ABSTRACT

We report the fabrication and optical characteristics of europium silicate thin films. Layer structures of Eu$_2$O$_3$/SiO$_x$/Si (100) were deposited by an rf-sputtering method and annealed at 1100°C by rapid thermal annealing (RTA). Two methods were used for the deposition of SiO$_x$ layer: One was deposited by sputtering using SiO$_2$ target (Ar gas at a rate of 50 sccm) and the other was deposited by reactive sputtering using Si target (Ar gas at a rate of 45 sccm, with an O$_2$ gas at a rate of 5 sccm). Photoluminescence peak at 430 nm was observed in the sample composed of SiO$_x$ interlayer sputtered from SiO$_2$ target. In comparison, PL peak at 570 nm was observed in the other sample, the SiO$_x$ layer of which was deposited by reactive sputtering from Si target. The compositional distributions of these samples were analyzed by X-ray photoelectron spectroscopy (XPS).

1. INTRODUCTION

White light-emitting diodes (LEDs) can offer benefits in terms of high luminous efficiency, energy-saving, maintenance and environmental protection. Therefore, they are called the next-generation solid-state light, the replacement of conventional incandescent and fluorescent lamps. The technology of white LEDs which is connected with the blue LED coated with a YAG: Ce phosphor, has improved the white LED efficiencies [1 - 2]. However, the brightness and color purity of blue LED-based white LEDs are dependent on the conditions of forward-bias and phosphor coating. An alternative method of making a color conversion white LEDs is that a true white can be achieved using three colors from red, green, and blue phosphors excited by ultraviolet (UV) LEDs, similar to three colors based fluorescent lamp [3]. It is very important to improve the efficiency of the RGB phosphor as well as that of the UV LED chip to fabricate highly efficient white LEDs. Phosphors are usually made of zinc sulfide or yttrium oxides doped with certain transition metals or rare-earth metals to obtain specific colors. The efficiency of the currently applied red phosphor is much lower than that of green phosphor and blue phosphor. Therefore, it should be further improved for the applications such as florescence lamps.

On the other hand, rare-earth silicate compounds have attracted a great deal of interest for their luminescent properties. They have been applied to many practical devices, such as fluorescent lamps, the cathode-ray tube and x-ray recording devices, as well as electroluminescent (EL) devices [4 - 7]. In particular, europium silicate compounds are known as an intense and stable

Europium silicate thin films fabricated by rf magnetron...  

luminescent material in the visible region [8 - 12]. Several works have been done so far regarding the structure and the electrical/optical/magnetic properties of europium-silicate compounds [9 - 12]. However, the growth of single-phased europium silicate crystals is performed at high temperatures. For example, the bulk Eu₂SiO₄ crystals are grown at a temperature of 1800°C [9] and EuSiO₃ crystals have been obtained at 1400°C [10]. In addition, due to difficulties in growing pure crystals, a few studies of the applications of pure europium silicates have been done compared to other europium doped materials, which are known as the intense and stable luminescent materials in the visible region.

In this work, we report the fabrication and optical characteristics of europium silicate thin films. Layer structures of Eu₂O₃/SiOₓ/Si (100) were deposited by an rf-sputtering method and annealed at 1100°C by rapid thermal annealing (RTA). The samples were characterized by using X-ray photoelectron spectroscopy (XPS). Then, photoluminescence (PL) properties of the europium-silicate thin films were investigated, and the results are discussed.

2. EXPERIMENTS

Figure 1 shows a schematic of the Eu₂O₃/SiOₓ/Si structures prepared rf-sputtering method. Two methods were used for the deposition of SiOₓ layer: One is deposited by using rf sputtering method in Ar gas at a rate of 50 sccm with SiO₂ (99.9%) target and the other is deposited by reactive sputtering using a sputtering atmosphere gas mixture of Ar and O₂ with Si (99.9%) target. The volume fraction of O₂ was adjusted to 10% (Ar gas at a rate of 45 sccm, with an O₂ gas at a rate of 5 sccm). Europium-oxide thin films were prepared on p-type Si(100) substrates and by using an rf sputtering method in Ar gas with an Eu₂O₃ (99.95%) target. During the sputtering process, the atmosphere gas pressure was kept at 4.4 mTorr, and the rf power was 70 W and the substrate was not heated during sputtering. The deposited film thickness was about 0.2 μm and 0.2 μm for europium oxide and silicon oxide, respectively. After sputtering, the films were annealed in the temperate range of 900 ~ 1100 °C for 5 min in a nitrogen ambient by using rapid thermal annealing (RTA).

![Fig. 1: A basic scheme of the thin film prepared rf-sputtering method](image)

The samples were investigated in order to determine the compositional distribution as a function of depth in the film by XPS ion beam sputtering with argon. This technique is usually used for...
removing contaminated surface layers. However, since sputtering physically removes material (i.e., it etches) from the surface, it can also be used for depth profiling. The XPS measurements were carried out in a Perkin-Elmer Model PHI 5800 ESCA system with a monochromatic x-ray source of Al Kα (1486.6 eV). The spectrometer was operated at a constant pass energy of 187.85 eV. An energy step of 0.125 eV was used to acquire the XPS spectra. The PL emission spectra of the samples were obtained using a 325 nm He-Cd laser at room temperature.

3. RESULTS

Table 1 describes two representative thin-film samples, labeled ES1 and ES2. These samples were prepared by the rf-sputtering method. The thin films of the samples ES1 and ES2 were prepared on Si(100) substrates. After sputtering, the films were annealed at the temperature of 1100°C for 5min in nitrogen ambient by rapid thermal annealing method.

| Sample | Substrate | Target for EuO layer | Sputter gas | Target for SiO₂ layer | Sputter gas |
|--------|-----------|----------------------|-------------|-----------------------|-------------|
| ES1    | Si(100)   | Eu₂O₃                | Ar          | Si                    | Ar/O₂       |
| ES2    | Si(100)   | Eu₂O₃                | Ar          | SiO₂                  | Ar          |

The samples have been studied by the XPS to investigate the compositional distribution of the thin film samples. The peaks monitored in these spectra correspond to Si 2p, O 1s, and Eu 3d core levels. Depth profiles are used to determine the elemental composition as a function of depth. A rastered, differentially pumped argon ion gun was used to sputter the surface of the reflective dielectric film. The sputter rate of SiO₂ was used to express the thickness of the layers in the europium silicate thin films. The atomic concentrations are deduced from the XPS spectra using Physical Electronics Inc., MULTIPAK program [13] and by taking atomic-sensitivity factors into consideration. XPS measurements were done in a system separate from the growth chamber and the samples were exposed to the ambient gases during the transfer process. Due to this, these films had a surface layer of carbonaceous compounds. Figure 2 shows the XPS depth profiles of the thin films (a) as-deposited and (b) annealed at 1100°C for 5min for the sample ES1. The depth profile of the as-deposited thin film shows clearly the different oxide layers of the europium oxide and the silicon oxide. The 1100°C-annealed thin films of the sample ES1 are composed of Eu, O and Si. The variations of the atomic concentration show that some Si atoms are diffused into the europium oxide thin film out of the silicon oxide while Eu atoms are diffused into the silicon oxide, leading to a composite film of Eu, O and Si. Figure 3 shows the XPS depth profiles of the thin films (a) as-deposited and (b) annealed at 1100°C for 5min for the sample ES2. The depth profile of the as-deposited thin film shows clearly the different oxide layers similar to that of as-deposited thin film of the sample ES2. It is observed that the silicon concentration in the europium silicate layer of the sample ES1 annealed at 1100°C is greater than that in the layer of the sample ES2 annealed at 1100°C. On the other hand, the europium concentration in the layer of the sample ES1 annealed at 1100°C is less than that in the layer of the sample ES2 annealed at 1100°C. This indicates that a composite film of Eu, O and Si is easy to form in the thin film of the sample ES1 rather than that of the sample ES2. In other words, the reaction between the europium oxide and the silicon oxide was suppressed in the sample ES2.

Figure 4 shows the PL peak wavelengths from the thin films of the samples ES1 and ES2 after thermal treatment at 900 ~ 1100°C. In case of the sample ES2, the PL peak wavelength does not change as the annealing temperature changes from 900°C to 1100°C. The PL signal is centered
at 430 nm in the sample ES2 after thermal treatment. By contrast, the red-shift of the PL peak occurred when the sample ES1 was annealed above 1000°C. A very strong luminescence in the visible region was observed from the thin film in the sample ES1 annealed at 1100°C, with the maximum intensity at 570 nm and a full width at maximum of 190 nm. This broad spectrum is thought to originate from the 4f^5d-4f^7 transition of divalent europium ions Eu^{2+} at different sites [12]. The intense and broad luminescent properties of the europium-silicate thin films are expected to have wide applications in areas of passive optical components, like thin film phosphors, and active components, like electroluminescence devices.

4. CONCLUSION

We report the effect of SiO$_x$ Intermediate Layers on PL properties of europium silicate thin films. Layer structures of Eu$_2$O$_3$/SiO$_x$/Si (100) were deposited by an rf-sputtering method and annealed at 1100°C by RTA. Two methods were used for the deposition of SiO$_x$ layer: One was deposited by sputtering using Si$_2$O$_3$ target (Ar gas at a rate of 50 sccm) and the other was deposited by reactive sputtering using Si target (Ar gas at a rate of 45 sccm, with an O$_2$ gas at a rate of 5 sccm). Photoluminescence peak at 430 nm was observed in the sample composed of SiO$_x$ interlayer sputtered from SiO$_2$ target. In comparison, the intense and broad PL peak at 570 nm was observed in the other sample, the SiO$_x$ layer of which was deposited by reactive sputtering from Si target.
