left( 1 - \gamma_E^2 \right) \left[ \frac{17}{12} (2\gamma_1 - \beta_1) + 2\gamma_2 \right]
+ \left( 3\gamma_E^2 - 6\gamma_E - \frac{\pi^2}{2} \right) \frac{1}{12} \frac{1}{12} \left( 2\gamma_1 - \beta_1 \right),
\] (38)
\[
\delta_{\pm}^{(2)} = -2\tau \left[ 1 + \left( \frac{\alpha_s}{\pi} \right) C_F (4 + 3\gamma_E) \right] (\overline{m}_u^2 + \overline{m}_d^2)
+ \left[ 1 + \left( \frac{\alpha_s}{\pi} \right) C_F (7 + 3\gamma_E) \right] \overline{m}_u \overline{m}_d,
\] (39)
where \( C_F = 4/3 \) and \( \gamma_E = 0.5772 \ldots \) is the Euler constant; \( \gamma_1, \gamma_2 \) and \( \beta_1, \beta_2 \) are respectively the mass anomalous dimensions and \( \beta \)-function coefficients defined in a previous chapter. For three colours and three flavours, they read:

\[
\begin{align*}
\gamma_1 &= 2, & \gamma_2 &= 91/12, & \beta_1 &= -9/2, & \beta_2 &= -8.
\end{align*}
\]  

(39)

In practice, the perturbative correction to the sum rule simplifies as:

\[
\delta_{\pm}^{(0)} = 4.82 a_s + 21.98 a_s^2 + 53.14 a_s^3 + \mathcal{O}(a_s^4) \quad : \quad a_s \equiv \left( \frac{\bar{\alpha}_s}{\pi} \right).
\]  

(40)

Introducing the RGI condensates defined in the previous chapter, the non-perturbative contributions are \([54]\):

\[
\begin{align*}
\delta_{\pm}^{(4)} &= \frac{4\pi^2}{3} \tau^2 \left[ \frac{1}{4} \left( \frac{\alpha_s}{\pi} G^2 \right) + \frac{1}{\beta_1} \frac{\alpha_s}{\pi} \sum_i \langle m_i \psi_i \rangle - \frac{3}{8\pi^2} \left( \frac{11}{4} + \frac{3}{2} \gamma_E \right) \sum_i m_i^4 \\
&+ \left[ 1 + \frac{\alpha_s}{\pi} C_F \left( \frac{11}{4} \right) \frac{3}{2} \gamma_E \right] \left( \langle m_j \psi_j \rangle + \langle m_i \psi_i \rangle \right) \\
&= \left[ 2 + \frac{\alpha_s}{\pi} C_F \left( 7 + 3 \gamma_E \right) \right] \left( \langle m_j \psi_j \rangle + \langle m_i \psi_i \rangle \right) \\
&- \frac{3 \pi}{2 \tau^2} \left[ \frac{1}{4 \gamma_1 + \beta_1} \left( \frac{\pi}{\alpha_s} + C_F \left( \frac{11}{4} \right) \frac{3}{2} \gamma_E \right) + \frac{1}{6} \left( 4 \gamma_1 + \beta_1 \right) \right] \\
&- \frac{1}{4 \gamma_1} \left( 4 \gamma_2 + \beta_2 \right) \left[ \langle m_i \psi_i \rangle - \frac{1}{4} \left( 1 - 2 \gamma_E \right) \langle m_j \psi_j \rangle - \frac{3 \pi^2 m_j^2 m_i^2}{2 \tau^2} \right] \\
&\pm \left[ \left( \frac{\gamma_E}{4 \gamma_1 + \beta_1} \right) \frac{2 \pi}{\alpha_s} + \frac{1}{3} \left( 4 \gamma_1 + \beta_1 \right) - \frac{1}{2 \gamma_1} \left( 4 \gamma_2 + \beta_2 \right) + C_F \left( 7 + 3 \gamma_E \right) \right] \\
&+ \gamma_E \left( m_i \langle m_i \psi_i \rangle + m_j \langle m_j \psi_j \rangle \right)
\end{align*}
\]

(41)

Beyond the SVZ expansion, one can have two contributions:

- The direct instanton contribution can be obtained from \([47]\) and reads:

\[
\delta_{\pm}^{\text{inst}} = \frac{\rho_c^2}{r_c^3} \exp \left( -r_c \right) \left[ K_0(r_c) + K_1(r_c) \right]
\]  

(42)

with: \( r_c \equiv \rho_c^2/(2\tau) \); \( \rho_c \approx 1/600 \text{ MeV}^{-1} \) being the instanton radius; \( K_i \) is the Mac Donald function. However, one should notice that analogous contribution in the scalar channel leads to some contradictions (\([47]\) and private communication from Valya Zakharov).

- The tachyon gluon mass contribution can be deduced from \([27]\):

\[
\delta_{\pm}^{\text{tach}} = -4 \left( \frac{\alpha_s}{\pi} \right) \lambda^2,
\]  

(43)

where \( (\alpha_s/\pi) \lambda^2 \approx -0.06 \text{ GeV}^2 \) \([27]\),

which completes the different QCD contributions to the two-point correlator.
5.2 The $\bar{u}d$ channel

From the experimental side, we do not still have a complete measurement of the pseudoscalar spectral function. In the past [9], one has introduced the radial excitation $\pi'$ of the pion using a NWA where the decay constant has been fixed from chiral symmetry argument [7] and from the pseudoscalar sum rule analysis itself [56, 57, 3], through the quantity:

$$ r_\pi \equiv \frac{M_\pi^4 f_\pi^2}{m_\pi^2 f_\pi^2} . $$

Below the QCD continuum $t_c$, the spectral function is usually saturated by the pion pole and its first radial excitation and reads:

$$ \int_0^{t_c} dt \exp(-\tau r_\pi) \frac{1}{\pi} \text{Im}\Psi_5(t) \simeq 2m_\pi^4 f_\pi^2 \exp(-m_\pi^2 \tau) \left[ 1 + r_\pi \exp \left( \frac{m_\pi^2 - M_\pi^2}{\tau} \right) \right]. $$

The theoretical estimate of the spectral function enters through the not yet measured ratio $r_\pi$. Detailed discussions of the sum rule analysis can be found in [26, 27, 28]. However, this channel is quite peculiar due to the Goldstone nature of the pion, where the value of the sum rule scale (1/$\tau$ for Laplace and $t_c$ for FESR) is relatively large of about 2 GeV$^2$ compared with the pion mass, where the duality between QCD and the pion is lost. Hopefully, this paradox can be cured by the presence of the new $1/q^2$ [26, 27, 28] due to the tachyonic gluon mass, which enlarges the duality region to lower scale and then minimizes the role of the higher states into the sum rule. This naive NWA parametrization has been improved in [58] by the introduction of threshold effect and finite width corrections. Within the advent of ChPT, one has been able to improve the previous parametrization by imposing constraints consistent with the chiral symmetry of QCD [59]. In this way, the spectral function reads:

$$ \frac{1}{\pi} \text{Im}\Psi_5(t) \simeq 2m_\pi^4 f_\pi^2 \left( \delta(t - m_\pi^2) + \theta(t - 9m_\pi^2) \frac{1}{(16\pi^2 f_\pi^2)^2} \frac{1}{18} \rho^{\bar{u}d}(t) \right) $$

with:

$$ \rho^{\bar{u}d}(t) = \int_{4m_\pi^2}^{(\sqrt{t} - m_\pi)^2} \frac{d\lambda}{t} \left( \sqrt{1 - \frac{u}{\lambda}} \frac{m_\pi^2}{t} - \frac{1}{t} \right) \left( 5 + \frac{1}{2(t - m_\pi^2)^2} \left[ \frac{4}{3} (t - 3(u - m_\pi^2))^2 \right] \right) $$

$$ + \frac{8}{3} \lambda(t, u, m_\pi^2) \left( 1 - \frac{4m_\pi^2}{u} \right) + 10m_\pi^4 \left( t - 10m_\pi^2 \right) + \frac{1}{(t - m_\pi^2)} \left[ 3((u - m_\pi^2) - t + 10m_\pi^2) \right] , $$

where $\lambda(a, b, c) = a^2 + b^2 + c^2 - 2ab - 2bc - 2ca$ is the usual phase space factor. Based on this parametrization but including finite width corrections, a recent re-analysis of this sum rule has been given to order $\alpha_s^2$ [59]. Result from the LSR is, in general, expected to be more reliable than the one from the FESR due to the presence of the exponential factor which suppresses the high-energy tail of the spectral function, though the two analysis are complementary. In [59], FESR has been used for matching by duality the phenomenological and theoretical parts of the sum rule. This matching has been achieved in the energy region around 2 GeV$^2$, where the optimal value of $m_u + m_d$ has been extracted. In [4], the LSR analysis has been updated by including the $\alpha_s^3$ correction obtained in [58]. In this way, we get:

$$ (m_u + m_d)(2 \text{ GeV}) = (9.3 \pm 1.8) \text{ MeV} , $$

where we have converted the original result obtained at the traditional 1 GeV to the lattice choice of scale of 2 GeV through:

$$ \overline{m}_i(1 \text{ GeV}) \simeq (1.38 \pm 0.06) \overline{m}_i(2 \text{ GeV}) , $$

for running, to order $\alpha_s^3$, the results from 1 to 2 GeV. This number corresponds to the average value of the QCD scale $\Lambda_3 \simeq (375 \pm 50) \text{ MeV}$ from PDG [38] and [60]. Analogous value of $(9.8 \pm 1.9) \text{ MeV}$
for the quark mass has also been obtained in [61] to order $\alpha^3_s$ as an update of the [59] result. We take as a final result the average from [1] and [61]:

$$\langle m_u + m_d \rangle (2 \text{ GeV}) = (9.6 \pm 1.8) \text{ MeV} ,$$

(50)

The inclusion of the tachyonic gluon mass term reduces this value to [27]:

$$\Delta^{\text{tach}} \langle m_u + m_d \rangle (2 \text{ GeV}) \simeq -0.5 \text{ MeV} .$$

(51)

As already mentioned, adding to this effect the one of direct instanton might lead to a double counting in a sense that they can be alternative ways for parametrizing the nonperturbative QCD vacuum. Considering this contribution as another source of errors, it gives:

$$\Delta^{\text{inst}} \langle m_u + m_d \rangle (2 \text{ GeV}) \simeq -0.5 \text{ MeV} .$$

(52)

Therefore, adding different sources of errors, we deduce from the analysis:

$$\langle m_u + m_d \rangle (2 \text{ GeV}) = (9.6 \pm 1.8 \pm 0.4 \pm 0.5 \pm 0.5) \text{ MeV} ,$$

(53)

leading to the conservative result for the sum of light quark masses:

$$\langle m_u + m_d \rangle (2 \text{ GeV}) = (9.6 \pm 2.0) \text{ MeV}$$

(54)

The first error comes from the SR analysis, the second one comes from the running mass evolution and the two last errors come respectively from the (eventual) tachyonic gluon and direct instanton contributions. This result is in agreement with previous determinations [3], [55]–[58], [62, 63] though we expect that the errors given there have been underestimated. One can understand that the new result is lower than the old result [3, 55] obtained without the $\alpha^2_s$ and $\alpha^3_s$ terms as both corrections enter with a positive sign in the LSR analysis. However, it is easy to check that the QCD perturbative series converge quite well in the region where the optimal result from LSR is obtained. Combining the previous value in Eq. (54) with the ChPT mass ratio, one can also deduce:

$$\langle m_s \rangle (2 \text{ GeV}) = (116.0 \pm 18.1) \text{ MeV} ,$$

(55)

5.3 The $\bar{u}s$ channel and QSSR prediction for the ratio $m_s/(m_u + m_d)$

Doing analogous analysis for the kaon channel, one can also derive the value of the sum $(m_u + m_s)$. The results obtained from [55] updated to order $\alpha^3_s$ and from [53] are shown in Table 3 given in [1] but updated. We add to the original errors the one from the tachyonic gluon (5.5%), from the direct instanton (5.5%) and the one due to the evolution from 1 to 2 GeV (4.4%), which altogether increases the original errors by 8.9%. Therefore, we deduce the (arithmetic) average from the kaon channel:

$$\langle m_s \rangle (2 \text{ GeV}) = (117.1 \pm 25.4) \text{ MeV} .$$

(56)

One should notice here that, unlike the case of the pion, the result is less sensitive to the contribution of the higher states continuum due to the relatively higher value of $M_K$, though the parametrization of the spectral function still gives larger errors than the QCD series. It is interesting to deduce from Eqs. (54) and (56), the sum rule prediction for the scale invariant quark mass ratios:

$$r_3 \equiv \frac{2m_s}{m_u + m_d} \simeq 24.2 ,$$

(57)

where we expect that the ratio is more precise than the absolute values due to the cancellation of the systematics of the SR method. This ratio compares quite well with the ChPT ratio [7]:

$$r_3^{\text{CA}} = 24.4 \pm 1.5 ,$$

(58)
and confirms the self-consistency of the pseudoscalar SR approach. This is a non-trivial test of the SR method used in this channel and may confirm a posteriori the neglect of less controlled contributions like e.g. direct instantons.

Table 3: QSSR determinations of $\bar{m}_s(2)$ in MeV to order $\alpha_s^3$. Some older results have been updated by the inclusion of the higher order terms. The error contains the evolution from 1 to 2 GeV. In addition, the errors in the (pseudo)scalar channels contain the ones due to the small size instanton and tachyonic gluon mass. Their quadratic sum increases the original errors by 8.9%. The estimated error in the average comes from an arithmetic average of the different errors.

* Not included in the average.

6 Direct extraction of the chiral condensate $\langle \bar{u}u \rangle$

As mentioned in previous section, the chiral $\bar{u}u$ condensate can be extracted directly from the nucleon, $B^*-B$ splitting and vector form factor of $D \to K^*\ell\nu$, which are particularly sensitive to it and to the mixed condensate $\langle \bar{\psi}\sigma^{\mu\nu}(\lambda_2/2)G^{\mu\nu}_{\mu\nu}\psi \rangle \equiv M_0^2(\bar{\psi}\psi)$ [51]. We have already used the result from the $D \to K^*\ell\nu$ form factor in order to derive upper and lower bounds on $(m_u + m_d)$. Here, we shall use the informations from the nucleon and from the $B^*-B$ splitting in order to give a more accurate
estimate. In the nucleon sum rules \[72\]–\[78\], \[3\], which seem, at first sight, a very good place for determining \(\langle \bar{\psi} \psi \rangle\), we have two form factors for which spectral sum rules can be constructed, namely the form factor \(F_1\) which is proportional to the Dirac matrix \(\gamma_5 p\) and \(F_2\) which is proportional to the unit matrix. In \(F_1\) the four quark condensates play an important role, but these are not chiral symmetry breaking and are related to the condensate \(\langle \bar{\psi} \psi \rangle\) only by the factorization hypothesis \[21\] which is known to be violated by a factor 2-3 \[72, 79, 3\]. The form factor \(F_2\) is dominated by the condensate \(\langle \bar{\psi} \psi \rangle\) and the mixed condensate \(\langle \bar{\psi} \sigma G \psi \rangle\), such that the baryon mass is essentially determined by the ratio \(M_0^2\) of the two condensates:

\[
M_0^2 = \langle \bar{\psi} \sigma G \psi \rangle / \langle \bar{\psi} \psi \rangle
\]

(59)

Therefore from nucleon sum rules one gets a rather reliable determination of \(M_0^2\) \[78, 74\]:

\[
M_0^2 = (0.8 \pm 0.1) \text{ GeV}^2.
\]

(60)

A sum rule based on the ratio \(F_2/F_1\) would in principle be ideally suited for a determination of \(\langle \bar{\psi} \psi \rangle\) but this sum rule is completely unstable \[74\] due to fact that odd parity baryonic excitations contribute with different signs to the spectral functions of \(F_1\) and \(F_2\). In the correlators of heavy mesons (\(B, B^*\) and \(D, D^*\)) the chiral condensate gives a significant direct contribution in contrast to the light meson sum rules \[3\], since, here, it is multiplied by the heavy quark mass. However, the dominant contribution to the meson mass comes from the heavy quark mass and therefore a change of a factor two in the value of \(\langle \bar{\psi} \psi \rangle\) leads only to a negligible shift of the mass. However, from the \(B-B^*\) splitting one gets a precise determination of the mixed condensate \(\langle \bar{\psi} \sigma G \psi \rangle\) with the value \[80\]

\[
\langle \bar{\psi} \sigma G \psi \rangle = - (9 \pm 1) \times 10^{-3} \text{ GeV}^5,
\]

(61)

which combined with the value of \(M_0^2\) given in Eq. (60) gives our first result for the value of \(\langle \bar{\psi} \psi \rangle\) at the nucleon scale:

\[
\langle \bar{\psi} \psi \rangle(M_N) = -[(225 \pm 9 \pm 9) \text{ MeV}]^3,
\]

(62)

where the last error is our estimate of the systematics and higher order contributions. Using the GMOR relation, one can translate the previous result into a prediction on the sum of light quark masses. The resulting value is: \[51\]

\[
(m_u + m_d)(2 \text{ GeV}) = (10.6 \pm 1.8 \pm 0.5) \text{ MeV},
\]

(63)

where we have added the second error due to the quark mass evolution. Combining this value with the ChPT mass ratio, one obtains:

\[
\overline{m}_s(2 \text{ GeV}) \simeq 129.3 \pm 23.2 \text{ MeV}.
\]

(64)

Alternatively, one can use the central value of the range given in Eq. \[63\] in order to deduce the estimate:

\[
(m_u + m_d)(2 \text{ GeV}) = (9.6 \pm 4 \pm 0.4) \text{ MeV} \quad \Rightarrow \quad \overline{m}_s(2 \text{ GeV}) \simeq (117.1 \pm 49.0) \text{ MeV}.
\]

(65)

The results for \(m_s\) are shown in Table 3.

7 Final estimate of \((m_u + m_d)\) from QSSR and consequences on \(m_u\), \(m_d\) and \(m_s\)

One can also notice the impressive agreement of the previous results from pseudoscalar and from the other channels. As the two results in Eqs. \[54\], \[63\] and \[65\] come from completely independent analysis, we can take their geometric average and deduce the final value from QSSR:

\[
(m_u + m_d)(2 \text{ GeV}) = (10.1 \pm 1.3 \pm 1.3) \text{ MeV},
\]

(66)
where the last error is our estimate of the systematics. One can combine this result with the one for the light quark mass ratios from ChPT:

\[ r^C_A \equiv \frac{m_u}{m_d} = 0.553 \pm 0.043 , \quad r^C_A \equiv \frac{2m_s}{(m_d + m_u)} = 24.4 \pm 1.5 . \]  

Therefore, one can deduce the running masses at 2 GeV:

\[ \hat{m}_u(2) = (3.13 \pm 0.6) \text{ MeV}, \quad \hat{m}_d(2) = (6.5 \pm 1.2) \text{ MeV}, \quad \hat{m}_s(2) = (123.2 \pm 23.2) \text{ MeV}. \]  

Alternatively, we can use the relation between the invariant mass \( \hat{m}_q \) and running mass \( m_q(2) \) to order \( \alpha_3^s \) in order to get:

\[ \hat{m}_q = (1.14 \pm 0.05) \hat{m}_q(2) , \]

for \( \Lambda_3 = (375 \pm 50) \text{ MeV} \). Therefore, one can deduce the invariant masses:

\[ \hat{m}_u = (4.1 \pm 0.7) \text{ MeV}, \quad \hat{m}_d = (7.4 \pm 1.4) \text{ MeV}, \quad \hat{m}_s = (140.4 \pm 26.4) \text{ MeV}. \]

8 Light quark mass from the scalar sum rules

As can be seen from Eq. (68), one can also (in principle) use the isovector–scalar sum rule for extracting the quark mass-differences \((m_d - m_u)\) and \((m_s - m_u)\), and the isoscalar–scalar sum rules for extracting the sum \((m_d + m_u)\).

8.1 The scalar \( \bar{u}d \) channel

In the isovector channel, the analysis relies heavily on the less controlled nature of the \( a_0(980) \) \[5, 55, 56, 36\] which has been speculated to be a four-quark state \[85\]. However, it appears that its \( \bar{q}q \) nature is favoured by the present data \[86\], and further tests are needed for confirming its real \( \bar{q}q \) assignment.

In the \( I = 0 \) channel, the situation of the \( \pi\pi \) continuum is much more involved due to the possible gluonium nature of the low mass and wide \( \sigma \) meson \[87, 88, 86\], which couples strongly to \( \pi\pi \) and then can be missed in the quenched lattice calculation of scalar gluonia states.

Assuming that these previous states are quarkonia states, bounds on the quark mass-difference and sum of quark masses have been recently derived in \[36, 48, 49\], while an estimate of the sum of the quark masses has been obtained in \[89\]. However, in view of the hadronic uncertainties, we expect that the results from the pseudoscalar channels are much more reliable than the ones obtained from the scalar channel. Instead, we think that it is more useful to use these sum rules the other way around. Using the values of the quark masses from the pseudoscalar sum rules and their ratio from ChPT, one can extract their decay constants which are useful for testing the \( \bar{q}q \) nature of the scalar resonances \[3, 88\] (we shall come back to this point in the next section). The agreement of the values of the quark masses from the isovector scalar channel with the ones from the pseudoscalar channel can be interpreted as a strong indication for the \( \bar{q}q \) nature of the \( a_0(980) \). In the isoscalar channel, the value of the sum of light quark masses obtained recently in \[54\], though slightly lower, agrees within the errors with the one from the pseudoscalar channel. This result supports the maximal quarkonium-gluonium scheme for the broad low mass \( \sigma \) and narrow \( f_0(980) \) meson: the narrowness of the \( f_0 \) is due to a destructive interference, while the broad nature of the \( \sigma \) is due to a constructive interference allowing its strong coupling with \( \pi \pi \). These features are very important for the scalar meson phenomenology, and need to be tested further.

8.2 The scalar \( \bar{u}s \) channel

Here, the analysis is mostly affected by the parametrization of the \( K\pi \) phase shift data, which strongly affects the resulting value of the strange quark mass as can be seen from the different determinations given in the Table.
9 Light quark mass-difference from \((M_{K^+} - M_{K^0})_{QCD}\)

The mass difference \((m_d - m_u)\) can be related to the QCD part of the kaon mass difference \((M_{K^+} - M_{K^0})_{QCD}\) from the current algebra relation [4]:

\[
r_2^{CA} \equiv \frac{(m_d - m_u)}{(m_d + m_u)} = \frac{m^2_u}{M_K^2} \frac{(M_{K^0}^2 - M_{K^+}^2)_{QCD}}{M_{K^0}^2 - m^2_d} = (0.52 \pm 0.05) 10^{-3} (r_3^2 - 1),
\]

(71)

where \(2\hat{m} = m_u + m_d\); the QCD part of the \(K^+ - K^0\) mass-difference comes from the estimate of the electromagnetic term using the Dashen theorem including next-to-leading chiral corrections [59]. Using the sum rule prediction of \(r_3\) from the ratio of \((m_u + m_d)\) in Eq. (68) with the average value of \(m_s\) in Table 3 or the ChPT ratio given in the previous section, one can deduce to order \(\alpha_s^3\):

\[
(m_d - m_u) (2 \text{ GeV}) = (2.8 \pm 0.6) \text{ MeV}.
\]

(72)

Analogous result has been obtained from the heavy-light meson mass-differences [90]. We shall come back to the values of these masses at the end of this chapter.

10 The strange quark mass from \(e^+e^-\) and \(\tau\) decays

10.1 \(e^+e^- \rightarrow I = 0\) hadrons data and the \(\phi\)-meson channel

Its extraction from the vector channel has been done in [92, 93, 3] and more recently in [52], while its estimate from an improved Gell-Mann-Okubo mass formula, including the quadratic mass corrections, has been done in [12, 84, 3]. More recently, the vector channel has been reanalysed in [52] using a \(\tau\)-like inclusive decay sum rule in a modern version of the Das-Mathur-Okubo (DMO) sum rule [94] discussed in previous chapter. The analysis in this vector channel is interesting as we have complete data from \(e^+e^-\) in this channel, which is not the case of (pseudo) scalar channels where some theoretical inputs related to the realization of chiral symmetry have to be used in the parametrization of spectral function. One can combine the \(e^+e^- \rightarrow I = 0, 1\) hadrons and the rotated recent \(\Delta S = 0\) component of the \(\tau\)-decay data in order to extract \(m_s\). Unlike previous sum rules, one has the advantage to have a complete measurement of the spectral function in the region covered by the analysis. We shall work with:

\[
R_{\tau,\phi} \equiv \frac{3|V_{ud}|^2}{2\pi\alpha_s} S_{EW} \int_0^M ds \left(1 - \frac{s}{M_{\tau}^2}\right)^2 \left(1 + \frac{2s}{M_{\tau}^2}\right) \frac{s}{M_{\tau}^2} \sigma_{\tau \rightarrow e^- e^+ \phi, \phi^*},
\]

and the \(SU(3)\)-breaking combinations [52] :

\[
\Delta_{1\phi} \equiv R_{\tau,1} - R_{\tau,0}, \quad \Delta_{10} \equiv R_{\tau,1} - 3R_{\tau,0},
\]

(73)

which vanish in the \(SU(3)\) symmetry limit; \(\Delta_{10}\) involves the difference of the isoscalar \((R_{\tau,0})\) and isovector \((R_{\tau,1})\) sum rules à la DMO. The PT series converges quite well at the optimization scale of about 1.6 GeV [52]. E.g., normalized to \(m_s^2\), one has:

\[
\Delta_{1\phi} \approx -12 \frac{m_s^2}{M_{\tau}^2} \left\{1 + \frac{13}{3} a_s + 30.4 a_s^2 + (173.4 \pm 109.2) a_s^3\right\}
+ 36 \frac{m_s^4}{M_{\tau}^4} - 36 a_s^2 \left(\frac{m_s d^2 - m_s d d}{M_{\tau}^4}\right)
\]

(74)

The different combinations \(\Delta_{1\phi}\) and \(\Delta_{10}\) have the advantage to be free (to leading order) from flavour blind combinations like the tachyonic gluon mass and instanton contributions. We have checked using the result in [27] that, to non-leading in \(m_s^2\), the tachyonic gluon contribution is also negligible. It has been argued in [13] that \(\Delta_{10}\) can be affected by large SU(2) breakings. This claim has been tested using some other sum rules not affected by these terms [52] but has not been confirmed. The average from different combinations is given in Table 3. An upper bound deduced from the positivity of \(R_{\tau,0}\) is also given in Table 3.
10.2 Tau decays

Like in the case of $e^+e^-$, one can use tau decays for extracting the value of $m_s$. However, data from $\tau$ decays are more accurate than the one from $e^+e^-$. A suitable combination of sum rule sensitive to leading order to the $SU(3)$ breaking parameter is needed. It is easy to construct a such combination which is very similar to the one for $e^+e^-$. One can work with the DMO-like sum rule involving the difference between the $\Delta S = 0$ and $\Delta S = -1$ processes [66]–[71]:

$$\delta R_{\tau}^{kl} \equiv \frac{R_{\tau,V+A}^{kl}}{|V_{ud}|^2} - \frac{R_{\tau,S}^{kl}}{|V_{us}|^2} = 3S_{EW} \sum_{D \geq 2} \left\{ \delta_{ud}^{(D)} - \delta_{us}^{(D)} \right\},$$

(75)

where the moments are defined as:

$$R_{\tau}^{kl} \equiv \int_0^{M_{\tau}^2} ds \left(1 - \frac{s}{M_{\tau}^2}\right)^k \left(\frac{s}{M_{\tau}^2}\right)^l \frac{dR_{\tau}}{ds},$$

(76)

with $R_{\tau}^{00} \equiv R_{\tau}$ is the usual $\tau$-hadronic width. The QCD expression reads:

$$\delta R_{\tau}^{kl} \simeq 24S_{EW} \left\{ \frac{m_s^2}{M_{\tau}^2} \Delta_{kl}^{(2)} - 2\pi^2 \frac{m_s^2 - m_d^2}{M_{\tau}^4} \Delta_{kl}^{(4)} \right\},$$

(77)

where $\Delta_{kl}^{(D)}$ are perturbative coefficients known to order $\alpha_s^2$:

$$\Delta_{kl}^{(D)} \equiv \frac{1}{4} \left\{ 3\Delta_{kl}^{(D)} \big|_{L+T} + \Delta_{kl}^{(D)} \big|_L \right\},$$

(78)

where the indices $T$ and $L$ refer to the tranverse and longitudinal parts of the spectral functions. For $D = 2$, the $L$ piece converges quite badly while the $L + T$ converge quite well such that the combination has can still an acceptable convergence. For the lowest moments, one has:

$$\Delta_{00}^{(2)} = 0.973 + 0.481 + 0.372 + 0.337 + ...$$

$$\Delta_{10}^{(2)} = 1.039 + 0.558 + 0.482 + 0.477 + ...$$

$$\Delta_{20}^{(2)} = 1.115 + 0.643 + 0.608 + 0.647 + ...$$

(79)

The authors advocate that though the convergence is quite bad, the behaviour of the series is typical for an asymptotic series close to their point of minimum sensitivity. Therefore, the mathematical procedure for doing a reasonable estimate of the series is to truncate the expansion where the terms reach their minimum value. However, the estimate of the errors is still arbitrary. The authors assume that the error is given by the last term of the series. The result of the analysis is given in Table 3. The different numbers given in the table reflects the difference of methods used to get $m_s$ but the results are consistent each others within the errors. Like in the case of the $e^+e^-$ DMO-like sum rule, the combination used here is not affected to leading order by flavour blind contribution like the tachyonic gluon and instanton contribution. We have checked [27] that the contribution of the tachyonic gluon to order $m_s^2 \alpha_s \lambda^2/M_{\tau}^2$ gives a tiny correction and does not affect the estimate done without the inclusion of this term.

10.3 Summary for the estimate of light quark masses

Here, we summarize the results from the previous analysis:

- The sum $(m_u + m_d)$ of the running up and down quark masses from the pion sum rules is given in Eq. (54), while the one of the strange quark mass from the kaon channel is given in Eq. (56). Their values lead to the pseudoscalar sum rules prediction for the mass ratio in Eq. (57) which agrees nicely with the ChPT mass ratio.
• The sum \((\bar{m}_u + \bar{m}_d)\) of the running up and down quark masses averaged from the pseudoscalar sum rule and from a direct extraction of the chiral condensate \(\langle \bar{u}u \rangle\) obtained from a global fit of the nucleon, \(B^* - B\) mass-splitting and the vector part of the \(D^* \to K^*l\nu\) form factor is given in Eq.\(68\) and reads for \(\Lambda_3 = (375 \pm 50)\) MeV:

\[
(\bar{m}_u + \bar{m}_d)(2 \text{ GeV}) = (10.1 \pm 1.8) \text{ MeV},
\]

(80)

implying with the help of the ChPT mass ratio \(m_u/m_d\), the value:

\[
\bar{m}_u(2 \text{ GeV}) = (3.6 \pm 0.6) \text{ MeV}, \quad \bar{m}_d(2 \text{ GeV}) = (6.5 \pm 1.2) \text{ MeV},
\]

(81)

which leads to the invariant mass in Eq. \(70\):

\[
\hat{m}_u = (4.1 \pm 0.7) \text{ MeV}, \quad \hat{m}_d = (7.4 \pm 1.4) \text{ MeV},
\]

(82)

• We have combined the result in Eq. \(66\) with the sum rule prediction for \(m_s/(m_u + m_d)\) in order to deduce the quark mass-difference \((m_d - m_u)\) from the QCD part of the \(K^0 - K^+\) mass-difference. We obtain the result in Eq. \(72\):

\[
(\bar{m}_d - \bar{m}_u)(2 \text{ GeV}) = (2.8 \pm 0.6) \text{ MeV}.
\]

(83)

This result indeed agrees with the one taking the difference of the mass given previously. The fact that \((m_u + m_d) \neq (m_d - m_u)\) disfavours the possibility to have \(m_u = 0\).

• We give in Table 3 the different sum rules determinations of \(m_s\). The results from the pion SR and \(\langle \bar{\psi}\psi \rangle\) come from the determination of \((\bar{m}_u + \bar{m}_d)\) to which we have added the ChPT constraint on \(m_s/(m_u + m_d)\). One can see from this table that different determinations are in good agreement each others. Doing an average of these different results, we obtain:

\[
\bar{m}_s(2 \text{ GeV}) = (117.4 \pm 23.4) \text{ MeV} \quad \Rightarrow \quad \hat{m}_s = (133.8 \pm 27.3) \text{ MeV}.
\]

(84)

Aware on the possible correlations between these estimates, we have estimated the error as an arithmetic average which is about 10% as generally expected for the systematics of the SR approach.

It is informative to compare the above results with the average of different quenched and unquenched lattice values \[96\]:

\[
\bar{m}_{ud}(2 \text{ GeV}) \approx \frac{1}{2}(\bar{m}_u + \bar{m}_d)(2 \text{ GeV}) = (4.5 \pm 0.6 \pm 0.8) \text{ MeV},
\]

\[
\bar{m}_s(2 \text{ GeV}) = (110 \pm 15 \pm 20) \text{ MeV},
\]

(85)

where the last error is an estimate of the quenching error. We show in the Table 4 a compilation of the lattice unquenched results including comments on the lattice characterisitics (action, lattice spacing \(a\), \(\beta\)). Also shown is the ratio over \(m_s/m_{ud}\) and quenched (quen) over unquenched (unq) results.

11 Decay constants of light (pseudo)scalar mesons

11.1 Pseudoscalar mesons

Due to the Goldstone nature of the pion and kaon, we have seen that their radial excitations play an essential rôle in the sum rule. This unusual property allows a determination of the radial excitation parameters. In the strange quark channels, an update of the results in \[52, 56, 55, 3, 57\] gives:

\[
r_K \equiv M_K^4 f_K^2 / M_K f_K^2 \simeq 9.5 \pm 2.5 \simeq r_\pi,
\]

(86)
Table 4: Simulation details and physical results of unquenched lattice calculations of light quark
masses from [96], where original references are quoted.

$^{\dagger}$ From vector WI; $^{\ddagger}$ from axial WI. The errors on the ratios $m_s/m_{ud}$ and $\overline{m}_s^{\text{quen}}/\overline{m}_s^{\text{unq}}$ are estimates based on the original data.

where $r_π$ has been defined previously. The optimal value has been obtained at the LSR scale $\tau \approx GeV^{-2}$ and $t_c \simeq 4.5 - 6.5$ GeV$^2$ as shown in Fig. 4. This result implies for $π'(1.3)$ and $K'(1.46)$:

$$f_{π'} \simeq (3.3 \pm 0.6)$ MeV ,

$$f_{K'} \simeq (39.8 \pm 7.0)$ MeV .

(87)

It is easy to notice that the result satisfies the relation:

$$\frac{f_{K'}}{f_{π'}} \approx \frac{M_K^2}{m_π^2} \approx \frac{m_s}{m_d},$$

(88)

as expected from chiral symmetry arguments.

11.2 Scalar mesons

We expect that the scalar channel is more useful for giving the decay constants of the mesons which are not well known rather than predicting the value of the quark masses. Such a programme has been initiated in [58, 59, 60]. Since then, the estimate of the decay constants has not mainly changed. The analysis is shown in Figs. 5 and 6. Recent estimate gives [63]:

$$f_{a_0} = (1.6 \pm 0.15 \pm 0.35 \pm 0.25)$ MeV ,

$$f_{K^0*} \simeq (46.3 \pm 2.5 \pm 5 \pm 5)$ MeV ,

(89)

where the errors are due respectively to the choice of $t_c$ from 4.5 to 8 GeV$^2$, the value of the quark mass-difference obtained previously and the one of $Λ_3$. The decay constants are normalized as:

$$\langle 0|\partial_a V^µ(x)|a_0\rangle = \sqrt{2}f_a M_a^2,$$

(90)
corresponding to $f_{\pi} = 92.4$ MeV. We have used the experimental masses 0.98 GeV and 1.43 GeV in our analysis\footnote{The masses of the $a_0$ and $K^*_0$ are also nicely reproduced by the ratio of moments\cite{9},\cite{19}.}. It is also interesting to notice that the ratio of the decay constants are:

$$\frac{f_{K^*_0}}{f_{a_0}} \approx 29 \approx \frac{m_s - m_u}{m_d - m_u} \approx 40 ,$$

(91)

as naively expected. We are aware that the values of these decay constants might have been overestimated due to the eventual proliferations of nearby radial excitations. Therefore, it will be interesting to have a direct measurement of these decay constants for testing these predictions. The values of these decay constants will be given like other meson decay constants in the table of the next chapter.

12 Flavour breakings of the quark condensates
6.5
8.5
0.2 0.4 0.6 0.8 1.0
τ [GeV−2]

Figure 6: LSR analysis of the decay constant \( f_{K^*_0} \) of the \( K^*_0(1.43) \) meson normalized as \( f_\pi = 92.4 \) MeV. We use \( \overline{m}_s(2) = 117.4 \) MeV.

12.1 \( SU(3) \) corrections to kaon PCAC

Let’s remind that the (pseudo)scalar two-point function obeys the twice subtracted dispersion relation:

\[
\Psi_{(5)}(q^2) = \Psi_{(5)}(0) + q^2 \Psi'_{(5)}(0) + q^4 \int_0^\infty \frac{dt}{t^2(t - q^2 - i\epsilon)} \text{Im}\Psi_{(5)}(t). \tag{92}
\]

The deviation from kaon PCAC has been firstly studied in [97] using the once subtracted pseudoscalar sum rule of the quantity:

\[
\frac{\Psi_{(5)}(q^2) - \Psi_{(5)}(0)}{q^2} \tag{93}
\]

sensitive to the value of the value of the correlator at \( q^2 = 0 \) \(^{10}\). The Ward identity obeyed by the (pseudo)scalar two-point function leads to the low-energy theorem:

\[
\Psi_{(5)}(0) = -\left( m_i \pm m_j \right) \langle \bar{\psi}_i \psi_i \pm \bar{\psi}_j \psi_j \rangle, \tag{94}
\]

in terms of the normal ordered condensates. However, as emphasized in different papers \[34, 35, 41, 38\], \( \Psi_{(5)}(0) \) contains a perturbative piece which cancels the mass singularities appearing in the OPE evaluation of \( \Psi_{(5)}(q^2) \). This leads to the fact that the quark condensate entering in Eq. \[94\] are defined as a non-normal ordered condensate, which has a slight dependence on the scale and renormalization scheme. This mass correction effect is only quantitatively relevant for the \( \bar{u}s \) channel but not for the \( \bar{u}d \) one. To order \( \alpha^3 \) for the perturbative term and to leading order for the condensates, the (pseudo)scalar sum rule for the \( \bar{u}s \) channel reads, by neglecting the up quark mass:

\[
\int_0^{t_c} \frac{dt}{t} \exp(-t\tau) \frac{1}{\pi} \text{Im}\Psi_{(5)}(t) \simeq \Psi_{(5)}(0) + \frac{3}{8\pi^2} \tau^{-1} \left( 1 - \rho_0 \right) \left[ 1 + 6.82 \left( \frac{\overline{m}_u}{\pi} \right) + 58.55 \left( \frac{\overline{m}_u}{\pi} \right)^2 + 537.6 \left( \frac{\overline{m}_u}{\pi} \right)^3 \right] \\
+ 3.15 \overline{m}_u^2 \tau \left[ 1 + 3.32 \left( \frac{\overline{m}_u}{\pi} \right) \right] \\
- \frac{\pi}{3} \langle \alpha_s G^2 \rangle - \frac{8\pi^2}{3} \left( \left( \overline{m}_s - \frac{\overline{m}_u}{2} \right) \langle \bar{u}u \rangle \pm (u \leftrightarrow s) \right) \tau^2
\]

\(^{10}\)This sum rule has also been used in \[99, 100\] for estimating the \( U(1)_A \) topological susceptibility and its slope, and which has been checked on the lattice \[101\].
\[
\frac{1}{2} (2 \mp 9) \left( \frac{128}{81} \right) \pi^3 \rho \alpha_s \langle \bar{u}u \rangle^2 \tau^3 \right) , \quad (95)
\]

where we have neglected the \( SU(3) \) breaking for the four-quark condensates. This assumption does not however affect the analysis due to the small contribution of this operator at the optimization scale. The analysis is shown in Fig. 7. Examining the different curves, on can notice that they deviate notably from the kaon PCAC prediction:

\[
\Psi_5(0) \simeq 2 M_K^2 f_K^2 , \quad (96)
\]

therefore confirming the early findings in \[97\]. The LSR indicates a slight stability point at \( \tau \approx (0.50 \sim 0.75) \) GeV\(^{-2} \), where:

\[
\Psi_5(0) \approx (0.5 \pm 0.2) 2 M_K^2 f_K^2 . \quad (97)
\]

However at this scale, PT series has a bad convergence:

\[
\text{Pert} = \text{Parton} \times \left\{ 1 + 2.17 \alpha_s + 5.93 \alpha_s^2 + 17.34 \alpha_s^3 \right\} \simeq \text{Parton} \times \left\{ 1 + 0.86 + 0.92 + 1.06 \right\} , \quad (98)
\]

which might not be worriesome if one considers that asymptotic series close to its point of minimum sensitivity can be truncated when it's reaches the extremum value and add the last term as truncation error \[71\]. This convergence might \textit{a priori} be improved if one works with the combination of sum rules which is less sensitive to the high-energy behaviour of the spectral function (and then to the perturbative contribution) than the former \[57, 63, 55, 3, 52\]. The modified sum rule reads \[57, 58, 59, 52\]:

\[
\int_0^\infty \frac{dt}{t} \exp (-t \tau) (1 - t \tau) \frac{1}{\pi} \text{Im} \Psi_5(t) \simeq \Psi_5(0) + (\bar{m}_u \pm \bar{m}_s)^2 \frac{3}{8\pi^2} \tau^{-1} \times \left\{ 2 \left( \frac{\alpha_s}{\pi} \right) \left[ 1 + 18.3 \left( \frac{\alpha_s}{\pi} \right) + 242.2 \left( \frac{\alpha_s}{\pi} \right)^2 \right] + 5.15 \bar{m}_s^2 \tau \left[ 1 + 5.0 \left( \frac{\alpha_s}{\pi} \right) \right] \right\} + 2 \frac{\pi}{3} \langle \alpha_s G^2 \rangle - \frac{8\pi^2}{3} \bar{m}_s \left[ \langle \bar{u}u \rangle \mp \frac{1}{2} \langle \bar{s}s \rangle \right] \tau^2 + \frac{3}{2} (2 \mp 9) \left( \frac{128}{81} \right) \pi^3 \rho \alpha_s \langle \bar{u}u \rangle^2 \tau^3 \right) . \quad (99)
\]

\[11\] A similar argument has been used for the extraction of the strange quark mass from \( \tau \)-decay data discussed in the previous section, where the QCD series also has a quite bad behaviour.

\[12\] Notice that we have not yet introduced the QCD continuum into the LHS of the sum rule.

Figure 7: LSR analysis of the subtraction constant \( \Psi_5(0) \). We use \( \bar{m}_s(2) = 117.4 \) MeV, \( r_K = 9.5 \) and \( r_c = 6 \) GeV\(^2 \). The curves correspond to different truncations of the PT series: to \( \mathcal{O}(\alpha_s) \): dotted-dashed; to \( \mathcal{O}(\alpha_s^2) \): dashed; to \( \mathcal{O}(\alpha_s^3) \): continuous.
The analysis also leads to a similar result. The LSR has been also studied recently in \[102\], by including threshold effects and higher mass resonances, which enlarge the region of stability in the LSR variable. Within the previous hadronic parametrization, one obtains:

\[
\Psi_5(0) \simeq (0.56 \pm 0.04 \pm 0.15)2M_K^2f_K^2 , \tag{100}
\]

where we have added the error due to our estimate of the truncation of the QCD PT series as deduced from Fig. 7. An alternative estimate is the uses of FESR \[62\]. Parametrizing the subtraction constant as:

\[
\Psi_5(0) = 2M_K^2f_K^2(1 - \delta_K) , \tag{101}
\]

one has the sum rule \[62\]:

\[
\delta_K \simeq \frac{3}{16\pi^2} \frac{m_s^2t_c}{f_K^2M_K^2} \left\{ 1 + \frac{23}{3} \alpha_s + O(\alpha_s^2) \right\} - r_K \left( \frac{M_K}{M_K'} \right)^2 , \tag{102}
\]

which gives, after using the *correlated values* of the input parameters \[55, 3, 52\]:

\[
\delta_K = 0.34^{+0.23}_{-0.17} , \tag{103}
\]

leading to:

\[
\Psi_5(0) \simeq (0.66 \pm 0.20)2M_K^2f_K^2 , \tag{104}
\]

confirming the large violation of kaon PCAC obtained from LSR.

### 12.2 Subtraction constant from the scalar sum rule

One can do a similar analysis for the scalar channel. The analysis from LSR is shown in Fig. 8. One can also see that there is a slight stability for \( \tau \approx (0.50 \sim 0.75) \text{ GeV}^{-2} \), which gives:

\[
\Psi(0) \approx -10^{-3} \text{ GeV}^4 , \tag{105}
\]

in agreement with previous results \[3, 53, 60, 67\]. In \[102\], using LSR, a similar result but from a larger range of LSR stability, has been obtained within an Omnés representation for relating the scalar form factor to the \( K\pi \) phase shift data:

\[
\Psi(0) \simeq -(1.06 \pm 0.21 \pm 0.20)10^{-3} \text{ GeV}^4 , \tag{106}
\]
where the last term is our estimate of the error due to the truncation of the QCD series. The sum rule scale one can use an alternative approach by working with FESR:

\[ \Psi(0)^{u s} = 2M_{K}^{2}f_{K}^{2} - \frac{3}{16\pi^{2}}m_{c}^{2}t_{c}\left\{ 1 + \frac{23}{3}a_{s} + \mathcal{O}(a_{s}^{2})\right\} , \]  

(107)

which gives \[ [52] \]

\[ \Psi(0)^{u s} = -\left(7.8^{+5.5}_{-2.7}\right) \times 10^{-4} \text{ GeV}^{4}. \]  

(108)

12.3 \( \langle \bar{s}s \rangle / \langle \bar{u}u \rangle \) from the (pseudo)scalar sum rules

We take the arithmetic average of the previous determinations for our final estimate:

\[ \Psi_{5}(0) \simeq (0.57 \pm 0.19)2M_{K}^{2}f_{K}^{2}, \quad \Psi(0) \simeq -(0.92 \pm 0.35)10^{-3} \text{ GeV}^{4}, \]  

(109)

Taking the ratio of the scalar over the pseudoscalar subtraction constants expressed in terms of the normal-ordered condensates, one can deduce:

\[ \langle \bar{s}s \rangle / \langle \bar{u}u \rangle = 0.57 \pm 0.12. \]  

(110)

12.4 \( \langle \bar{s}s \rangle / \langle \bar{u}u \rangle \) from the \( B_{s} \) meson

One can also extract the flavour breakings of the condensates from a sum rule analysis of the \( B_{s} \) and \( B_{s}^{*} \) masses, which are sensitive to the chiral condensate as it enters like \( m_{b}\langle \bar{s}s \rangle \) in the OPE of the heavy light meson (see next section). The masses of the mesons are found to decrease linearly with the value of the chiral condensate. Using the observed value of the \( B_{s} \) meson mass \( M_{B_{s}} = 5.375 \text{ GeV} \), one can deduce from Fig 3 of [80]:

\[ \langle \bar{s}s \rangle / \langle \bar{u}u \rangle \simeq 0.75 \pm 0.08, \]  

(111)

where the error is the expected typical sum rule estimate. The effect of the strange quark mass is less important than this one here, such that the result given in [81] remains valid though obtained with slightly different values of \( m_{s} \) and \( \Lambda_{S} \). This estimate is expected to be more reliable than the one from the (pseudo)scalar light mesons, which are affected by the bad convergence of the PT QCD series. Using this value of ratio of the condensates in the curve of the \( B_{s}^{*} \) mass, one can also predict:

\[ B_{s}^{*} = 5.64 \text{ GeV}, \]  

(112)

which can be tested in \( B \) factories.

12.5 Final sum rule estimate of \( \langle \bar{s}s \rangle / \langle \bar{u}u \rangle \)

Using the previous results, one can deduce that the sum rules from the light (pseudo)scalar and from the \( B_{s} \) meson predict for the normal ordered condensate ratio:

\[ \langle \bar{s}s \rangle / \langle \bar{u}u \rangle \simeq 0.66 \pm 0.10, \]  

(113)

confirming earlier findings [53, 8, 92, 52] on the large flavour breaking of the chiral condensate. This number comes from the arithmetic average of the two values in Eqs. (110) and (111). If one instead works with the non-normal ordered condensate, one should add to the expression in Eq. (94) a small perturbative piece first obtained by Becchi et al. [35] (see also [3, 93, 40]):

\[ \langle \bar{s}s \rangle_{\overline{MS}} = \langle \bar{s}s \rangle - \frac{3}{2\pi^{2}}\frac{2}{7}\left(\frac{1}{a_{s}} - \frac{53}{24}\right)m_{s}^{3}, \]  

(114)
This leads to the ratio of the non-normal ordered condensates:

\[
\langle \bar{s}s \rangle / \langle \bar{u}u \rangle_{\text{MS}}^{0} = 0.75 \pm 0.12. \tag{115}
\]

The previous estimates are in good agreement with the ones from chiral perturbation theory [7] (see also [103]). They are also in fair agreement with the one from the baryonic sum rules [72–78], though we expect that the result from the latter is less accurate due to the complexity of the analysis in this channel (choice of the interpolating operators, eventual large effects of the continuum due to the nearby Roper resonances,...).

12.6 SU(2) breaking of the quark condensate

The SU(2) breaking of the quark condensate has been studied for the first time in [63] and in [62, 3]. Using similar approaches, the estimate is [3, 55]:

\[
\langle \bar{d}d \rangle / \langle \bar{u}u \rangle \approx 1 - 9 \times 10^{-3}. \tag{116}
\]

The previous estimate is in good agreement with the one from FESR [62].

13 Heavy quark masses

In the previous part of this book, we have already discussed the different definitions of the heavy quark masses and given their values. Contrary to the light quark masses, the definition of pole quark masses \( p^2 = M^2_H \) can (in principle) be introduced perturbatively for heavy quarks [11, 12, 13] similarly to the one of the electron as here the quark mass is much heavier than the QCD scale \( \Lambda \) such the perturbative approach makes sense. However, a complication arises due to the resummation of the QCD series [23] such that the pole mass definition has an intrinsic ambiguity, which can be an obstacle for its improved accurate determination though the effect is relatively small. Alternative definitions free from such ambiguities have been proposed in the literature [24, 25]. In this section, we shall discuss the determinations of the perturbative running quark masses which do not have such problems.

13.1 The quarkonia channel

Charmonium and bottomonium are the standard channels for extracting the charm and bottom quark masses. Most of the sum rule analysis are based on the \( Q^2 = 0 \) moments (MOM) originally introduced by SVZ for the study of the charmonium systems:

\[
\mathcal{M}_n = \frac{1}{n!} \left( -\frac{d}{dQ^2} \right)^n \Pi \Big|_{Q^2 = 0} = \int_{4m^2}^{\infty} \frac{dt}{t^{n+1}} \frac{1}{\pi} \text{Im} \Pi(t), \tag{117}
\]

but convenient for the bottomonium systems due to a much better convergence of the OPE. In [8], the \( Q^2 \neq 0 \) moments have been introduced for improving the convergence of the QCD series:

\[
\mathcal{M}_n(Q^2_0) = \frac{1}{n!} \left( -\frac{d}{dQ^2} \right)^n \Pi \big|_{Q^2 = Q^2_0} = \int_{4m^2}^{\infty} \frac{dt}{(t + Q^2_0)^{n+1}} \frac{1}{\pi} \text{Im} \Pi(t), \tag{118}
\]

The spectral function can be related to the \( e^+e^- \to Q\bar{Q} \) total cross-section via the optical theorem:

\[
\text{Im} \Pi(t + i\varepsilon) = \frac{1}{12\pi Q^2_Q} \frac{\sigma(e^+e^- \to Q\bar{Q})}{\sigma(e^+e^- \to \mu^+\mu^-)}. \tag{119}
\]

\( Q_Q \) is the heavy quark charge in units of e. The contribution to the spectral function is as usual saturated by the lowest few resonances plus the QCD continuum above the threshold \( t_c \):

\[
\text{Im} \Pi_Q(t) = \frac{3}{4\alpha_s} \frac{1}{Q^2_Q} \sum_i \Gamma_i M_i \delta(t - M_i^2) + \theta(t - t_c) \text{Im} \Pi_Q^{\text{QCD}}(t), \tag{120}
\]

25
where $\Gamma_i$ is the electronic width of the resonances with the value given in PDG \[20\]. Retaining the observed resonances, the value of $\sqrt{t_c}$ fixed from stability analysis is about $(11 \sim 12)$ GeV for the $\Upsilon$– and about 5 GeV for the $J_\Psi$–families. However, the result will be practically independent from this choice of $t_c$ due to the almost complete dominance of the lowest ground state to the spectral function at the stability point. An alternative approach used in \[13, 104\] is the LSR:

$$L(\tau) = \int_{4m^2}^{\infty} dt \exp^{-t\tau} \frac{1}{\pi} \text{Im}\Pi(t).$$

(121)

This sum rule is particularly convenient for the analysis of the charmonium systems as the corresponding OPE converges faster than the moment sum rules. It has been noticed in \[104\] that the ratios of sum rules (and their finite energy sum rule (FESR) variants) are more appropriate for the estimate of the quark mass as these ratios equate directly the mass squared of ground state to that of the quark:

$$R_n \equiv \frac{M(n)}{M(n+1)} \quad \text{and} \quad R_\tau \equiv -\frac{d}{d\tau} \log L,$$

(122)

They also eliminate, to leading order, some artefact dependence due to the sum rules (exponential weight factor or number of derivatives) and some other systematic errors appearing in each individual moments. For the perturbative part, we shall use (without expanding in $1/M$) the Schwinger extrapolation formula to two-loops:

$$\text{Im}\Pi_{Q}^{\text{pert}}(t) \simeq \frac{3}{12\pi} v_Q \left( \frac{3 - v_Q^2}{2} \right) \left\{ 1 + \frac{4}{3} \alpha_s f(v_Q) \right\},$$

(123)

where:

$$v_Q = \sqrt{1 - 4M_Q^2/t}, \quad f(v_Q) = \frac{\pi}{2v_Q} - \frac{3 + v_Q}{4} \left( \frac{\pi}{2} - \frac{3}{4\pi} \right)$$

(124)

are respectively the quark velocity and the Schwinger function \[105\]. We express this spectral function in terms of the running mass by using the two-loops relation given in previous chapter and including the $\alpha_s \log(t/M_Q^2)$-term appearing for off-shell quark. We shall add to this perturbative expression the lowest dimension $\langle \alpha_s G^2 \rangle$ non-perturbative effect (it is known as explained in the previous part of the book that, for a heavy-heavy quark correlator, the heavy quark condensate contribution is already absorbed into the gluon one) which among the available higher dimension condensate-terms can only give a non-negligible contribution. The gluon condensate contribution to the moments $M^{(n)}$ and so to $R_n$ can be copied from the original work of SVZ \[21\] and reads:

$$M_G^{(n)} = -M_{\text{pert}}^{(n)} \frac{(n+3)!}{(n-1)!(2n+5)} \frac{4\pi}{9} \frac{\langle \alpha_s G^2 \rangle}{(4M_Q^2)^2},$$

(125)

where $M_{\text{pert}}^{(n)}$ is the lowest perturbative expression of the moments. The one to the Laplace ratio $R_\tau$ can be also copied from the original work of Bertlmann \[106\], which has been expanded recently in $1/M_Q$ by \[107\]. It reads:

$$R_\tau^G \simeq (4M_Q^2) \frac{2\pi}{3} \frac{\langle \alpha_s G^2 \rangle}{2\omega} \left( 1 + \frac{4}{3\omega} - \frac{5}{12\omega^2} \right),$$

(126)

where $\omega \equiv 4M_Q^2 \tau$. The results of the analysis from the ratios of moments and Laplace sum rules give the values of the running masses to order $\alpha_s$ \[13\]:

$$\overline{m}_c(\overline{m}_c) = (1.23 \pm 0.03 \pm 0.03) \text{ GeV ,} \quad \overline{m}_b(\overline{m}_b) = (4.23 \pm 0.04 \pm 0.02) \text{ GeV .}$$

\[13\]The inclusion of the $\alpha_s^2$ correction is under study.
where the errors are respectively due to $\alpha_s(M_Z) = 0.118 \pm 0.006$ and $\langle \alpha_s G^2 \rangle = (0.06 \pm 0.03) \text{ GeV}^4$ used in the original work. These running masses can be converted into the pole masses at this order. Non-relativistic versions of these sum rules (NRSR) introduced by [108] have also been used in [13, 104] for determining the $b$ quark mass. These NRSR approaches have been improved by the inclusion of higher order QCD corrections and resummation of the Coulomb corrections from ladder gluonic exchanges. Some recent different determinations are given in Tables 5 and 6.

Table 5: QSSR direct determinations of $\overline{m_c}(m_c)$ in $\overline{MS}$-scheme and of the pole mass $M_c$ from $J/\Psi$-family, $e^+e^-$ data and $D$-meson and comparisons with lattice results. Determinations from some other sources are quoted in PDG [20]. The results are given in units of GeV. The estimated error in the SR average comes from an arithmetic average of the different errors. The average for the pole masses is given at NLO. The one of the running masses is almost unchanged from NLO to NNLO determinations. $\iff$ means that perturbative relation between the different mass definitions have been used to get the quoted values.

13.2 The heavy-light $D$ and $B$ meson channels

Heavy quark masses can also be extracted from the heavy-light quark channels because the corresponding correlators are sensitive to leading order to the values of these masses \[3, 80, 104, 109, 110\]. Again, we shall be concerned here with the LSR $L(\tau)$ and the ratio $R(\tau)$. The latter sum rule, or its slight modification, is useful, as it is equal to the resonance mass squared, in the simple duality ansatz parametrization of the spectral function:

$$\frac{1}{\pi} \text{Im} \psi_3(t) \simeq f_D^2 M_D^4 \delta(t - M_D^2) + \text{“QCD continuum”} \theta(t - t_c), \quad (128)$$

where $f_D$ is the decay constant analogue to $f_\pi = 130.56$ MeV. The QCD side of the sum rule reads:

$$L_{QCD}(\tau) = M_Q^2 \left\{ \int_{M_Q^2}^{\infty} dt \, e^{-\tau t} \frac{1}{8\pi^2} \left[ 3t(1 - x)^2 \left( 1 + \frac{4}{3} \frac{\alpha_s}{\pi} f(x) \right) + \left( \frac{\alpha_s}{\pi} \right)^2 R2s \right] 
+ \left[ C_4(O_4) + C_6(O_6) \tau \right] e^{-M_Q^2 \tau} \right\}, \quad (129)$$

where $R2s$ is the new $\alpha_s^2$-term obtained semi-analytically in \[19\] and is available as a Mathematica package program Rvs.m. Neglecting $m_d$, the other terms are:

- $x = M_Q^2 / t$,
- $f(x) = 9 \frac{1}{4} + 2 \text{Li}_2(x) + \log x \log(1 - x) - \frac{3}{2} \log(1/x - 1)$
  $\quad - \log(1 - x) + x \log(1/x - 1) - (x/(1 - x)) \log x,$
- $C_4(O_4) = -M_Q^2 \{dd\} + (\alpha_s G^2) / 12\pi$
- $C_6(O_6) = \frac{M_Q^4}{2} \left( 1 - \frac{1}{2} M_Q^2 \tau \right) g(\bar{d}C_{\mu \nu} \frac{A}{2} \bar{C}^\mu_{\nu} d)$
  $\quad - \left( \frac{8\pi}{27} \right) \left( 2 - \frac{M_Q^2 \tau^2}{2} - \frac{M_Q^4 \tau^2}{6} \right) \rho \alpha_s \langle \bar{\psi} \psi \rangle^2. \quad (130)$

The previous sum rules can be expressed in terms of the running mass $\bar{m}_Q(\nu)$ \[19\]. From this expression, one can easily deduce the expression of the ratio $R(\tau)$, where the unknown decay constant disappears, and from which we obtain the running quark masses:

$$\bar{m}_c(m_c) = (1.10 \pm 0.04) \text{ GeV}. \quad (131)$$

The analysis is shown in Fig. \[8\], where a simultaneous fit of the decay constant from $L$ and of $\bar{m}_c(\overline{m}_c)$ from $R$ is shown \[19\].

Our optimal results correspond to the case where both stability in $\tau$ and in $t_c$ are reached. However, for a more conservative estimate of the errors we allow deviations from the stability points, and we take:

$$t_c \simeq (6 \sim 9.5) \text{ GeV}^2, \quad \tau \simeq (1.2 \pm 0.2) \text{ GeV}^{-2}, \quad (132)$$

and where the lowest value of $t_c$ corresponds to the beginning of the $\tau$-stability region. Values outside the above ranges are not consistent with the stability criteria. One can inspect that the dominant

\[14\]
Notice that we have adopted here the lattice normalization for avoiding confusion. We shall discuss its determination in the next chapter.

\[15\]
It is clear that, for the non-perturbative terms which are known to leading order of perturbation theory, one can use either the running or the pole mass. However, we shall see that this distinction does not affect notably the present result.

\[16\]
We shall discuss the decay constant in the next section.
non-perturbative contribution is due to the dimension-four $M_c \langle \bar{d}d \rangle$ light quark condensate, and test that the OPE is not broken by high-dimension condensates at the optimization scale. However, the perturbative radiative corrections converge slowly, as the value of $f_D$ increases by 12% after the inclusion of the $\alpha_s$ correction and the sum of the lowest order plus $\alpha_s$-correction increases by 21% after the inclusion of the $\alpha_s^2$ term, indicating that the total amount of corrections of 21% is still a reasonable correction despite the slow convergence of the perturbative series, which might be improved using a resummed series. However, as the radiative corrections are both positive, we expect that this slow convergence will not affect in a sensible way the final estimate. A similar analysis is done for the pole mass. The discussions presented previously apply also here, including the one of the radiative corrections. We quote the final result:

$$M_c = (1.46 \pm 0.04) \text{ GeV}$$  \hspace{1cm} (133)$$

where the error is slightly smaller here due to the absence of the subtraction scale uncertainties. One can cross-check that the two values of $\bar{m}_c(m_c)$ and $M_c$ give the ratio:

$$M_c/\bar{m}_c(m_c) \simeq 1.33$$  \hspace{1cm} (134)$$

which satisfies quite well the three-loop perturbative relation $M_c/\bar{m}_c(m_c) = 1.33$. This could be a non-trivial result if one has in mind that the quark pole mass definition can be affected by non-perturbative corrections not present in the standard SVZ-OPE. In particular, it may signal that $1/q^2$ correction of the type discussed in [24, 27, 28], if present, will only affect weakly the standard SVZ-phenomenology as observed explicitly in the light quark, gluonia and hybrid channels [27]. Using analogous analysis for the $B$ meson, we obtain at the optimization scale $\tau = 0.375 \text{ GeV}^{-2}$ and $t_c = 38 \text{ GeV}^2$:

$$\bar{m}_b(m_b) = (4.05 \pm 0.06) \text{ GeV}$$  \hspace{1cm} (135)$$

while using the pole mass as a free parameter, we get:

$$M_b = (4.69 \pm 0.06) \text{ GeV}$$  \hspace{1cm} (136)$$

Figure 9: Laplace sum rule analysis of $f_D$ and $\bar{m}_c(m_c)$. 

non-perturbative contribution is due to the dimension-four $M_c \langle \bar{d}d \rangle$ light quark condensate, and test that the OPE is not broken by high-dimension condensates at the optimization scale. However, the perturbative radiative corrections converge slowly, as the value of $f_D$ increases by 12% after the inclusion of the $\alpha_s$ correction and the sum of the lowest order plus $\alpha_s$-correction increases by 21% after the inclusion of the $\alpha_s^2$ term, indicating that the total amount of corrections of 21% is still a reasonable correction despite the slow convergence of the perturbative series, which might be improved using a resummed series. while using the pole mass as a free parameter, we get:

$$M_b = (4.69 \pm 0.06) \text{ GeV}$$  \hspace{1cm} (136)$$

29
One can again cross-check that the two values of $\bar{m}_b(m_b)$ and $M_b$ lead to
\[ M_b/\bar{m}_b(m_b) = 1.16 \, , \]
to be compared with 1.15 from the three-loop perturbative relation between $M_b$ and $\bar{m}_b$, and might indirectly indicate the smallness of the $1/q^2$ correction if any. One can immediately notice the agreement of the results from quarkonia and heavy-light quark channels. Comparisons with other determinations are given in Tables 5 and 6.

### Summary for the heavy quark masses and consequences

From Tables 5 and 6, we conclude that the running $c$ and $b$ quark masses to order $\alpha_s^2$ from the different sum rules analysis are likely to be:

\[ \bar{m}_c(\bar{m}_c) = (1.23 \pm 0.05) \, \text{GeV} \, , \quad \bar{m}_b(\bar{m}_b) = (4.24 \pm 0.06) \, \text{GeV} \, , \]

(138)
where the estimated errors come from the arithmetical average of different errors. We have not tried to minimize the errors from weighted average as the correlations between these different determinations are not clear at all. However, as one can see in the tables, the quoted errors are typical for each individual determinations. These results are consistent with other determinations given in \[20\] and in particular with LEP average from three-jet events and lattice values reported in the tables. Using the previous relation between the short distance perturbative pole and running masses, one obtains, in particular with LEP average from three-jet events and lattice values reported in the tables. Using individual determinations. These results are consistent with other determinations given in \[20\] and are not clear at all. However, as one can see in the tables, the quoted errors are typical for each minimum the errors from weighted average as the correlations between these different determinations where the estimated errors come from the arithmetical average of different errors. We have not tried to minimize the errors from weighted average as the correlations between these different determinations are not clear at all. However, as one can see in the tables, the quoted errors are typical for each individual determinations. These results are consistent with other determinations given in \[20\] and in particular with LEP average from three-jet events and lattice values reported in the tables. Using individual determinations. These results are consistent with other determinations given in \[20\] and are not clear at all. However, as one can see in the tables, the quoted errors are typical for each

\[
m_c = (1.21 \pm 0.07) \text{ GeV}, \quad n_b = (6.9 \pm 0.2) \text{ GeV}.
\]

(141)

We have used \(\Lambda_4 = 325 \pm 40 \text{ MeV} \) and \(\Lambda_5 = 225 \pm 30 \text{ MeV}\). Taking into account threshold effects and using matching conditions, we can also evaluate the running masses at the scale 2 GeV and obtains:

\[
\overline{m}_c(2) = (1.23 \pm 0.05) \text{ GeV}, \quad \overline{m}_b(2) = (5.78 \pm 0.26) \text{ GeV}.
\]

(142)

Combining the values of \(m_b\) and \(m_s\) obtained in the previous section, one can deduce the scale independent mass ratio:

\[
\frac{m_b}{m_s} = 48.8 \pm 9.8,
\]

(143)

which is useful for model buildings. One can also run the value of \(m_b\) at the Z-mass, and obtains the value of \(\overline{m}_b(M_Z)\) quoted in the table:

\[
\overline{m}_b(M_Z) = (2.83 \pm 0.04) \text{ GeV}.
\]

(144)

This value compares quite well with the ones measured at \(M_Z\) from three-jet heavy quark production at LEP where the average \((2.83 \pm 0.04) \text{ GeV}\) of different measurements \([12\]) is given also in the table. This is a first indication for the running of \(m_b\) in favour of the QCD predictions based on the renormalization group equation.

14 The weak leptonic decay constants \(f_{D(s)}\) and \(f_{B(s)}\)

In this section \([17]\), we summarize the different results obtained from the QCD spectral sum rules (QSSR) on the lepton decay constants of the \(B\) and \(D\) mesons which are useful in the analysis of the leptonic decay and on the \(B\)-\(\bar{B}\) mixings. Intensive activities have been devoted to this subject during the last few years using QSSR and lattice calculations.

The leptonic constant of the pseudoscalar \(P \equiv D, B\) meson is defined as:

\[
\langle 0 | \bar{P} M \mu^\nu | P \rangle = f_P M_P^2 \bar{P},
\]

(145)

where \(\bar{P}\) is the pseudoscalar meson field and \(f_P\) is the pseudoscalar decay constant which controls the \(P \to l\nu\) leptonic decay width, normalized as \(f_\pi = 130.56 \text{ MeV}\) \([18]\). The current:

\[
\partial_{\mu} A^\mu(x)^i_j = (m_i + M_j) \bar{\psi}_i (i \gamma_\mu) \psi_j \quad (i \equiv u, d, s; \quad j \equiv c, b),
\]

(146)

\(\bar{P}\) This is an extension and an update of the some parts of the reviews given in \([2]\).\(\bar{P}\) In this chapter, we adopt this normalization used by the lattice and experimental groups. In the previous sections, we have used \(f_\pi \equiv f_\pi/\sqrt{2} \text{ MeV}\).
is the divergence of the axial current. In the sum rule analysis, we shall be concerned with the pseudoscalar two-point correlator:

\[ \Psi_5(q^2) = i \int d^4x e^{iqx} \langle 0 | \mathcal{T} \partial_\mu A^\mu(x) (\partial_\mu A^\mu(0)) | 0 \rangle. \] (147)

In the case of the \( B(\bar{u}b) \) meson, the decay width into \( \tau \nu_\tau \) reads:

\[ \Gamma(B \to \tau \nu_\tau + B \to \tau \nu_\tau \gamma) = \frac{G_F^2 |V_{ub}|^2}{4\pi} M_B \left( 1 - \frac{M_\tau^2}{M_B^2} \right) \frac{M_B^2}{M_\tau^2} f_B^2 . \] (148)

where \( M_\tau \) expresses the helicity suppression of the decay rate into light leptons \( e \) and \( \mu \). This expression shows that a good determination of \( f_B \) will allow a precise extraction of the CKM mixing angle \( V_{ub} \).

One the other hand, \( f_B \) and the so-called bag parameter \( B_B \) also control the matrix element of the \( \Delta B = 2 \ B^0 - \bar{B}^0 \) mixing matrix, which is of a non-perturbative origin, as we shall discuss in another chapter.

However, contrary to the case of the \( \pi \) and \( K \) mesons, the leptonic width of the heavy meson is small as the corresponding decay constant vanishes as \( 1/\sqrt{M_Q} \), while the presence of the neutrino in the final state renders difficult the reconstruction of the signal and the rejection of background. Moreover, the \( B \) leptonic rate is Cabibbo suppressed, which makes it unreachable with present measurements. \( (\sim |V_{ub}|^2) \), while the \( D_s \) leptonic rate is Cabibbo favoured \( (\sim |V_{cs}|^2) \). Recent measurements of \( f_{D_s} \) are given in Fig. 10, where the quoted average is \( [129] \):

\[ f_{D_s} \simeq (264 \pm 37) \text{ MeV} . \] (149)

Figure 10: Different measurements of \( f_{D_s} \) compared with theoretical predictions from \( [129] \).

14.1 Upper bound on the value of \( f_D \)

Within the QSSR framework, the decay constants of the \( B \) and \( D \) mesons have been firstly estimated in \( [131] \), while the first upper bounds on their values have been derived in \( [132] \) and updated in the recent review \( [2] \). Indeed, a rigorous upper bound on these couplings can be derived from the second-lowest superconvergent moment:

\[ \mathcal{M}^{(2)} \equiv \frac{1}{2!} \left. \frac{\partial^2 \Psi_5(q^2)}{(\partial q^2)^2} \right|_{q^2=0}, \] (150)

32
where for this low-moment, the OPE well behaves. Using the positivity of the higher-state contributions to the spectral function, one can deduce \[132, 93\]:

\[
f_P \leq \frac{M_P}{4\pi} \left\{ 1 + 3 \frac{m_q}{M_Q} + 0.751\bar{\alpha}_s + \ldots \right\},
\]

where one should not misinterpret the mass-dependence in this expression compared to the one expected from heavy-quark symmetry. Applying this result to the \(D\) meson, one obtains:

\[
f_D \leq 2.14 f_\pi,
\]

which is not dependent to leading order on the value of the charm quark mass. Although presumably quite weak, this bound, when combined with the recent determination of the \(SU(3)_F\) breaking effects to two loops on the ratio of decay constants \[133\]:

\[
\frac{f_{D_s}}{f_D} \simeq (1.15 \pm 0.04) f_\pi,
\]

implies

\[
f_{D_s} \leq (2.46 \pm 0.09) f_\pi \simeq (321.2 \pm 11.8) \text{ MeV},
\]

which is useful for a comparison with the recent measurement of \(f_{D_s}\), with the average value given previously. One cannot push, however, the uses of the moments to higher \(n\) values in this \(D\) channel, in order to minimize the continuum contribution to the sum rule with the aim to derive an estimate of the decay constant from this method, and to derive its "correct" mass dependence, because the QCD series will not converge at higher \(n\) values.

### 14.2 Estimate of the \(D\) decay constant \(f_D\)

The decay constant \(f_D\) can be extracted from the pseudoscalar Laplace sum rules given in Eq. [129]. Prior 1987, the different sum rules estimate of the decay constant \(f_P\) have been inconsistent among each others. To our knowledge, the first attempt to understand such discrepancies has been done in \[134, 135\] (see also \[136\]), where it has been shown, for the first time and a long time before the lattice results, that:

\[
f_D \approx f_B \approx (1.2 \sim 1.5) f_\pi,
\]

which differs from that expected from the heavy quark symmetry scaling law \[137\]:

\[
f_B \approx \sqrt{\frac{M_D}{M_B}} f_D \left( \frac{\alpha_s(M_c)}{\alpha_s(M_b)} \right)^{-1/\beta_1},
\]

valid in the extreme case where the heavy quark mass is infinite \[20\]. It has also been understood that the apparent disagreement among different existing QSSR numerical results in the literature is not only due to the choice of the continuum threshold \(t_c\) [ its effect is \((7 \sim 10)\%\) of the result when one moves \(t_c\) from the one at the beginning of sum rule variable to the one where the \(t_c\) stability is reached,\(22\) as misleadingly claimed in the literature. Indeed, the main effect is also due to the different values of the quark masses used \[22\], which is shown explicitly in the table of \[133\].

In the \(D\) channel, the most appropriate sum rule is the (relativistic) Laplace sum rule, as the OPE of the \(q^2 = 0\) moments does not converge for larger value of the number of derivatives \(n\), at which the \(D\) meson contribution to the spectral integral is optimized. The results from different groups are

19 For reviews, see e.g. \[130\].
20 Finite mass corrections to this formula will be discussed later on.
21 In some papers in the literature, the value of \(t_c\) is taken smaller than the previous range. In this case, the \(t_c\) effect is larger than the one given here.
22 A critical review on the discrepancy between different existing estimates is given in \[133\].
consistent with each other for a given value of the \( c \)-quark mass. For the \( D \) meson, the optimal result is obtained for:

\[
6 \leq t_c \leq 9.5 \, \text{GeV}^2, \quad \tau \simeq (1.2 \pm 0.2) \, \text{GeV}^{-2}.
\]  

where the QCD corrections are still reasonably small. The most recent estimate including \( \alpha_s^2 \) corrections from a simultaneous fit of the set either \((f_D, \Pi_c(m_c))\) or \((f_D, M_c^\text{pole})\) is given in Fig. 4. The obtained values of the quark masses have been quoted in Table 5. The resulting value of \( f_D \) is [110]:

\[
f_D \simeq (203 \pm 23) \, \text{MeV},
\]  
in agreement with the recent evaluation \((195 \pm 20) \, \text{MeV} \) at order \( \alpha_s^2 \) but using the pole mass as input [139].

14.3 Ratio of the decay constants \( f_{D_s}/f_D \) and \( f_{B_s}/f_B \)

The \( SU(3) \) breaking ratios \( f_{D_s}/f_D \) and \( f_{B_s}/f_B \) have been obtained semi-analytically in [133]. In order to have a qualitative understanding of the size of these corrections, we start from the global hadron-quark duality sum rule:

\[
\int_0^{\omega_c} d\omega \, \text{Im} \Psi_5^{\text{res}}(\omega) \simeq \int_0^{\omega_c} d\omega \, \text{Im} \Psi_5^{\text{Q}}(\omega),
\]  

where \( \omega_c \) is the continuum energy defined as:

\[
t = (E + M_Q)^2 \equiv M_Q^2 + \omega M_Q.
\]  

Keeping the leading order terms in \( \alpha_s \) and in \( 1/M_Q \), it leads to:

\[
R_P \simeq \rho_P \left\{ 1 + 3 \left( \frac{m_s}{\omega_c} \right) \left( 1 - \frac{m_s}{M_Q} \right) - 6 \left( \frac{m_s}{\omega_c} \right)^2 - \left( \frac{m_s}{M_Q} \right) \left( 1 - \frac{m_s}{M_Q} \right) \right\},
\]  

where:

\[
\rho_P \equiv \left( \frac{M_P}{M_{P_c}} \right)^2 \left( 1 + \frac{m_s}{M_Q} \right).
\]  

The value of \( \omega \) is fixed from stability criteria to be [134, 138, 141, 142]:

\[
\omega_c \simeq (3.1 \pm 0.1) \, \text{GeV}.
\]  

The sum rule indicates that the \( SU(3) \) breaking corrections are of two types, the one \( m_s/M_Q \) and the other \( m_s/\omega_c \). More quantitatively, we work with the Laplace sum rule:

\[
\mathcal{L} = \int_0^{\omega_c} d\omega \, e^{-\omega \tau} \text{Im} \Psi_5^{\text{res}}(\omega)
\]  

Analogously the Laplace sum rule gives:

\[
R_P^2 \simeq \rho_P^2 \left\{ 1 + 2(2.2 \pm 0.2) \left( \frac{m_s}{\omega_c} \right) \left( 1 - \frac{m_s}{M_Q} \right) - 2(8.2 \pm 1.6) \left( \frac{m_s}{\omega_c} \right)^2 \right\},
\]  

where the numerical integration includes a slight \( M_Q \) dependence. Including \( m_s \alpha_s \) and \( m_s^2 \alpha_s \)-corrections, the resulting values of the ratio are:

\[
R_D \equiv \frac{f_{D_s}}{f_D} = 1.15 \pm 0.04, \quad R_B \equiv \frac{f_{B_s}}{f_B} = 1.16 \pm 0.05.
\]  

This result implies:

\[
f_{D_s} \simeq (235 \pm 24) \, \text{MeV},
\]  

which agrees within the errors with the data [29] and lattice [40] averages both quoted in Fig. 10. This feature increases the confidence in the uses of the QSSR method for predicting the not yet measured decay constant of the \( B \) meson.
Table 7: Estimate of $f_{B(*)}$ to order $\alpha_s^2$ and $f_B/f_B$ to order $\alpha_s$ from QSSR and comparison with the lattice.

14.4 Estimate of the $B$ decay constant $f_B$

For the estimate of $f_B$, one can either work with the Laplace, the moments or their non-relativistic variants because the $b$-quark mass is relatively heavy. The optimal result which we shall give here comes from the Laplace relativistic sum rules. They correspond to the conservative range of parameters:

$$0.6 \leq E_c^{(b)} \equiv \sqrt{t_c} - M_B \leq 1.8 \text{ GeV} , \quad \tau \simeq 0.38 \text{ GeV}^{-2} , \quad \text{(168)}$$

which have been used in the previous section for getting the $b$-quark mass. As shown in the figure given in [143, 146], the dominant corrections come from the $\langle \bar{u}u \rangle$ quark condensate with the strength ($30 \sim 40\%$) of the lowest order term in $f_B$, while the higher condensate effects are smaller, which are respectively $-(20 \sim 30\%)$ and $(5 \sim 8\%)$ for the $d = 5$ and 6 condensates. This shows, despite the large value of the quark condensate contribution, that the OPE is convergent. It has been noticed in [143, 146], that the convergence of the OPE is faster for the relativistic LSR than for the moments, such that the most precise result should come from the LSR. In both cases the perturbative corrections are small. One obtains from the relativistic LSR, the results to order $\alpha_s^2$ [110]:

$$f_B \simeq (203 \pm 23) \text{ MeV} \simeq (1.55 \pm 0.18)f_\pi , \quad \text{(169)}$$

and to order $\alpha_s$ (see previous discussion) [133]:

$$\frac{f_{B*}}{f_B} \simeq 1.16 \pm 0.04 . \quad \text{(170)}$$

These values of $f_B$ and $f_D$ agree quite well with the previous QSSR findings in [133, 135] and [136]. They also agree with the non-relativistic sum rules estimate in the full theory [134], in HQET [147, 138] and in [141, 142]. However, unlike the relativistic sum rules, the HQET sum rule is strongly affected by the huge perturbative radiative corrections of about 100%, which is important at the sum rule scale of about 1 GeV at which the HQET sum rule optimizes. These results are also in good agreement with the lattice average estimate given in Table 7.

35
14.5 Static limit and $1/M_b$-corrections to $f_B$

As noticed previously, the first result $f_B \simeq f_D$ in \[133\], which has been confirmed by recent estimates from different approaches, shows a large violation of the scaling law expected from heavy-quark symmetry. This result suggests that finite quark mass corrections are still huge at the $D$ and $B$ meson masses. The first attempt to understand this problem analytically is in \[135\] in terms of large corrections of the type $E_c/M_b$ if one expresses in this paper the continuum threshold $t_c$ in terms of the threshold energy $E_c$:

$$t_c \equiv (E_c + M_b)^2.$$  \hspace{1cm} (171)

Later on different approaches have been investigated for the estimate of the size of these corrections. In the lattice approach, these mass corrections have been estimated from a fit of the obtained value of the meson decay constant at finite and infinite (static limit) values of the heavy quark mass and by assuming that these corrections are polynomial in $1/M_Q$ up to log. corrections. A similar analysis has been done with the sum rule in the full theory \[145, 146\], by studying numerically the quark mass dependence of the decay constant until the quark mass value ($M_Q \leq 15$ GeV) until which one may expect that the sum rule analysis is still valid. In so doing, we use the parametrization:

$$f_B \sqrt{M_B} \simeq \tilde{f}_B \alpha_s^{1/\beta_1} \left( 1 - \frac{2}{3} \frac{\alpha_s}{\pi} - \frac{A}{M_b} + \frac{B}{M_b^2} \right),$$  \hspace{1cm} (172)

by including the quadratic mass corrections. The analysis gives \[3\]

$$\tilde{f}_B \equiv \left( f_B \sqrt{M_B} \right)_\infty \simeq (0.65 \pm 0.06) \text{ GeV}^{3/2},$$  \hspace{1cm} (173)

which one can compare with the results from the HQET Laplace sum rule \[47\] and \[142, 148\]:

$$\tilde{f}_B \simeq (0.35 \pm 0.10) \text{ GeV}^{3/2},$$  \hspace{1cm} (174)

and from FESR \[142\]:

$$\tilde{f}_B \simeq (0.57 \pm 0.10) \text{ GeV}^{3/2},$$  \hspace{1cm} (175)

Taking the average of these three (independent) determinations, one can deduce:

$$\tilde{f}_B \simeq (0.58 \pm 0.09) \text{ GeV}^{3/2},$$  \hspace{1cm} (176)

where we have done an arithmetic average of the errors. This result is in good agreement with the lattice value given in \[141, 149\] using nonperturbative clover fermions. One can translate this result into the value of $f_B$ in the static limit approximation:

$$f^{stat}_B \simeq (1.9 \pm 0.3) f_\pi.$$  \hspace{1cm} (177)

We can also use the previous value of $f^{stat}_B$ together with the previous values of $f_B$ and $f_D$ at the “physical” quark masses in order to determine numerically the coefficients $A$ and $B$ of the $1/M_b$ and $1/M_b^2$ corrections. In so doing, we use the values of the quark "pole" masses given in Tables 5 and 6. Then, we obtain from a quadratic fit:

$$A \approx 0.98 \text{ GeV} \quad \text{and} \quad B \approx 0.35 \text{ GeV}^2,$$  \hspace{1cm} (178)

while a linear fit gives a large uncertainty:

$$A \approx (0.74 \sim 0.91) \text{ GeV}.$$  \hspace{1cm} (179)

\[23\]The numbers given in \[141, 149\] correspond to the quark mass $M_b = 4.6$ GeV and should be rescaled until the meson mass $M_B$. In the following, we shall also work with $f_B$ normalized to be $\sqrt{2}$ bigger than in the original papers.
One can notice that the fit of these coefficients depends strongly on the input values of $f_D$ and $f_B$. Indeed, using some other set of values as in [143, 146, 141], one obtains values about 2 times smaller. Therefore, we consider as a conservative value of these coefficients an uncertainty of about 50%: The value of $A$ obtained is comparable with the one from HQET sum rules [150] and [145, 141] of about $0.7 \sim 1.2$ GeV. A similar value of $A$ has been also obtained from the recent NR lattice calculations with dynamical fermions and using a linear fit [149]:

$$A \approx 0.7 \text{ GeV}.$$ (180)

One can qualitatively compare this result with the one obtained from the analytic expression of the moment in the full theory [3, 133, 148]:

$$f_B^2 \simeq \frac{1}{\pi^2} \frac{E_c^2}{M_b^2} \left[ 1 - \frac{2}{3} \frac{\alpha_s}{\pi} - \frac{3(n + 2)E_c}{M_b} + \ldots - \frac{\pi^2 \langle \bar{u}u \rangle}{2 E_c^3} + \ldots \right].$$ (181)

Here, one can notice that the size of the $1/M_b$ corrections depends on the number of moments, such that their estimate using literally the expression of the moments can be inconclusive. A qualitative estimate of these corrections can be done from the semilocal duality sum rule, which has more intuitive physical meaning due to its direct connection with the leptonic width and total cross-section through the optical theorem. It corresponds to $n = -2$, and leads to the interpolating formula [148]:

$$\sqrt{2}f_B \sqrt{M_B} \approx \frac{E_c^{3/2}}{\pi} \alpha_s^{1/3} \left( \frac{M_b}{M_B} \right)^{3/2} \left\{ 1 - \frac{2}{3} \frac{\alpha_s}{\pi} + \frac{3}{88} \frac{E_c^2}{M_b^2} - \frac{\pi^2 \langle \bar{u}u \rangle}{2 E_c^3} + \ldots \right\},$$ (182)

from which, one obtains:

$$A \approx \frac{3}{2} (M_B - M_b) \simeq 1 \text{ GeV},$$

$$B \approx \frac{3}{88} E_c^2 + \frac{27}{32} (M_B - M_b)^2 \simeq 0.45 \text{ GeV}^2,$$ (183)

which is in good agreement with the previous numerical estimate.

### 15 Conclusions

We have reviewed the determinations of the quark masses and leptonic decay constants of (pseudo)scalar mesons which are useful in particle physics phenomenology. The impressive agreements of the QSSR results with the data when they are measured and/or with lattice calculations in different channels indicate the self-consistency of the QSSR approach making it as one of the most powerful semi-analytical QCD nonperturbative approach available today. Applications of these results for studying the $B$-$\bar{B}$ mixings and $CP$-violation will be discussed in the next chapter.

### Acknowledgements

It is a pleasure to thank Valya Zakharov for the hospitality at the Max-Planck Institute für Physik (Munich) where this work has been completed and for some discussions.
