We collected 19.4 days of data from four 750 g TeO$_2$ bolometers, and in three of them we were able to set the energy threshold around 3 keV using a new analysis technique. We found a background rate ranging from 25 cpd/keV/kg at 3 keV to 2 cpd/keV/kg at 25 keV, and a peak at 4.7 keV. The origin of this peak is presently unknown, but its presence is confirmed by a reanalysis of 62.7 kg-days
of data from the finished CUORICINO experiment. Finally, we report the expected sensitivities of the CUORE-0 (52 bolometers) and CUORE (988 bolometers) experiments to a WIMP annual modulation signal.

I. INTRODUCTION

Tellurium dioxide bolometers are excellent detectors to search for rare processes. Operated at a temperature of about 10 mK, these detectors feature an energy resolution of a few keV over an energy range extending from a few keV up to several MeV. This, together with the low level of radioactive background achievable and the low cost, makes them ideal detectors for CUORE, an experiment that will search for neutrinoless double beta decay ($0\nu$DBD) of $^{130}$Te [1, 2].

CUORE will consist of 988 TeO$_2$ bolometers of 750 g each and is expected to reach a background level at the $^{130}$Te Q-value (around 2528 keV [3, 4]) of the order of 0.01 counts/keV/kg/y, thus allowing a sensitivity to $0\nu$DBD down to the inverted hierarchy of neutrino masses. CUORE is currently being installed at the Laboratori Nazionali del Gran Sasso (LNGS) in Italy and is scheduled to start taking data in 2014. The experimental design was validated by CUORICINO, an array of 62 TeO$_2$ bolometers (for total mass of 40.7 kg) which took data at LNGS from 2003 to 2008 and put stringent limits on the $0\nu$DBD half-life [5, 6]. To test the new assembly line and the materials chosen for CUORE, an array of 52 TeO$_2$ bolometers, named CUORE-0, has been recently built. It is expected to have a smaller background than CUORICINO and will start taking data in Fall 2012.

Given the high mass, the good energy resolution, and the low background, CUORE-0 and CUORE experiments can search for rare processes such as Dark Matter interactions. While there is significant evidence that Dark Matter exists [7], its composition is as of yet unknown. Weakly Interacting Massive Particles (WIMPs) are the theoretically favored candidates [8], and several earth-bound experiments have been designed to detect their scattering off nuclei, which should produce energy releases of a few keV [9]. Many experiments use multiple signatures (e.g. phonon, scintillation and ionization) to discriminate nuclear recoils from the $\beta/\gamma$ background originating from natural radioactivity. Other experiments search for the expected annual modulation of the interaction rate as the Earth traverses the uniform Dark Matter distribution in the galactic halo [10]. Some experiments have reported compatibility with the signal expected for a galactic halo WIMP population, but have been met with skepticism [11]. As our knowledge of the properties of Dark Matter is limited, a variety of different experimental approaches are required and the search for Dark Matter with TeO$_2$ bolometers could provide important new information.

Such searches were not performed in CUORICINO because the energy threshold was too high, of the order of tens of keV. A new software trigger was developed to lower the energy threshold [12]. The trigger is based on the matched filter algorithm [13, 14] and also provides a pulse shape parameter to suppress false signals generated by detector vibrations and electronics noise.

In this paper we show the energy spectrum of four TeO$_2$ bolometers originally operated at LNGS to test the performances of CUORE crystals [10]. In three of them we were able to set the energy threshold around 3 keV, while the fourth was set to 10 keV because of higher detector noise. The energy spectrum of the three bolometers exhibits a peak at 4.7 keV whose origin is presently unknown. The peak has a constant rate in time, and its presence is confirmed by a reanalysis of the data from the last two months of operation of CUORICINO. Given the observed counting rate, we also evaluate the sensitivity of CUORE-0 and CUORE to an annual modulation signal induced by WIMP Dark Matter candidates, comparing it to the results of other experiments.

II. EXPERIMENTAL SETUP

A CUORE bolometer is composed of two main parts: a TeO$_2$ crystal and a neutron transmutation doped Germanium (NTD-Ge) thermistor [17, 18]. The crystal, a 750 g cube of side length 5 cm, is held by PTFE supports in copper frames. The frames are connected to the mixing chamber of a dilution refrigerator, which keeps the bolometers at a temperature of about 10 mK. The thermistor is glued to the crystal and acts as thermometer. The temperature increase due to an energy deposition in the crystal is measured by the decrease in the resistance of the thermistor [19, 20]. The thermistor is biased by a constant current and a change in the voltage across it constitutes the signal [21]. In the setup presented in this paper, called CUORE Crystal Validation Run 2 (CCVR2), each crystal was provided with two thermistors for redundancy. Two Joule heaters were also glued on two crystals and used to inject heat pulses with controlled amounts of energy to monitor the detector gain and efficiencies [22, 24]. The bolometers were operated in
the cryogenic R&D facility of CUORE whose details can be found in Refs. [25–27].

Data were collected over 23 days with small interruptions for calibrations and cryostat maintenance. The effective live time amounted to 19.4 days. On each of the four bolometers, labeled B1, B2, B3 and B4, we selected the thermistor in which the trigger reached the lowest energy threshold.

The energy calibration was performed by inserting two wires of thoriated tungsten in proximity of the detector, between the cryostat and the lead shields placed externally. The main γ lines of $^{232}$Th, ranging from 511 to 2615 keV, and the lines generated by metastable Te isotopes in the crystals, ranging from 30 to 150 keV, were used for the determination of the calibration function. These isotopes are produced by cosmogenic activation during production and air-shipment of the crystals outside the underground laboratory.

III. DETECTOR PERFORMANCE

The energy resolution was evaluated both at the baseline level and on the lowest energy peak in the spectrum. Randomly triggered events, not containing pulses, were used to evaluate the fluctuation of the baseline after the application of the matched filter. A Gaussian fit was performed on the 30.5 keV Sb line, which is due to EC decays of metastable Te isotopes. As one can see from Tab. I, baseline and 30.5 keV resolutions are quite close, since at these energies the resolution of bolometers is expected to be dominated by the noise. The bolometers feature excellent energy resolution, with B2, B3, and B4 below 1 keV FWHM, and B1 at 3.3 keV FWHM.

The detection efficiencies were measured via an energy scan performed at the end of the run by using the Joule heaters to provide sequences of pulses from 1 to 50 keV. However, heater events and actual particle events have slightly different pulse shapes which could result in slightly different energies and detection efficiencies. The trigger efficiency and any differences that may result from the difference between the heater pulses and particle events were investigated by Monte Carlo simulations.

Heater pulses between 1–50 keV and particle pulses in the same energy range were simulated separately using the tools described in Ref. [28]. Only B2 and B3 were simulated for heater pulses while all the four bolometers were considered for the particle pulses simulation. Both Monte Carlo runs included simulated detector noise and the background from particle pulses, randomly generated to match the event rate and the entire measured energy spectrum from threshold up to 5.4 MeV, i.e. the energy of $^{210}$Po decays in the crystal. We processed the output of the simulation in the same way as the heater scan measurement. The estimated efficiencies on B2 are shown in Fig. 2, where the good agreement between Monte Carlo and data is evident.

The energy dependence demonstrates that the trigger acts in the same way on particle and heater pulses. This feature is visible also on B3, the other bolometer with a heater. We estimate the detection efficiencies on the two bolometers without heater (B1 and B4) using the Monte Carlo. For each bolometer, we set the energy threshold for the data analysis as the energy at which the plateau is reached. The detection efficiency $\epsilon_D$ is computed as the weighted average of each point in the plateau and it is considered constant in the data analysis above threshold. The energy threshold, the heater-measured, and particle-simulated detection efficiencies of each bolometer are reported in Tab. I. The heater-simulated detection efficiencies are found consistent with the heater-measured ones within 1σ.

The residual 10–20% inefficiency in the plateau is due to the trigger dead time, which is mainly due to $^{210}$Po decays. $^{210}$Po is introduced in the crystal growth and has a half-life of 147 days. For sufficiently aged crystals, such as the CUORE-0 and CUORE ones, the dead time is expected to be negligible because this activity has decayed away, raising the efficiencies up to 100% (see Ref. [13] for further details).

Table I. Baseline resolution ($\Delta E_{\text{base}}$), resolution at 30.5 keV ($\Delta E_{30.5} \text{ keV}$), software energy threshold ($\theta_E$) and detection efficiencies measured with the Joule heater ($\epsilon_D^{\text{heater}}$) and estimated from the Monte Carlo simulation of the four bolometers ($\epsilon_D^{\text{MC}}$).

| Bolo | $\Delta E_{\text{base}}$ [keV FWHM] | $\Delta E_{30.5} \text{ keV}$ | $\theta_E$ [keV] | $\epsilon_D^{\text{heater}}$ | $\epsilon_D^{\text{MC}}$ |
|------|----------------------------------|-----------------------------|-----------------|---------------------------|------------------------|
| B1   | 3.3 ± 0.7                        | 3.3 ± 0.3                   | n/a             | 0.878 ± 0.002             |
| B2   | 0.66 ± 0.08                      | 0.53 ± 0.08                 | 3.0             | 0.910 ± 0.005             | 0.913 ± 0.001          |
| B3   | 0.76 ± 0.09                      | 0.83 ± 0.09                 | 2.5             | 0.828 ± 0.007             | 0.825 ± 0.001          |
| B4   | 0.82 ± 0.12                      | 0.59 ± 0.12                 | 2.5             | n/a                       | 0.828 ± 0.002          |

IV. ENERGY CALIBRATION

The calibration function is a third order polynomial without intercept. The residual with respect to the nominal energy of the peaks in the low energy spectrum is shown in Fig. 3.

The accuracy at energies lower than 30 keV was verified by using events from $^{121}$Te and $^{40}$K contaminations in the crystals. These isotopes may decay via EC to $^{121}$Sb and $^{40}$Ar, respectively, with the emission of a γ-ray from the daughter nucleus de-excitation ($507.6 \text{ keV}$ or $573.1 \text{ keV}$ from $^{121}$Te and $1461 \text{ keV}$ from $^{40}$K) and the de-excitation of the atomic shell L K ($E_{L1} = 4.6983 \text{ keV}$ or $E_{K} = 30.4912 \text{ keV}$ from $^{121}$Te and $E_{K} = 3.2060 \text{ keV}$ from $^{40}$K). The atomic de-excitation process is fully contained in the crystal while, in some cases, the γ can escape and hit another crystal, thus producing a double hit event. To select double hit events,
we set the time coincidence window to 10 ms, i.e. the measured jitter between the response of the bolometers. We required that in one of the two crystals there is an energy release corresponding to the $\gamma$-rays from $^{121}$Te or $^{40}$K, and then, after applying the SI cut, we selected energy depositions between threshold and 40 keV in the other crystal (Fig. 3). Two events from $^{40}$K were found (3.04 and 3.18 keV), three from the L$_1$ (4.48, 4.67 and 4.74 keV), and ten from the K de-excitation after the $^{121}$Te decay (30.53 $\pm$ 0.04 keV). Since all the events are compatible with their expected energy, the accuracy of the low-energy calibration is confirmed. We also note that the K/L capture ratio for $^{121}$Te is compatible within two standard deviations with the expected value of 7 [29].

Figure 2. Residuals of the calibration function of B2 on metastable Te lines.

Figure 3. Summed energy spectrum from B2, B3 and B4 in time coincidence with an energy deposition on another bolometer (including B1) compatible with the $\gamma$ lines from $^{40}$K (solid) or $^{121}$Te decays (hashed). The dashed lines represent the nominal values of the de-excitation energies. No event is observed away from these lines.

Figure 4. Pulse shape indicator (SI) distribution on B2. The band at low SI is populated by signal events. At higher values there are triggered mechanic vibrations, electronic spikes and pileups. The optimal cut for this bolometer was found to be SI < 2.2.

V. EVENT SELECTION

We selected signal events using the shape indicator variable (SI) described in Ref. [13]. This variable is based on the $\chi^2$ of the fit of the waveforms with the expected shape of the signal. The distribution of SI versus energy for B2 is shown in Fig. 4. The signal region is easily identified, and a considerable part of the pulses generated by thermal and electronic noise can be removed with a cut on this variable.

We evaluated the optimal value of the cut on SI using the Sb K line at 30.5 keV. We performed a series of extended unbinned maximum-likelihood fits, selecting
the events below a fixed SI value. For each SI cut, the spectra of cut accepted events and cut rejected events were simultaneously fitted with a Gaussian, representative of the signal, plus a first-order polynomial function, representative of the background. Signal ($\epsilon_S$) and background ($\epsilon_B$) efficiencies after the cut were evaluated directly in the fit. For each bolometer we selected the cut which maximized the statistical significance, defined as $\epsilon_S/\sqrt{\epsilon_B}$, corresponding in this case to $\epsilon_S = 1$.

No anti-coincidence cut is applied. Since over the entire energy range multiple-hit events are mainly due to random coincidences, the application of anti-coincidence cuts reduces the statistics without gaining in background reduction.

VI. MEASURED SPECTRA

The energy spectra of the four detectors show several $\gamma$ and $\alpha$ peaks that are clearly identified as due to U, Th and K contaminations (of the crystals themselves and of the experimental setup) and few low energy peaks identified as being due to Te metastable isotopes. The region between threshold and 40 keV is shown in Fig. 5. In the three bolometers with the lowest threshold, a peak appears at about 4.7 keV, the energy of the L$_1$ atomic shell of Sb. This in principle indicates that the line could be ascribed to the EC decay of a Te isotope, however none of the known or predicted isotope decays can explain our observation:

- The $^{121m}$Te and its daughter $^{121}$Te decay via EC with half-lives of 154 and 17 days, respectively. However the intensity of the observed peak is higher than the K line of Sb at 30.5 keV. This is in contradiction with the measured value of the K/L$_1$ capture ratio for these isotopes which is greater than one.
- The other EC decaying metastable Te isotopes

![Figure 5. Low energy spectra of the four bolometers. Full statistics (19.4 days) with pulse shape cut applied.](image)

To further investigate the peak origin, in the next future we will operate crystals enriched in $^{121m}$Te and $^{130}$Te (therefore depleted in other Te isotopes) and see if the peak intensity changes. In the following we report the analysis of the peak in the energy distribution of single bolometers, to provide all the possible details and to stimulate a discussion within the scientific community that will hopefully lead to its identification.

To determine the intensity, the peaking background due to the EC decay of $^{121m}$Te-$^{121}$Te was removed. The $\gamma$-rays produced by these isotopes can escape without hitting another crystal, such that only the K or the L de-excitations are measured. The number of pure L events from $^{121}$Te and $^{121m}$Te ($N_{121}$) were estimated using a Monte Carlo simulation based on GEANT4 [34], normalizing the single hit spectra to the measured rate of the most intense $^{121m}$Te peak (294.0 keV).

To estimate the intensity and the energy of the line from the data, we performed a separate extended unbinned maximum-likelihood fit for each bolometer, using a likelihood function constituted by a Gaussian plus two exponential functions to reproduce the background. We set the pulse shape cuts at the estimated optimal values. Since the events in the 4.7 keV peak are more plentiful than in the Sb K peak at 30.5 keV, the selection efficiencies were recomputed, and confirmed to be equal to 1. The obtained number of events $N_e$ was then corrected taking into account the detection and cut efficiencies and the expected background $N_{121}$, according to the equation $N_{\text{sig}} = (N_e - N_{121})/(\epsilon_P \epsilon_S)$. Best fits are shown in Fig. 6. In Tab. II we report the summary of the peak parameters of each bolometer, also including the estimated peaking background $N_{121}$.

We combined the profile negative log-likelihoods of $N_e$ and $N_{121}$ of the three bolometers (Fig. 6) to compute the average rate. The estimated value of the number of signal events is $223 \pm 22$ counts/crystal, from which we evaluated the line intensity in TeO$_2$ to be $I = 15.3 \pm 0.1$ counts/s/keV. 

- $^{123}$Te is a naturally occurring isotope of Tellurium (abundance 0.908 $\pm$ 0.002% [30]) which may decay via EC to $^{123}$Sb with a Q-value of 52.2 $\pm$ 1.5 keV. Since the transition is 2nd-forbidden unique, it has been estimated that very little K capture actually occurs and that the majority of EC decays take place from the L$_3$ shell. Several searches for Sb K lines from EC of $^{123}$Te have been performed. Positive evidence, $T_{1/2} = (1.24 \pm 0.10) \cdot 10^{24}$ yr, was claimed [31] but subsequently ruled out [32, 33]. In this paper, we show for the first time an energy spectrum down to the L energy region. The line we observe however cannot be attributed to $^{123}$Te, since, as described in the next section, the energy is compatible with the L$_1$ shell (4.6983 keV) and not with the L$_3$ one (4.132 keV).
The energy averaged over the three bolometers is $4.72 \pm 0.18 \text{ keV}$.

Figure 7 shows the rate of the 4.7 keV peak versus time in all three CCVR2 bolometers summed together. No variation is appreciable.

Table II. Best fit results for the 4.7 keV line and estimated peaking background from $^{121}\text{Te}$. The error on the energy includes the systematic due to the calibration.

| Bolometer | Energy [keV] | FWHM [keV] | $N_{\text{sig}}$ [counts] | $N_{121}$ [counts] |
|-----------|-------------|------------|-----------------|-----------------|
| B2        | 4.75 $\pm$ 0.28 | 0.57 $\pm$ 0.11 | 191$^{+31}_{-34}$ | 6.1 $\pm$ 1.3 |
| B3        | 4.66 $\pm$ 0.28 | 0.87 $\pm$ 0.10 | 255$^{+35}_{-38}$ | 13.5 $\pm$ 1.6 |
| B4        | 4.76 $\pm$ 0.38 | 0.75 $\pm$ 0.12 | 205$^{+45}_{-34}$ | 7.5 $\pm$ 1.4 |

1.5 counts/day/kg. The energy averaged over the three bolometers is $4.72 \pm 0.18 \text{ keV}$.

Figure 6 shows the best fits at the 4.7 keV line on the three bolometers with low threshold. On the bottom right, the combined profile negative log-likelihood projected over the number of signal events.

As the calibration was based on the $^{232}\text{Th}$ source only, and given the lack of low energy peaks, the accuracy of the calibration function at low energies cannot be checked directly on CUORICINO data. To have an estimate of the calibration accuracy, during a new CCVR run we built a new setup in which a $^{55}\text{Fe}$ source was deposited on the copper holder. The detector was operated in the same setup used for the CCVR2 one, reaching an energy resolution of 1.4 keV FWHM and an energy threshold of around 3 keV. To emulate the CUORICINO conditions, the calibration function was estimated using the peaks from the $^{232}\text{Th}$ source only. The X-rays produced by the $^{55}\text{Fe}$, with nominal energies between 5.888 and 6.490 keV, resulted in detected energies that were shifted, on average, by only $+(48 \pm 16)$ eV from their nominal values. Even if the operating conditions of this setup were not identical to the CUORICINO ones, this shift can be taken as an indication of the systematics associated to the calibration function.

### VII. Sensitivity to WIMPS

WIMPs can couple to nucleons via both spin-independent and spin-dependent (axial vector) interactions. Spin-independent scattering dominates when $A \geq$
Figure 8. Comparison of CCVR2 (black circles) and CUORICINO (red triangles) data, with a zoom on the 4.7 keV. Unlike in CCVR2, CUORICINO data are not corrected for the efficiencies and the calibration at low energies is not optimized.

30 because, for low momentum transfer, it benefits from coherence across the nucleus. In addition, spin-dependent scattering is significant only on nuclei with an odd number of nucleons. Since 99.8% of Oxygen is constituted by $^{16}\text{O}$ and 92% of Tellurium is composed by even isotopes (mainly $^{130}\text{Te}$, $^{128}\text{Te}$ and $^{126}\text{Te}$), TeO$_2$ will be most sensitive for spin-independent interacting WIMPs. It has to be remarked that TeO$_2$ bolometers, unlike other bolometric detectors for Dark Matter, do not discriminate the nuclear recoils induced by WIMPs from the radioactive $\beta/\gamma$ background. Nevertheless, the high mass and low background achievable with these detectors make it possible to search for an annual modulation of the counting rate.

Compared to CUORICINO, the CCVR2 rate has the same behavior at energies greater than 10 keV, but is considerably higher at lower energies (Fig. 8). We are unable to explain this difference at present, however we expect that the CUORE-0 and CUORE low energy background will not be higher than the CCVR2 one. All the materials used in detector construction, in fact, will be the same as those employed for CCVR2. Moreover, in the case of CUORE-0, the bolometers will be operated in the same cryostat of CUORICINO, which has lower radioactive contaminations compared to the one used to operate CCVR2. To be conservative, we estimate the CUORE-0 and CUORE sensitivity to WIMPs assuming the background rate of these experiments to be equal to the one measured on CCVR2. We assume that the noise will be under control and that all bolometers will achieve a 3 keV threshold. We focus on the energy region between threshold and 25 keV, featuring an observed background counting rate ranging from about 25 cpd/keV/kg to 2 cpd/keV/kg.

We perform toy Monte Carlo simulations generating background events from the CCVR2 fit function shown in Fig. 8 and WIMP events from the predicted distribution described in Ref. 36, using the following WIMP parameters: density $\rho_W = 0.3 \text{ GeV/cm}^3$, average velocity $v_0 = 220 \text{ km/s}$ and escape velocity from the Galaxy $v_{esc} = 600 \text{ km/s}$. The quenching factor (QF) of the interactions in TeO$_2$ is set to 1. We include the dependence of the WIMP interaction rate on the time in the year, and estimate the background+signal asymmetry subtracting the 3-month integrated spectrum across December the 2nd from the 3-month integrated spectrum across June the 2nd. The resulting differential spectrum is fitted with the expected shape induced by the modulation, $H_1$ (examples are given in Fig. 9), and with a flat line at zero counts, $H_0$. The cross section in the toy simulation is lowered as long as, in a set of experiments, the fit probability of the $H_1$ hypothesis is greater than the $H_0$ one at least 90% of the times.

This procedure defines the cross section that could be sensed for a fixed WIMP mass. The 90% CL upper limit sensitivity to the cross-section as a function of the WIMP mass is reported in Fig. 10 for 3-years of CUORE-0 data-taking and 5-years of CUORE. The comparison with other experiments shows that CUORE-0 could completely test the DAMA results, under the hypothesis that Dark Matter is purely made of spin-independent interacting WIMPs. We reiterate that because the quenching factor for nuclear recoils compared to electron recoils in TeO$_2$ bolometers is 1, the 2-6 keV energy region of DAMA corresponds to 7-20 keV assuming scattering on Na (QF=0.3) or 22-67 keV assuming scattering on I (QF=0.9). Therefore, in TeO$_2$ bolometers it will be possible to look at lower energies and to study with larger detail the shape of the modulation spectrum, thus providing new information to this complicated search.
Figure 10. 90% sensitivity to WIMP spin-independent scattering of CUORE-0 and CUORE assuming a 3 keV threshold for all detectors and the same background level of the CCVR2 detectors. Evidences of DAMA-3σ [38], CoGeNT-90% [39] and CRESST-2σ [40] are reported for comparison.
