The problem of Andreev reflection between a normal metal and a multiband superconductor is addressed. The appropriate matching conditions for the wave function at the interface are established on the basis of an extension of quantum waveguide theory to these systems. Interference effects between different bands of the superconductor manifest themselves in the conductance and the case of FeAs superconductors is specifically considered, in the framework of a recently proposed effective two-band model, in the sign-reversed s-wave pairing scenario. Resonant transmission through surface Andreev bound states is found as well as destructive interference effects that produce zeros in the conductance at normal incidence. Both these effects occur at nonzero bias voltage.

I. INTRODUCTION

Electronic scattering at the interface between a normal metal (N) and a superconductor has been used as a probe to investigate the electronic properties of superconductors¹ and, more recently, FeAs superconductors (FAS), leading, in the latter case, to different conclusions regarding the pairing symmetry. As compared to conventional and high-Tc materials, the recently discovered FeAs based superconductors have a more complex band structure, with a Fermi surface (FS) consisting of four sheets, two of them hole-like, and the other two electron-like. S-wave, d-wave and p-wave pairing scenarios have been proposed to describe the superconducting state.¹⁻³ One of the suggested pairing scenarios is the so-called sign-reversed s-wave state (s±-state). One of the suggested pairing scenarios is the so-called sign-reversed s-wave state (s±-state), where the gap function has opposite signs in the hole-like and the electron-like sheets of the FS. Since this is a novel possibility, it deserves some theoretical development. A recent experiment seems to confirm this pairing scenario in a 122 compound.²⁻⁴

Blonder et al.¹⁴ devised a theory for Andreev scattering in isotropic s-wave superconductors which has been later generalized to unconventional (anisotropic) superconductors.¹⁵ These theories apply to one band superconductors. In the case of multiband superconductors (MBS), such as FAS and heavy-fermion compounds, the bands are usually treated as separate conduction channels with (classically) additive conductances, like parallel resistors, thereby neglecting the quantum mechanical nature of the scattering problem at the interface, where interference effects between the transmitted waves in different bands of the MBS are expected. Such interference effects will lead to new features in the conductance.

We are thus posed the problem of finding the wave function for the scattering state of an incident particle from a one-band metal which is transmitted through two or more bands inside the superconductor. The splitting of the incident electron’s probability amplitude among several conduction channels is the same quantum mechanical problem as in a quantum waveguide. Thus, in order to derive the appropriate matching conditions for the wave function at the interface, we need to make an extension of quantum waveguide theory.

Applying to the case of FAS, we obtain the differential conductance curves vs bias voltage and explicitly show the emergence of Andreev bound states (ABS) in the s±-state scenario, as a manifestation of interference effects between the bands, unlike the usual ABS in one-band superconductors. An unusual feature of the ABS is that they occur at a finite energy above the Fermi level and disperse with the electron’s transverse momentum. On the other hand, interference effects may also suppress the conductance at certain energies.

II. QUANTUM WAVEGUIDE THEORY

The splitting of the incident electron’s probability amplitude among several conduction channels is the same quantum mechanical problem as in a quantum waveguide. In a quantum waveguide, three one-dimensional conductors intercept at one point (see Figure 1). The wavefunction for a particle must be continuous and single-valued at the circuit node O, implying that

$$\psi(x_1 \rightarrow O) = \psi(x_2 \rightarrow O) = \psi(x_3 \rightarrow O),$$  

where $x_1, x_2, x_3$ are coordinates along branches 1, 2 and 3 respectively. The (probability and charge) current conservation at the node is guaranteed by the "quantum Kirchhoff" law

$$\sum_{j=1}^{3} m_j \frac{\partial \psi(x_j \rightarrow O)}{\partial x_j} = 0,$$

where the coordinates $x_j$ ($j = 1, 2, 3$) must be all of them directed to (or away from) the node O and $m_j$ denotes the particle’s effective mass in branch j.

A simple one-dimensional version of the N/MBS interface is a tight-binding chain which has a bifurcation at
some point, as shown in Figure 2. We further assume the sites in branch 1 to be coupled to branch 2 through a hybridization operator, $\hat{V}$. An integer $n$ labels the two-atom unit cell along the chain.

\text{FIG. 2: Tight-binding waveguide with three branches. In branches 1 and 2 there is electron hopping along } (t,t') \text{ and perpendicular } (V) \text{ to the chains. An integer } n \text{ labels unit cells along the chain.}
\end{array}
\]

Let $|n, j\rangle$ denote the site in cell $n$ of chain $j$. Then, the incoming particle in branch 3 with wavevector $p$ is described by the wavefunction $\psi_{\text{inc}}(n) = e^{ipn} + b e^{-ipn}$, where $b$ denotes the reflection amplitude.

If chains 1 and 2 were decoupled, a Bloch state in chain $j$ would have momentum $k$ and energy $\epsilon_j(k)$. But now suppose that an operator $\hat{V}$ hybridizes Bloch states in the two chains. The Hamiltonian matrix for the coupled chains $1+2$, $\hat{H}_{1+2}$, has an off-diagonal element, $V(k)$, and its eigenstates follow from the eigenproblem:

\[
\begin{pmatrix}
\epsilon_1(k) & V(k) \\
V(k) & \epsilon_2(k)
\end{pmatrix}
\begin{pmatrix}
\alpha \\
\beta
\end{pmatrix}
= \mathcal{E}
\begin{pmatrix}
\alpha \\
\beta
\end{pmatrix},
\]

which yields two bands, $\mathcal{E}_\pm(k)$, so that a Bloch state in the coupled chains $1+2$ has the form

\[
\phi(n) = \begin{pmatrix}
\alpha_k \\
\beta_k
\end{pmatrix} e^{ikn}.
\]

The eigenvector components, $\alpha$ and $\beta$, denote the wavefunction projections on branches 1 and 2, respectively. The wavefunction for the transmitted particle in chains $1+2$ reads, for $n > 0$,

\[
\psi_t(n) = C \begin{pmatrix}
\alpha_k \\
\beta_k
\end{pmatrix} e^{ikn} + D \begin{pmatrix}
\alpha_{k'} \\
\beta_{k'}
\end{pmatrix} e^{ik'n},
\]

where the momenta satisfy the energy conservation condition $\mathcal{E}_-(k) = \mathcal{E}_+(k') = \epsilon(p)$. We now join the wavefunction in branch 3 with that in branches $1+2$ applying condition (1) and by considering that the node is reached by formally taking $n \to 0$:

\[
1 + b = C\alpha_k + D\alpha_{k'} = C\beta_k + D\beta_{k'}. \tag{5}
\]

In order to write Kirchhoff rule, we use the following expression for the probability current:

\[
\dot{j}(r) = \text{Re} \left\{ \psi^\dagger(r) (\partial\hat{H}/\partial\mathbf{k}) \psi(r) \right\} \tag{6}
\]

where the Hamiltonian is written in momentum space and the operator $\mathbf{k} = -i\nabla$ in the continuum limit. In the tight-binding problem above, $\nabla$ reduces to $\partial/\partial n$, and the Hamiltonian $\hat{H}$ is just the scalar dispersion $\epsilon(\mathbf{p})$ in branch 3, or the Hamiltonian matrix $\hat{H}_{1+2}$ in equation (3) in branches $1+2$. If we write the Kirchhoff rule as the following relation between the wavefunctions at the circuit node:

\[
\left[ \frac{\partial\epsilon}{\partial p} \psi_{\text{inc}} \right]_{n \to 0^-} = (1, 1) \cdot \left[ \frac{\partial\hat{H}_{1+2}}{\partial k} \psi_t \right]_{n \to 0^+}, \tag{7}
\]

then, it can easily be checked that the current $j(n)$ is conserved at the node, by virtue of equation (5). The left multiplication by $(1,1)$ gives the sum of the currents through branches 1 and 2. Equation (4) reads:

\[
\frac{p}{m_n}(1-b) = C(1,1) \cdot \frac{\partial\hat{H}_{1+2}}{\partial k} \begin{pmatrix}
\alpha_k \\
\beta_k
\end{pmatrix} + D(1,1) \cdot \frac{\partial\hat{H}_{1+2}}{\partial k'} \begin{pmatrix}
\alpha_{k'} \\
\beta_{k'}
\end{pmatrix}, \tag{8}
\]

where the effective mass $m_n$ is defined as the ratio between the momentum, $p$, and the group velocity, $d\epsilon(p)/dp$. The three equations (5) and (8) uniquely determine the amplitudes $b, C, D$.

The generalization to two spatial dimensions is straightforward: the chain in figure 2 may be identified with the $x$ direction and is repeated identically in the perpendicular ($y$) direction. The unit cell label and momentum become two-dimensional, $n$ and $k$, respectively. The interface is attained as $n_x \to 0$, the transverse momentum component, $k_y$, is conserved. In equation (8), $k$ ($k'$) is replaced by $k$ ($k'$) and the Kirchhoff rule (5) is replaced with:

\[
\frac{p_x}{m_n}(1-b) = C(1,1) \cdot \frac{\partial\hat{H}_{1+2}}{\partial k_x} \begin{pmatrix}
\alpha_k \\
\beta_k
\end{pmatrix} + D(1,1) \cdot \frac{\partial\hat{H}_{1+2}}{\partial k'_{x'}} \begin{pmatrix}
\alpha_{k'} \\
\beta_{k'}
\end{pmatrix}, \tag{9}
\]

ensuring the conservation of the longitudinal current $j_x$ at the node.

III. MODEL FOR A FE-PNICTIDE SUPERCONDUCTOR

A recent tight-binding model for the FAS band structure assumes two orbitals per unit cell, $d_{xz}$ and $d_{yz}$. The
Hamiltonian matrix is
\[ \hat{H}(k) = \begin{pmatrix} \varepsilon_x - \mu & \varepsilon_{xy} \\ \varepsilon_{xy} & \varepsilon_y - \mu \end{pmatrix}, \]
where \( \mu \) denotes the chemical potential and
\[
\begin{align*}
\varepsilon_x &= -2t_1 \cos(k_x) - 2t_2 \cos(k_y) - 4t_3 \cos(k_x) \cos(k_y) \\
\varepsilon_y &= -2t_2 \cos(k_x) - 2t_1 \cos(k_y) - 4t_3 \cos(k_x) \cos(k_y) \\
\varepsilon_{xy} &= -4t_4 \sin(k_x) \sin(k_y).
\end{align*}
\]
This is analogous to branches 1 and 2 of the waveguide above, with the matrix element \( \varepsilon_{xy} \) now playing the role of the hybridization \( V(k) \) between the branches 1 and 2 and \( \varepsilon_{x(y)}(k) \) playing the role of \( \varepsilon_{1(2)}(k) \). The parameter choice \( t_1 = -1, t_2 = 1.3, t_3 = t_4 = -0.85, \mu = 1.45 \) reproduces the FAS band structure. In the unfolded Brillouin Zone (BZ), the Fermi surface obtained from \((10)\) has two electron pockets, centered at \((0, \pm \pi)\) and \((\pm \pi, 0)\), and two hole pockets, centered at \((0, 0)\) and \((\pi, \pi)\).

We assume the edge of the superconductor lying along the \( y \) direction. Then, an incident electron on the interface with small \( p_y \) is transmitted through two Fermi surface pockets: the electron pocket ("e FS") and the hole pocket ("h FS"). See Figure 3. We here work out the Andreev reflection problem in a FS consisting of just one hole and one electron pocket. The generalization of the theory to the four pocket FS in the reduced BZ or to a model with more atoms per unit cell is straightforward. We shall concentrate below on the \( s^\pm \)-state scenario for superconductivity that has recently been suggested, and show that it produces ABS as a consequence of interference between transmitted waves in the two FS pockets.

An elementary excitation in the bulk superconductor with wavevector \( k \) has the wavefunction:
\[ \phi_k(r) = e^{ikr} \begin{pmatrix} u_k \alpha_k \\ u_k \beta_k \\ v_k \alpha_k \\ v_k \beta_k \end{pmatrix}, \]
where the coherence factors \( u_k, v_k \), denoting the amplitudes of the particle and hole components, respectively, obey the Bogoliubov-de Gennes equations:
\[ \begin{pmatrix} \hat{H}(k) - \Delta \varepsilon_k \varepsilon_k & \hat{\Delta} u_k \alpha_k \\ \hat{\Delta} v_k \beta_k & \hat{H}(k) - \Delta \varepsilon_k \varepsilon_k \end{pmatrix} = \mathcal{E} \begin{pmatrix} u_k \alpha_k \\ u_k \beta_k \\ v_k \alpha_k \\ v_k \beta_k \end{pmatrix}, \]
with \( \hat{\Delta} = \Delta(k) \text{diag}(1, 1). \) The superconducting gap \( \Delta(k) \) is assumed to take on different values, \( \Delta_{\text{AS}}(k) \) and \( \Delta_{\text{FS}}(q) \), in the \( h \) and \( e \) FS, respectively. In the \( s^\pm \)-state scenario, \( \Delta_{\text{AS}}(k) \) and \( \Delta_{\text{FS}}(q) \) have opposite signs.

The quasi-particle has a transverse momentum \( \hbar p_y \) which is conserved. The incident particle from the normal metal has momentum \( \mathbf{p}^+ = \hbar(p^+, p_y) \) and the Andreev reflected hole has momentum \( \mathbf{p}^- = \hbar(p^-, p_y) \).

The transmitted particle (hole) in the superconductor’s \( e \) band has momentum \( \mathbf{q}^+ = \hbar(q^+, p_y) \) \( [\mathbf{q}^- = \hbar(-q^-, p_y)] \); but the transmitted particle (hole) in the superconductor’s \( h \) band has momentum \( \mathbf{k}^- = \hbar(-k^-, p_y) \) \( [\mathbf{k}^+ = \hbar(k^+, p_y)] \) because the effective mass, \( m_\text{eff} \), of the h FS is negative and transmitted particles/holes must have positive group velocity. See Figure 3. The wavefunction for a scattering state with transverse momentum \( \hbar p_y \) can be written as:
\[ \Psi(r) = e^{ip_y y} [\psi_N(x)\theta(-x) + \psi_S(x)\theta(x)] \]
where \( \theta(x) \) denotes the Heaviside function. The wave function in the normal single-band metal has both particle (\( u \)) and hole (\( v \)) components:
\[ \psi_N(x < 0) = \begin{pmatrix} 1 \\ 0 \end{pmatrix} e^{ip^+ x} + b \begin{pmatrix} 1 \\ 0 \end{pmatrix} e^{-ip^+ x} + a \begin{pmatrix} 0 \\ 1 \end{pmatrix} e^{ip^- x}, \]
where \( a \) is the Andreev reflection amplitude. Near the Fermi level, \( p^+ \approx p^- \approx pf \sqrt{1 - (p_y/p_F)^2} \), where \( hF \) denotes the Fermi momentum in the normal metal, which has Fermi velocity \( v_F = hF/m_n \). The transmitted quasi-particle into the superconductor is a linear superposition of Bloch states of the form \((12)\) in the two bands:
\[ e^{ip_y y} \psi_S(x > 0) = C\phi_{k^+}(r) + D\phi_{k^-}(r) \]
\[ + E\phi_{q^+}(r) + F\phi_{q^-}(r) \]

We now apply the waveguide matching conditions, at \( x = 0 \), between \((14)\) and \((15)\), to the \( u \) and \( v \) components of the wave function, separately. The condition for the wave function to be single valued at the node reads as:
\[ 1 + b = Cu_{k^+} \alpha_{k^+} + Du_{k^-} \alpha_{k^-} + Eu_{q^+} \alpha_{q^+} + Fu_{q^-} \alpha_{q^-}, \]
\[ 1 + b = Cu_{k^-} \beta_{k^-} + Du_{k^+} \beta_{k^+} + Eu_{q^-} \beta_{q^-} + Fu_{q^+} \beta_{q^+}, \]
\[ a = Cv_{q^-} \alpha_{q^-} + Du_{k^+} \alpha_{k^+} + Eu_{q^+} \alpha_{q^+} + Fu_{q^-} \alpha_{q^-}, \]
\[ a = Cv_{q^+} \beta_{q^+} + Du_{k^-} \beta_{k^-} + Eu_{q^-} \beta_{q^-} + Fu_{q^+} \beta_{q^+}. \]

By solving the system \((16)\) by the determinant method, the amplitudes \( C, D, E, F \) can be expressed as functions
of $a$ and $b$, as:

\[
C = \frac{(1 + b)\Gamma_1 + a\Gamma_2}{\Lambda},
\]

\[
D = \frac{(1 + b)\Gamma_3 + a\Gamma_4}{\Lambda},
\]

\[
E = \frac{(1 + b)\Gamma_5 + a\Gamma_6}{\Lambda},
\]

\[
F = \frac{(1 + b)\Gamma_7 + a\Gamma_8}{\Lambda},
\]

where $\Lambda$ is the determinant of the system (16) and reads:

\[
\Lambda = \left| \begin{array}{cccc}
  u_+\alpha_+ & u_-\alpha_- & u'_+\alpha'_+ & u'_-\alpha'_- \\
  u_+\beta_+ & u_-\beta_- & u'_+\beta'_+ & u'_-\beta'_- \\
  v_+\alpha_+ & v_-\alpha_- & v'_+\alpha'_+ & v'_-\alpha'_- \\
  v_+\beta_+ & v_-\beta_- & v'_+\beta'_+ & v'_-\beta'_-
\end{array} \right|,
\]

and the coefficients $\Gamma_i$ are obtained from Cramer’s rule.

We now define:

\[
\Theta(k) = \frac{m_0}{p_+ (1, 1)} \cdot \left( \frac{\partial \hat{H}}{\partial k_x} - \frac{\partial \hat{\Delta}}{\partial k_x} \right) \begin{pmatrix} \alpha \\ \beta \end{pmatrix},
\]

\[
\Phi(k) = \frac{m_0}{p_- (1, 1)} \cdot \left( \frac{\partial \hat{H}}{\partial k_x} + \frac{\partial \hat{\Delta}}{\partial k_x} \right) \begin{pmatrix} \alpha \\ \beta \end{pmatrix},
\]

and write condition (9) for this case as:

\[
1 - b = C\Theta(k_+) + D\Theta(k_-) + E\Theta(q_+) + F\Theta(q_-),
\]

\[
a = C\Phi(k_+) + D\Phi(k_-) + E\Phi(q_+) + F\Phi(q_-).
\]

In order to simulate interface disorder, a potential barrier $U\delta(x - \epsilon)$ is assumed in the normal metal ($\epsilon < 0$) and the limit $\epsilon \to 0^-$ is taken. We now show that the effect of the barrier amounts to making the replacement:

\[
1 - b \to 1 - b - 2iZ(1 + b)p_F/p^+ \quad (25)
\]

\[
a \to a(1 - 2iZp_F/p^+) \quad (26)
\]

on the right-hand side of equation (24), where the dimensionless barrier parameter $Z = U/\hbar v_F$. To see this, we write the wave function in the normal single-band metal with both particle and hole components:

\[
\psi_N(x \leq \epsilon) = \begin{pmatrix} 1 \\ 0 \end{pmatrix} e^{ip^+x} + b \begin{pmatrix} 0 \\ 1 \end{pmatrix} e^{-ip^+x} + a \begin{pmatrix} 0 \\ 1 \end{pmatrix} e^{ip^-x},
\]

and

\[
\psi_N(\epsilon < x < 0) = \tilde{a} \begin{pmatrix} 1 \\ 0 \end{pmatrix} e^{ip^+x} + \tilde{b} \begin{pmatrix} 0 \\ 1 \end{pmatrix} e^{-ip^+x} + \tilde{\gamma} \begin{pmatrix} 0 \\ 1 \end{pmatrix} e^{ip^-x} + \tilde{\delta} \begin{pmatrix} 0 \\ 1 \end{pmatrix} e^{-ip^-x}.
\]

The matching conditions at $x = \epsilon < 0$ give the equations:

\[
\psi_N(\epsilon^-) = \psi_N(\epsilon^+),
\]

\[
- \frac{\hbar^2}{2m_n} [\psi'_N(e^+) - \psi'_N(e^-)] + U\psi_N(e) = 0.
\]

Taking the limit $\epsilon \to 0^-$ we obtain:

\[
\tilde{a} + \tilde{\beta} = 1 + b,
\]

\[
\tilde{a} - \tilde{\beta} = \frac{2m_n U}{\hbar^2 p^+}(1 + b) + 1 - b,
\]

\[
\tilde{\gamma} + \tilde{\delta} = a,
\]

\[
\tilde{\gamma} - \tilde{\delta} = \left( \frac{2m_n U}{\hbar^2 p^-} + 1 \right) a.
\]

The waveguide matching conditions must be applied between (28) and (16) at $x = 0$. But equations (31) through (34) allow the elimination of the amplitudes $\tilde{a}, \tilde{\beta}, \tilde{\gamma}, \tilde{\delta}$ altogether, finally showing that the replacements (29) have to be done in equation (24).

The values of the Andreev and normal reflection amplitudes, $a$ and $b$, can be obtained by solving the linear system (16) and (24). Introducing

\[
\zeta_{11} = \Gamma_1\Theta(k_+) + \Gamma_3\Theta(k_-) + \Gamma_5\Theta(q_+) + \Gamma_7\Theta(q_-),
\]

\[
\zeta_{12} = \Gamma_2\Theta(k_+) + \Gamma_4\Theta(k_-) + \Gamma_6\Theta(q_+) + \Gamma_8\Theta(q_-),
\]

\[
\zeta_{21} = \Gamma_1\Phi(k_+) + \Gamma_3\Phi(k_-) + \Gamma_5\Phi(q_+) + \Gamma_7\Phi(q_-),
\]

\[
\zeta_{22} = \Gamma_2\Phi(k_+) + \Gamma_4\Phi(k_-) + \Gamma_6\Phi(q_+) + \Gamma_8\Phi(q_-),
\]

we obtain:

\[
a = \frac{2\zeta_{21}/\Lambda}{\left( 1 + 2iZ + \zeta_{11} \right) - \left( 1 - 2iZ - \zeta_{12} \right) + \zeta_{11} \zeta_{12} \zeta_{22} \zeta_{21} \Lambda^2},
\]

and

\[
b = \frac{\left( 1 - 2iZ - \zeta_{11} \right) - \left( 1 - 2iZ - \zeta_{12} \right) + \zeta_{11} \zeta_{12} \zeta_{22} \zeta_{21} \Lambda^2}{\left( 1 + 2iZ + \zeta_{11} \right) - \left( 1 - 2iZ - \zeta_{12} \right) + \zeta_{11} \zeta_{12} \zeta_{22} \zeta_{21} \Lambda^2}.
\]

The contribution of this scattering state to the differential conductance is given by:

\[
g_s = 1 + |a|^2 - |b|^2.
\]

The normal state conductance, $g_n = 1 - |b_n|^2$, is obtained when $\Delta(k) = 0$. Experimentally, the integral of $g_s$ (or $g_n$) over the transverse momenta of the incident electrons, $\sigma_S = \int g_s dp_y$ (or $\sigma_N = \int g_n dp_y$) is measured. We define the integrated relative differential conductance as $\sigma_S/\sigma_N$.

IV. RESULTS

The conductances $\sigma_S$ and $g_s(\xi)$ have been calculated from the above theory using the model (10). We discuss the results below. In the calculations, the normal metal is assumed to have Fermi wavevector $p_F = \pi$ and velocity $v_F = 1.83$. 
When $\Lambda = 0$ the reflection amplitudes, hence $g_s$, become independent of the barrier parameter $Z$ and this is precisely the condition for the occurrence of Andreev bound states. Figure 4 shows the energy of the Andreev bound state as function of the transverse momentum. Contrary to the usual case of single band non-conventional superconductors, the ABS energy is nonzero. It has a non monotonic dependence on $p_y$ and, for $p_y = 0$, it coincides with $\min(|\Delta_h|, |\Delta_e|)$. The dispersion of the ABS energy is in qualitative agreement with the results of Ref. 22.

\[ \Delta_e - \Delta_h = 0.02 \]

**FIG. 4:** Energy of the surface Andreev bound state as function of the transverse momentum. $\Delta_e - \Delta_h = 0.02$.

Figure 5 shows the conductance $g_s$ as function of incident electron energy above the Fermi level, for a clean $(Z = 0)$ interface in the case where $|\Delta_h| < |\Delta_e|$. When the transverse momentum increases, $g_s$ becomes more strongly peaked near the energy of the ABS. In the case where $|\Delta_h| > |\Delta_e|$ there is a destructive interference effect leading to a zero, at normal incidence, in the conductance, as shown in Figure 6.

\[ p_y = 0, \Delta_s = 0.025, \Delta_e = 0.01 \]

**FIG. 6:** Conductance $g_s$ as function of incident electron energy for three different values of the transverse momentum, for a clean $(Z = 0)$ interface. $\Delta_e = 0.01, \Delta_h = -0.025$.

The effect of interface disorder is shown in Figures 7, 8, and 9. Under increasing disorder, conductance peaks appear closer to the energy of ABS. The conductance $g_s$ is independent of the disorder parameter, $Z$, at the ABS energy, therefore, all the conductance curves $g_s(E)$, for different $Z$ values, intercept at the same point, as shown in Figure 7. As disorder increases the conductance tends to decrease and, therefore, the normal state conductance decreases as $Z$ increases. Since at the ABS the conductance $g_s$ is independent of the disorder parameter, $Z$, peaks appear in the relative conductance at the ABS, which become more pronounced as $Z$ gets larger. The relative conductance $g_s/g_n$ is plotted for two ratios of the gap parameters in Figures 8 and 9 illustrating the positions of the peaks. The case when $\Delta_h = -\Delta_e$ is shown in Figure 9. It is also seen, once again, that destructive interference effects in the superconductor between the $e$ and $h$ bands cause the conductance to vanish at normal incidence.

\[ p_y = 0.15\pi \]

**FIG. 7:** The conductance $g_s$ is independent of the barrier strength, $Z$, at the energy of the ABS. The latter can be checked from Fig. 9. This is shown for two transverse momenta: $p_y = 0.15\pi$ (left); $p_y = 0.05\pi$ (right). $\Delta_e = -\Delta_h = 0.02$. 

\[ p_y = 0.18\pi \]
FIG. 8: Relative conductance $g_s/g_n$ for a disordered interface, at two different values of transverse momentum. $\Delta_h = -0.01, \Delta_e = 0.025$.

FIG. 9: Behavior of the relative conductance for different disorder values, $Z$. Destructive interference effects cause a zero in the conductance. $\Delta_e = -\Delta_h = 0.02$.

Since the system is two-dimensional we have to integrate over the possible incident angles, or over $p_y$. The integrated relative conductance is shown in Figure 10 for three interface disorder strengths. The peak structure for large values of the barrier strength reveals the existence of ABS’s.

In a recent preprint, a theory is provided that qualitatively predicts the interference effects in the multiband superconductor, namely the suppression of conductance and the appearance of ABS, in agreement with our findings. In Ref. 23, the wave function in the superconductor is written in the same form as equation (15) but it is assumed that the ratios of the amplitudes $E/C$ and $F/D$ are equal (to a phenomenological parameter $\alpha$ introduced in Ref. 23). Using our waveguide theory for the interface matching conditions, we find that the ratios $E/C$ and $F/D$ are different, as can be seen from figure 11.

FIG. 10: Behavior of the integrated relative differential conductance, $\sigma_S/\sigma_N$, for different disorder values, $Z$. $\Delta_e = -\Delta_h = 0.02$.

FIG. 11: The ratio of the moduli of amplitudes $|E/C|$ and $|F/D|$ as a function of energy. The transverse momentum $p_y = 0.05\pi$ (left panel) and $p_y = 0.15\pi$ (right panel). $\Delta_e = -\Delta_h = 0.02$.

V. SUMMARY

We have introduced a generalization of the quantum waveguide theory to determine the appropriate boundary conditions for the wave function at the interface between a normal metal and a multiband superconductor. We have shown that resonant transmission and destructive interference effects occur in the sign-reversed scenario for pnictide superconductors. Unlike other unconventional superconductors, Andreev bound states at finite energies
are brought about by these interference effects.

On the experimental side, polycrystalline samples have been used so far. The results obtained above describe an interface parallel to the nearest Fe-Fe bonding. Therefore, experiments with single crystals are highly desirable. If the edge of the sample is such that the conservation of the transverse momentum \( p_y \) intercepts only one FS pocket, existing one band theories apply. The above quantum waveguide theory can in principle be used to describe other MBS, such as the heavy-fermion materials.\(^{22}\)
