Abstract. The dynamic behavior of nitrogen oxides (NOx=NO+NO2) and ozone (O3) above and within the canopy at the University of Michigan Biological Station AmeriFlux (UMBS Flux) site was investigated by continuous multi-height vertical gradient measurements during the summer and the fall of 2008. A daily maximum in nitric oxide (NO) mixing ratios was consistently observed during the morning hours between 06:00 and 09:00 EST above the canopy. Daily NO maxima ranged between 0.1 and 2 ppbv (with a median of 0.3 ppbv), which were 2 to 20 times above the atmospheric background. The sources and causes of the morning NO maximum were evaluated using NOx and O3 measurements and synoptic and micrometeorological data. Numerical simulations with a multi-layer canopy-exchange model were done to further support this analysis. The observations indicated that the morning NO maximum was caused by the photolysis of NO2 from non-local air masses, which were transported into the canopy from aloft during the morning breakup of the nocturnal boundary layer. The analysis of simulated process tendencies indicated that the downward turbulent transport of NOx into the canopy compensates for the removal of NOx through chemistry and dry deposition. The sensitivity of NOx and O3 concentrations to soil and foliage NOx emissions was also assessed with the model. Uncertainties associated with the emissions of NOx from the soil or from leaf-surface nitrate photolysis did not explain the observed diurnal behavior in NOx (and O3) and, in particular, the morning peak in NOx mixing ratios. However, a ~30% increase in early morning NOx and NO peak mixing ratios was simulated when a foliage exchange NO2 compensation point was considered. This increase suggests the potential importance of leaf-level, bidirectional exchange of NO2 in understanding the observed temporal variability in NOx at UMBS.

1 Introduction

Nitrogen oxides (NOx=NO+NO2), which originate from combustion, lightning, and soil emissions, play a critical role in regulating the photochemical production of ozone (O3) in the troposphere (Crutzen, 1970; Jacob, 2000; Crutzen and Lelieveld, 2001; Hauglustaine et al., 2001). Excessive deposition of NOx, which contributes to the total nitrogen input on ecosystems, and exposure of vegetation to toxic levels of O3 can cause foliage damage; NOx deposition is linked to acidification and eutrophication of forests (Mosier et al., 2001; Grunhage et al., 2002).

NOx and O3 concentrations (and fluxes) have been measured in forest ecosystems to quantify NOx and O3 dry deposition in relatively polluted conditions (e.g., CASTNET; US Environmental Protection Agency, 2009). Other measurements of NOx and O3 were done to study the role of canopy interactions between biogenic emissions, dry deposition, chemistry, and turbulence in determining bidirectional exchange of NOx between more pristine forests and the overlying atmosphere (e.g. Bakwin et al., 1990, 1994; Carroll and Thompson, 1995; Munger et al., 1996; Rummel et al., 2002). The University of Michigan Biological Station (UMBS) is one of those sites with a history of NOx and O3 measurements since 1997 from the Program for Research on Oxidants: PHotochemistry, Emissions

Published by Copernicus Publications on behalf of the European Geosciences Union.
and Transport (PROPHET; Carroll et al., 2001). At the PROPHET site, Thornberry et al. (2001) observed a periodic mixing ratio maximum of NO\textsubscript{x} in the morning hours above the forest canopy. A similar behavior was also observed at other forest sites (e.g. Parrish et al., 1993; Munger et al., 1996; Andere et al., 2002; Farmer and Cohen, 2008). Alaghmand et al. (2011) concluded that to understand the diurnal behavior in NO\textsubscript{x} mixing ratios at sites such as UMBS, the combined role of (nocturnal) mixing and transport processes needs to be considered, and this would require the coupling of canopy and boundary layer turbulence models.

In this study, we used the combined analysis of below, within, and above canopy observations and model simulations (1) to investigate the cause for the observed morning peak in NO\textsubscript{x} mixing ratios differentiating between the role of local versus distant sources of NO\textsubscript{x} and (2) to assess the sensitivity of in-canopy NO\textsubscript{x} (and O\textsubscript{3}) to potentially relevant in-canopy sources and sinks under atmospheric conditions encountered at UMBS. Results are based on an analysis of a five-month data set of NO\textsubscript{x}, NO, and O\textsubscript{3} vertical mixing ratio profiles, which were measured above and within the canopy of the UMBS forest in the summer and the fall of 2008. Simulations with a multi-layer canopy-boundary layer exchange model further supported the analysis.

2 Measurements

2.1 Site description

This study was conducted from 19 July to 21 November 2008 at the AmeriFlux site in the UMBS domain (45.5932° N, 84.7130° W; Schmid et al., 2003). This site is located in an area rather distant from major anthropogenic sources although it is quite often (~40% of the time) affected by advection of polluted air masses. The nearest metropolitan areas (population >200,000) are Detroit, Michigan, ~350 km to the southeast; Milwaukee, Wisconsin, ~350 km to the southwest; and Chicago, Illinois, ~450 km also to the southwest.

The UMBS forest falls in the transition zone between mixed hardwood and boreal forests with a mean annual (from 1979 to 2009) temperature of 6.7 °C and rainfall of 803.4 mm (Vande Kopple, 2011). The pre-settlement forest, dominated by white pine (Pinus strobus), red pine (Pinus resinosa), and hemlock (Tsuga canadensis), was cut around 1880. The area was disturbed repeatedly by fire until 1923. Today, within a 1 km radius of the AmeriFlux tower, the forest is composed mainly of bigtooth aspen (Populus grandidentata) and trembling aspen (Populus tremuloides), but there is also significant representation of maple (Acer rubrum), red oak (Quercus rubra), birch (Betula papyrifera), and beech (Fagus grandifolia). In patches, there is a dense understory of young white pine, up to ~6 m high. The understory layer near the forest floor is dominated by bracken fern (Pteridium aquilinum) and saplings of red maple, red oak, beech, and white pine (Gough et al., 2007).

The forest at UMBS has two distinctive layers: a crown layer and an understory layer (Fig. 1). The mean canopy height around the AmeriFlux tower was ~22 m (Schmid et al., 2003). The average seasonal maximum (from 1999 to 2009) of the cumulative single-sided leaf area index (LAI, m\textsuperscript{2} m\textsuperscript{-2}) was 3.5. The average seasonal LAI began to decrease in early-October, and it reached its average seasonal minimum of 1.5 by November.

2.2 Instrumentation

A UV absorbance monitor (DASIBI 1003-AH) was used to measure the mixing ratio of O\textsubscript{3} through the canopy. Before installing the DASIBI at the site, a 5-point calibration was conducted against a TEI 49C monitor (Thermo Environmental Instruments, Inc. (TEI), Franklin, MA, USA), which served as the transfer standard for the calibration. Brodin et al. (2010) describe the calibration of this transfer standard in detail. The calibration of the DASIBI resulted in a 1 ppbv offset with a 3% slope correction. The O\textsubscript{3} data from the DASIBI were corrected for this difference. The detection limit of the DASIBI was 1 ppbv.

The mixing ratio of NO\textsubscript{x} was determined with a chemiluminescence analyzer (TEI 42C-TL). This instrument follows the Federal Reference method as designated by the US EPA, which is also the most prevalent method of measuring ambient air NO\textsubscript{x} (Demerjian, 2000). The TEI 42C-TL has two channels. The first channel measures nitric oxide (NO) via NO + O\textsubscript{3} chemiluminescence. The second channel measures nitrogen dioxide (NO\textsubscript{2}) by redirecting air through a heated (325 °C) molybdenum converter, which causes NO\textsubscript{2} – and other oxidized nitrogen compounds – to convert to NO. The NO\textsubscript{2} mixing ratio is then determined by subtracting NO, measured in the first channel. There are several interferences in this NO\textsubscript{2} measurement scheme (Steinbacher et al., 2007). The error in the NO\textsubscript{2} measurement increases with rising amounts of interfering gases such as nitrous acid (HONO), peroxyacetyl nitrate (PAN), and alkyl nitrates that contribute to the NO\textsubscript{2}-mode signal. However, in urban environments, NO\textsubscript{x} typically constitutes the largest fraction of oxidized nitrogen compounds (Spicer, 1982; Steinbacher et al., 2007); hence, NO\textsubscript{2} mixing ratios obtained with the TEI 42C-TL will represent a reasonable estimate if the site is influenced by anthropogenic sources. Furthermore, a recent intercomparison of NO\textsubscript{x} measurement techniques showed that NO and NO\textsubscript{2} measured with a molybdenum oxide (MoO) converter instrument yielded values that differed from instruments using other techniques (e.g., photolytical converter) only by 2 and 3%, respectively, for ambient air measurements at a semi-rural site in Germany (Gilge et al., 2013). Before the deployment of the TEI 42C-TL analyzer in the summer of 2008, the instrument was sent to TEI for preventive maintenance. TEI reported the instrument to have a NO\textsubscript{2}
conversion efficiency of 99.9% after servicing it. Ultra-zero air (Airgas Great Lakes, Inc., Royal Oak, MI, USA) was used to establish baseline conditions and for dilution of a NIST-traceable 1 ppmv NO gas standard (Scott-Marrin, Inc., Riverside, CA) to multiple calibration gas levels between 0.5 and 10 ppbv. After propagating the uncertainties of the mass flow controllers and the NO gas standard, we estimated the uncertainty in the NO determination to be ~5%. The signal noise was 0.05 ppbv, which resulted in a detection limit of ~0.1 ppbv. The detection limit was determined by taking three times the standard deviation of the blank (the ultra-zero air).

Note that from hereon, we will use NO$_2$$_{\text{MO}}$ and NO$_x$$_{\text{MO}}$ to indicate that the NO$_2$ and NO$_x$ results in our study are those measured with a MoO converter instrument.

### 2.3 Sampling

Vertical mixing ratio profiles of NO$_x$$_{\text{MO}}$ and O$_3$ were measured from the AmeriFlux tower at 4, 15, 21, 25, 34, and 40 m above the ground (Fig. 1). Sampling through each inlet was done sequentially from the 40 m height down to the 4 m height. The sampling inlet at a particular height was selected through a manifold constructed of an array of six two-way solenoid valves with polytetrafluoroethylene (PTFE) body seals (Norgren USA, Littleton, CO, USA). Each sampling interval was 5 min long with gas mixing ratios being determined in this flow every minute. A complete cycle took 30 min, thus there were 48 cycles per day.

Perfluoroalkoxy (PFA) inlet funnels with 1 mm grids (Savillex Co., Minnetonka, MN, USA) were used to prevent large debris from being drawn into the sampling line. Single stage 47 mm PFA filter clamps (Savillex Co.) with 5 mm PTFE membrane filter (Millipore Co., Bellerica, MA, USA) were placed upstream of the instrument inlet to prevent fine particles from interfering with NO$_x$$_{\text{MO}}$ and O$_3$ measurements.

All sampling lines, valves, and filters were conditioned for three days with a flow of 2 L min$^{-1}$ of air containing 200 ppbv of O$_3$ prior to installation. This was done to minimize the loss of O$_3$ in the manifold during subsequent field sampling. Six equal-length 61 m-long PFA Teflon$^\circledR$ tubes with outer diameter of 6.4 mm and inner diameter of 3.6 mm (Parker Hannifin, Cleveland, OH, USA) were used as sampling lines. The excess tubing for the sampling inlets closer to the instruments were coiled and kept in the same housing unit as the instruments.

The flow rate through the DASIBI was 1.8 L min$^{-1}$, and the TEI 42C-TL flow rate was 1.2 L min$^{-1}$. Therefore, the total flow rate through each sampling line was 3 L min$^{-1}$. The theoretical transport time of air samples from the inlet to the gas analyzers was calculated (using tubing dimensions, manifold volume, and purge rate) to be 15 s.
2.3.1 Bias in the sampling lines

All the sampling inlets were intercompared by bringing them to the 15 m height of the tower. This was done to determine the potential measurement bias, as there are inherent differences in the sampling lines. Mixing ratios of NO and O₃ and line pressure were monitored through each line over a 2-day period. The sampling lines varied <0.1 ppbv in NO, <1 ppbv in O₃, and <2 kPa in pressure against each other.

2.3.2 Correcting for the loss of NO in the sampling lines

NO undergoes rapid oxidation through its reaction with O₃ and other free radicals, e.g., hydroperoxy (HO₂) and alkylperoxy (RO₂), in the atmosphere. Therefore, it is necessary to correct for the loss of NO during the transport in the sampling line to the analyzer. Since ambient air HO₂ and RO₂ levels are two to three orders of magnitude smaller than NO (Fuchs et al., 2008), it was assumed they would not affect the sampled NO mixing ratios. The loss of NO due to oxidation by O₃ alone was considered in the correction. In the absence of light, NO is oxidized to NO₂ by

\[
\text{NO} + \text{O}_3 \xrightarrow{k} \text{NO}_2 + \text{O}_2. \tag{R1}
\]

where \(k\) is the reaction rate constant \(k = 1.4 \times 10^{-12}e^{-1310/T} \text{ cm}^3 \text{ molecules}^{-1} \text{s}^{-1}\), for \(T\) between 195 and 308 K; Atkinson et al., 2004).

The reaction rate constants were calculated using ambient temperature recorded when the air sample was collected. The conversion rate of NO was then determined from (R1) using the O₃ mixing ratio measured at any given moment from the same inlet. From this conversion rate, the percentage of NO lost after 15 s, which was the residence time of the air sample in the tube, was calculated. Up to 32% of the NO was converted to NO₂ by O₃, depending on the air sample temperature, O₃ mixing ratio, and line pressure. The NO mixing ratio was corrected for this loss. NO₂,MO mixing ratios were recalculated accordingly by subtracting the correct NO mixing ratio from the 42C-TL’s output of the NOₓ,MO mixing ratio.

2.4 Ancillary data

Meteorological instrumentation on the AmeriFlux tower provided the ancillary data used in the analyses (see Schmid et al., 2003, for information about the instruments). Wind speed, wind direction, turbulence, and incoming solar radiation were measured from the 46 m height of the tower (Fig. 1). Turbulence data (\(u'\) and \(w'\)), measured from the 3-D sonic anemometer, were used to calculate the friction velocity \(u_* = -(u'w')^{0.5} \text{ m s}^{-1}\) above the canopy. Temperatures below and above the canopy were measured from temperature sensors at 4, 21, 34, and 46 m on the tower (Fig. 1). From the temperature data, temperature lapse rates \(\gamma = (T_{z_1} - T_{z_2})/(z_1 - z_2) \text{[°C m}^{-1}]\) through the canopy (4 and 21 m) and above the canopy (21 and 34 m) were calculated to diagnose atmospheric stability.

3 Single column canopy model

3.1 Model description and initialization parameters

A multi-layer atmospheric–biosphere exchange model implemented in a single column chemistry–climate model (SCM; Ganzeveld et al., 2002a, 2006, 2008) was used to evaluate the dynamical behavior of NOₓ and O₃ mixing ratios observed above and within the forest canopy. In contrast to most site-scale atmosphere–biosphere exchange models, the SCM does not use observed meteorological parameters to simulate exchanges. Instead, the SCM determines the dynamic behavior of the system (including the hydrological cycle, boundary layer dynamics, convection, and cloud formation) from initial vertical profiles and surface properties online and reanalysis of weather data (see below).

The atmosphere–biosphere trace gas exchange calculations in the SCM included dry deposition, biogenic emissions, in-canopy chemical transformations, turbulence, and the extinction of radiation within the canopy. All processes were simulated explicitly as a function of the SCM’s meteorological, hydrological, and atmospheric chemistry parameters as well as the canopy structure distinguishing a crown layer and an understory layer. Stomatal and non-stomatal removal in the dry deposition of NOₓ and O₃ (and other gases) is considered in the SCM. The stomatal conductance is calculated from in-canopy radiation profiles and soil moisture status, whereas the non-stomatal removal is a function of cuticular and soil uptake resistances (Ganzeveld and Lelieveld, 1995). The soil biogenic NO emission flux is normally calculated by the SCM according to a modified implementation of the Yienger and Levy (1995) algorithm. However in this study, a range of constant soil NO emission fluxes was applied in a sensitivity analysis with the reference soil NO emission flux being selected based on the observed emission flux of NO from the soil at the site (see Sect. 5.2.1). The model also considers the potentially relevant contribution to canopy NOₓ by photolysis of nitrate that has accumulated on leaf surfaces (e.g. Zhou et al., 2003, 2011). The emissions of biogenic volatile organic compounds (BVOCs; i.e. isoprene and monoterpenes) are calculated in the SCM according to Guenther et al. (1995) or alternatively with the Model of Emission of Gases and Aerosols from Nature (MEGAN; Guenther et al., 2006). In this study, we applied the Guenther et al. (1995) implementation based on observed emission factors at the leaf-scale reported for this site (Ortega et al., 2007, see Table 1). This results in a simulated canopy isoprene emission flux comparable to that reported by Pressley et al. (2005). Note that the canopy does not act as a uniform source of soil or foliar emissions in our model, but instead,

Atmos. Chem. Phys., 13, 7301–7320, 2013 www.atmos-chem-phys.net/13/7301/2013/
the source and sink strengths change with time and height inside the canopy.

The atmosphere–biosphere exchange simulations also require initialization of a selection of biogeochemical parameters, e.g., LAI, canopy height, surface roughness, and the vertical distribution of biomass (expressed by the leaf area density profile). Values used for these parameters to simulate conditions found at UMBS are also provided in Table 1 (and in Fig. 1 for the leaf area density profile).

A key feature of the SCM for site-scale evaluation is the consideration of advection and synoptic weather systems. To consider changes in weather, reanalysis data from the European Centre for Medium range Weather Forecast (ECMWF) were applied, which typically results in realistic representation of the site meteorology (Ganzeveld et al., 2006). For the representation of advection of long-lived trace gases, the simulated boundary layer mixing ratios above the canopy (but not those inside and below the canopy) of NOx and O3 in the SCM were "nudged" (forced) towards observed mixing ratios. In this study, our tracer nudging used a relaxation time of 300 s (for a model time step of 60 s) to capture some of the rapid fluctuations in the observed mixing ratios while avoiding numerical instabilities.

### 3.2 Model run scenarios

Three sets of model runs were performed to evaluate the role of the “biogenic” versus the “anthropogenic” exchange regime in explaining the observed diurnal variability in NOx and O3 at UMBS. All the model runs simulated the month of August observations. Two different model runs focused on the sensitivity to soil NO emissions and on foliage NOx emissions by varying the emission rates by 0, 1, 10, and 25 times the default values (see Table 1). One other additional simulation focused on the role of leaf-scale bidirectional NOx exchanges.

### Table 1. Model input parameters for the UMBS AmeriFlux site.

| Parameter              | Unit   | Value | Reference        |
|------------------------|--------|-------|------------------|
| Canopy height          | m      | 22    | Schmid et al. (2003) |
| Surface roughness      | m      | 2.2   | Schmid et al. (2003) |
| LAI                    | m² m⁻² | 3.5   | This study       |
| Albedo                 |        | 0.15  | Hollinger et al. (2010) |
| Isoprene emis. factor  | µg g⁻¹ h⁻¹ | 50 | Ortega et al. (2007) |
| Monoterpene emis. factor | µg g⁻¹ h⁻¹ | 0.7 | Ortega et al. (2007) |
| Soil NO emis. rate     | ng m⁻² s⁻¹ | 0.07 | Nave et al. (2011) |
| Leaf nitrate conc.     | nmol cm⁻² | 0.83 | Zhou et al. (2011) |
| O3 soil uptake rate    | cm s⁻¹ | 0.25  | Ganzeveld and Lelieveld (1995) |
| Synoptic meteorology   |        | ECMWF | Ganzeveld et al. (2006) |
| Chem. initialization   |        | NOx and O3 | This study |

### Table 2. UMBS 1979–2010 climatological data for months when measurements were taken.

| Month  | Temperature (°C) | Precipitation (mm) |
|--------|------------------|---------------------|
|        | 1979–2010        | 2008                | 1979–2010 | 2008 |
|        | Avg. Min | Avg. Max | Min | Max | Avg. Total (±1 std. dev.) | Total |
| Jul    | 15.1       | 25.7     | 15  | 25.6 | 700 (±150) | 600 |

### 4 Results and discussion of observations

#### 4.1 Meteorological data

We focus our analysis on observations for the months of August and November. These two months were selected since August represented a state of the forest canopy during a period of highest mean seasonal LAI. In contrast, November was chosen as a period after leaf abscission when the forest canopy was at its lowest mean seasonal LAI.

Weather conditions between July and November in 2008 were typical for UMBS. Temperature variations at UMBS were within the ranges of the temperature normal from 1979 to 2010, but total precipitation during this period was lower than the average climatic conditions. This deviation in total precipitation was not considered anomalous or extreme as they were within 1-standard deviation from the mean (Table 2).

Figure 2 shows the seasonal decline in the daily maximum of incoming solar radiation from July to November (i.e. daytime maxima of ~700 W m⁻² and ~250 W m⁻², respectively). Similarly, the daily temperature amplitude above canopy decreased from ~11 °C in July to ~4 °C in November. The daily amplitude in friction velocity tracks the pattern of the incoming solar
The evolution of solar radiation, temperature profile, friction velocity, and the mixing ratio profiles of $\text{NO}_x$, $\text{NO}$, and $\text{O}_3$ at the UMBS AmeriFlux site from 19 July to 21 November 2008. Missing data were due to taking the instruments offline for calibrations and repairs and due to running intercomparison tests of the sampling inlets. Gaps in the chemical data below the canopy from 27 September onward were due to failures in the 4 and 15 m switching valves.

Radiation with decreasing absolute amplitude (difference between daily minimum and daily maximum) over the five-month period with daytime maxima $> 1 \text{m s}^{-1}$, indicating intense daytime turbulent exchange and minimum nocturnal friction velocities $\sim 0.2 \text{m s}^{-1}$ reflecting the suppressed nighttime mixing conditions.

The monthly average daily cycle of solar radiation, temperature lapse rate, and friction velocity for August and November are shown in Fig. 3. Sunrise shifted from 06:00 to 07:30 EST between August and November. Sunset changed from 19:00 EST in August to 17:30 EST in November. The diurnal pattern of the observed above-canopy friction velocity closely followed the solar radiation cycle. Nocturnal friction velocities averaged 0.2 m s$^{-1}$ in August and 0.4 m s$^{-1}$ in November, implying inefficient turbulent mixing in the above-canopy layer at night. Apparent increases in mixing (or friction velocity) were observed $> 30 \text{min}$ after sunrise.

Since no direct turbulence measurements inside the canopy were available, temperature lapse rates from the vertical temperature profile measurements (see Sect. 2.4) were used, in addition to friction velocity, as a proxy for the efficiency of turbulent mixing inside and above the canopy. These layers were considered to be in the stable regime when the temperature lapse rate (for the canopy layer calculated from observed temperatures at 4 and 21 m and for the above-canopy layer calculated from temperatures observed at 21
and 34 m) was below 0.0098 °C m⁻¹, the dry adiabatic lapse rate (denoted as the dashed line in the lapse rate plots; Fig. 3). The atmosphere was considered unstable when the lapse rate was above the dry adiabatic lapse rate, and it was considered neutral when the lapse rate equaled the dry adiabatic lapse rate. The fact that changes in the above-canopy lapse rate, which reflect a transition from stable to unstable mixing conditions, coincide with the observed fast increase in friction velocity (> 30 min after sunrise) supports the use of these lapse rates as proxy for mixing conditions.

The daily amplitude (i.e. the difference between daily minimum and maximum) of the lapse rates decreased with a decrease in solar radiation from August to November. This suggests a decreasing role of buoyancy in turbulent exchanges. The timing when atmospheric stability changed varied as a function of the timing of sunrise and sunset implying also a dependence of the stability regime on solar radiation.

In August, stable atmospheric conditions were observed at night prior to sunrise through and above the canopy, indicating suppressed mixing between the two layers. Within 30 min after sunrise (~06:30 EST), the lapse rates diverge with enhanced mixing conditions in the above-canopy layer but increasing stability in the canopy layer. This response indicates differential heating of the above-canopy layer and the top of the canopy by the incoming solar radiation. The divergence in the lapse rates also indicates that the layers appear to be decoupled. These conditions suppress vertical mixing and cause accumulation of biogenically produced trace gases inside the canopy. As the sun sets (~ 19:00 EST), the temperature lapse rates of the two layers converge to a lapse rate reflecting a stable regime.

In November, the mixing of air mass into the canopy layer was strongly suppressed. The canopy layer remained decoupled from the above-canopy layer throughout the day. The above-canopy layer mixing conditions transitioned from a neutral regime to an unstable regime about 30 min after sunrise (~ 08:00 EST); after sunset (~ 17:30 EST), the above-canopy layer lapse rate transitioned from unstable to neutral mixing conditions. The canopy layer lapse rate remained stable throughout the day.

4.2 Chemical data

4.2.1 Seasonal data

The evolution of NO₃, MO, NO, and O₃ canopy mixing ratio profiles is shown in Fig. 2. Daily amplitudes of NO₃, MO, NO, and O₃ gradually decreased over the season. For instance, the daily amplitude in NO₃ mixing ratios averaged at 1 ppbv in August, then it declined to 0.5 ppbv in November. However, the daily NO₃ maximum increased with time. The daily NO₃ maxima in August ranged between 0.4 and 10 ppbv with a median of 2 ppbv. For NO, its daily amplitude averaged at 0.3 ppbv in August, and then it declined to 0.2 ppbv in November. The daily NO maximum in August ranged between 0.1 and 2 ppbv with a median of 0.3 ppbv. O₃ varied daily by an average of 20 ppbv in August; the daily amplitude decreased to 5 ppbv in November. Its daily maximum ranged between 16 and 66 ppbv with a median of 33 ppbv. These wide ranges in maximum NO₃ and O₃ mixing ratios reflect that this site is influenced by contrasting biogenic and anthropogenic footprints, which may be dependent on season (Cooper et al., 2001).

4.2.2 Diurnal data

Mean diurnal vertical mixing ratio profiles of NO₃, MO, NO, and O₃ for August and for November are shown in the color contour plots in Fig. 4.

- NO₃. The most prominent feature in the diurnal NO₃ cycle is the mixing ratio maximum seen during the early morning hours. Elevated NO₃ was observed throughout and above the canopy, with highest mixing ratios occurring right above the canopy. The diurnal cycle of NO₃ also shows elevated levels of NO₃ throughout the canopy during the night (~ 0.5 to 0.7 ppbv) and lower levels during the latter part of the day (~ 0.3 ppbv). The daily amplitude in NO₃...
mixing ratio and the magnitude of the morning peak are smaller in November than in August. The differences in the nocturnal NO$_x$\textsubscript{MO} mixing ratios between August and November are small.

- NO. The diurnal variation of NO also clearly shows a morning peak above the canopy after sunrise, coinciding with the morning NO$_x$\textsubscript{MO} maximum. This coincidence in timing of the NO peak suggests that this NO is formed from NO$_2$ photodissociation. During the night, despite the previously discussed canopy stratification, observed understory layer NO levels are slightly ($<0.1$ ppbv) larger than the above-canopy layer NO levels, which indicates that soil NO emission may have minor influence on the nocturnal NO profile.

- O$_3$. Ozone increased throughout the daylight hours reaching maxima in the early afternoon. Mixing ratios then began leveling out in the late afternoon and began dropping steadily throughout the evening and night until approximately sunrise time. In the understory layer ozone declined at a faster rate, with ozone loss first occurring right at the forest ground surface, and then from there slowly reaching up to the crown layer. During nighttime ozone mixing ratios above-canopy remained $\sim10$ ppbv higher than in the understory. Between 08:00 and 09:00 EST, the O$_3$ mixing ratio in the understory rapidly increased to levels measured in the above-canopy layer. During the day, from 10:00 to 17:00 EST, the vertical O$_3$ profile evolved uniformly all throughout below and above the canopy, with average O$_3$ maxima of $\sim30$ ppbv. It is notable that the temporal evolution of the nighttime O$_3$ loss near the ground coincided with the nighttime accumulation of NO$_x$\textsubscript{MO}. The main connecting processes here are limited turbulent transport and soil NO emissions explaining the accumulation of NO$_x$\textsubscript{MO} near the soil surface. It also partly explains the decrease in O$_3$ due to a reduced resupply of O$_3$ from higher up in the canopy and surface layer. The resupply of O$_3$ is insufficient to compensate for surface deposition and chemical destruction from reaction with soil-emitted NO. The NO mixing ratios are so small that the titration of O$_3$ would only be a minor term in O$_3$ destruction. Similar to the NO$_x$\textsubscript{MO} diurnal cycle, the daily amplitude in the O$_3$ mixing ratio was smaller in November than in August.

### 4.2.3 Air mass advection

Figure 5 shows a wind-pollution rose of the measured trace gases for August and for November. The length of the wedge corresponds to the frequency of readings from particular wind sectors, while the color corresponds to the magnitude of the pollutant mixing ratios. These wind-pollution roses show that the two predominant wind directions at UMBS are from the southeast (SE; 112°–157°, occurs $\sim20\%$) and the northwest (NW; 292°–315°, occurs $\sim23\%$), and somewhat less, from the west. The wind distribution did not change much between August and November.

The O$_3$-wind rose plots show enhanced O$_3$ being transported during SE–SW winds (112°–247°), most notably for November. During November, elevated O$_3$ levels were also observed during southwest (SW) winds. Relative to O$_3$, NO$_x$\textsubscript{MO} – and to a lesser extent – NO, display a more pronounced wind direction dependency, with elevated levels clearly being associated to SE and SW wind directions. During NW winds, NO$_x$\textsubscript{MO} remained $<1$ ppbv during most times, whereas SE–SW winds consistently were associated with NO$_x$\textsubscript{MO} $>2$ ppbv. There are major urban centers from 350 to 450 km upwind of UMBS in the SE–SW sectors (i.e. Detroit, Milwaukee, and Chicago); these urban areas are likely the source regions for the elevated NO$_x$\textsubscript{MO} transported to the site.

The diurnal breakup of the wind roses (Supplement Fig. S1) shows that the site experienced a diurnal shifting of transport direction. During August, from midnight to 06:00 EST, wind directions were predominantly from the NW and the SE – and occasionally from the W. Winds then gradually shifted to NW and SE–SW. During sunrise (06:00–09:00 EST), wind directions were predominantly from the NW and the SE–SW. From the morning hours to after sunset (09:00–21:00 EST), the frequency of SE–SW winds declined and the majority of the winds came from the W–NE directions. During the late evening (21:00–24:00 EST), the frequency of SE wind directions increased leading back to predominately NW and SE winds.
Fig. 5. Wind-pollution rose for NO$_x$, NO, and O$_3$ determined for (a) August and for (b) November using data from the 46 m level wind sensor and 34 m level gas inlet (see Fig. 1).

The diurnal frequency of wind directions in November varied from August in that the SE-S wind directions stayed more frequent throughout the night and day (Fig. S1). However, from sunrise until after sunset (09:00–21:00 EST), the SE-S wind direction dominance decreased and the frequency of W-NW wind directions increased. The steady frequency of SE-S wind directions in November may contribute to the smaller daily variation observed for NO$_x$, MO, and O$_3$ levels than that observed in August, as winds from these directions tend to bring elevated levels of NO$_x$, MO, and O$_3$ into the region.

The frequency of NO maxima increased during winds from the southerly directions (SE–SW sectors) (06:00–09:00 EST for August; 09:00–12:00 EST for November). Therefore, wind direction seems to be a key factor in the observed variations in gas mixing ratio. Cooper et al. (2001) and Thornberry et al. (2001) also observed higher levels of NO$_x$ and O$_3$ during transport from the SE–SW sectors at UMBS. Conversely, they saw lower levels of NO$_x$ and O$_3$ with NW winds. Back trajectory analysis done by Cooper et al. (2001) and by Alaghmand et al. (2011) showed that air transported to the site during SE–SW winds had passed through the three major urban areas of Detroit, Milwaukee, and Chicago. The lack of NO$_x$ increases during NW winds at night indicates the lack of major local emissions from that wind sector (Thornberry et al., 2001). Consequently, these
Fig. 6. The relationship between sunrise time and the time of observed NO,maxima from 03:00 to 15:00 EST from each sampling inlet. The dashed lines denote the change in time of sunrise over 18 weeks (five months) in 2008 at UMBS (regression: $y = 0.147x + 5.01$, $r^2 = 0.999$). Data for 7 days, starting on 19 July were binned together and are displayed as box-and-whisker plots that depict the mean, median, 25 and 75 percentile, and 5 and 95 percentile values. The solid regression lines were fit to the weekly median data. They denote the average change in time of the NO,maxima observed (regression: (a) $y = 0.135(SE ± 0.0355)x + 7.14(SE ± 0.384)$, $r^2 = 0.478$ and (b) $y = 0.159(SE ± 0.0321)x + 7.46(SE ± 0.348)$, $r^2 = 0.605$).

wind flow analyses support the hypothesis that the NO,max increases seen at UMBS are most likely non-local. The wind-pollution rose and wind rose analyses provide a strong indication that advection plays a major role in the observed morning maxima of NO,max and NO. This will be further substantiated by the sensitivity analysis with the model for this site presented in Sect. 5.2.

4.3 Seasonal shift of the morning NO,max peak

Figure 6 shows the relationship between the time of sunrise and the occurrence of NO,max and NO maxima from July to November for data falling into the 03:00 to 15:00 EST window (Supplement Fig. S2). The time of sunrise was determined when the radiation sensor registered $> 10 \text{Wm}^{-2}$ increase from its nighttime reading ($\sim 0.1 \text{Wm}^{-2}$). The daily sunrise time determinations are not plotted in the figure, but instead the linear regression line fit through the data is shown. The slope of the regression line indicates that the sunrise time shifted $\sim 0.147 \text{hwk}^{-1}$. The time of the NO,max peak was determined from the occurrence of the maximum NO,max reading at all measurement heights, box-and-whisker plots in Fig. 6 show the statistical distribution of the weekly data. The data in Fig. 6a clearly illustrate that the majority of the daily NO,maxima maxima measured from each tower inlet level occurred within a few hours after sunrise. A linear regression line through the median values of the weekly distribution plot of the daily NO,maxima (y = 0.136x + 7.14, $r^2 = 0.478$, where y is sunrise time and x is the weekly bin) indicates that the time of the NO,maximum shifted by $\sim 0.136$ (standard error $\pm 0.0355$) hwk$^{-1}$, similar to the change in sunrise time. The difference in the y-intercept of the two (sunrise and NO,maxima) regression lines can be used as an indicator of the delay of the NO,maximum relative to sunrise; the offset between the two regression analyses yields a result of $\sim 2 \text{h}$.

Figure 6b shows the relationship between sunrise time and the time of maximum NO. The linear regression through the median weekly NO maxima indicates that the time of NO maximum shifted by $\sim 0.159$ (standard error $\pm 0.0321$) hwk$^{-1}$. The lag between sunrise and when the NO maximum occurs is $\sim 2.5 \text{h}$. Notice that this corresponds to a time approximately half an hour after the NO,maximum.

This analysis suggests that the sunrise time and the occurrence of the NO,maximum are closely linked. Consequently, it appears that solar radiation driven processes, such as thermodynamically driven mixing and photochemistry, are the governing processes in the NO,max and NO morning peak occurrence.

5 Model results and discussion

5.1 Model validation and baseline performance

The model was used to simulate the month of August conditions for UMBS. To assess the performance of the model on simulating the main features of the site-specific micrometeorology and chemical boundary conditions, the results of the simulations were compared against observed incoming solar radiation, above-canopy air temperature at 34 m, above-canopy friction velocity (Fig. 7) and the NO,max and O3 mixing ratios (Fig. 8).

Figure 7 shows the SCM was able to simulate the diurnal cycle in radiation and temperature quite well as reflected by a strong correlation between measured and simulated parameter values ($r^2 > 0.95$). However, the model underestimated the daytime maximum friction velocity with a too strong decrease in turbulence intensity simulated by
the model in the afternoon. The latter seems to be due to a misrepresentation of the stability effect for unstable conditions in the SCM. Good agreement between the simulated and observed friction velocity was produced when soil moisture was reduced in the SCM, however, this resulted in simulated temperatures that were 4 °C warmer than observations.

Figure 8 shows the mean and median diurnal cycles of observed and simulated NO$_x$ and O$_3$ mixing ratios. The difference between the mean and median of the observed data is largest during the midday to early morning hours (00:00–06:00 EST). This feature indicates that the influence exerted by occasional events with elevated NO$_x$ is higher during those hours than during the remainder of the day. O$_3$ shows a similar behavior, but with generally smaller differences between the mean and median mixing ratios. In addition, the difference between the mean and median mixing ratios reflects the large temporal variability in the observations of air masses that are enhanced in NO$_x$ and O$_3$ under suppressed mixing conditions.

The simulated diurnal means of NO$_x$ and O$_3$ in Fig. 8 include the contribution by advection as the model was nudged towards the observed above-canopy NO$_x$ and O$_3$ mixing ratios. In other words, the simulations reflect the net result of the explicitly resolved sources, sinks, and vertical exchange processes complemented by the implicitly added “advection” term, which considers changes in chemical composition of air advected to the site. Consequently, the simulated diurnal O$_3$ above-canopy layer mixing ratios (Fig. 8) nearly resemble the observed data as anticipated. In contrast, agreement between simulated and observed mean NO$_x$ is less. The disagreement is greatest in the early morning hours, where simulated NO$_x$ is ~0.3 ppbv smaller compared to the observed peak mixing ratio of ~1.5 ppbv. The fact that the model output shows better agreement with the median data suggests that the morning NO$_x$ peak seen in the August mean data reflects the role of some large peak values associated with individual transport events, which are under-represented by the model. Apparently, these events are not captured by the model for the selected nudging relaxation time of 300 s. This underestimation of the above-canopy layer NO$_x$ peak mixing ratios has obvious consequences for explanation of the observed early morning peak in NO, which we discuss in later sections.

5.2 Sensitivity of the above and within canopy morning NO$_x$ peak

5.2.1 Soil emissions

The sensitivity of NO$_x$, NO, and O$_3$ to soil NO emissions is shown in Fig. 9 as the difference between observed and simulated diurnal mixing ratio profiles (Δ = simulated – observed). The soil NO emission rates tested include a “zero” soil NO emissions flux (0; Fig. 9b), a soil NO emission flux reflecting reported values (0.07 ng N m$^{-2}$ s$^{-1}$; Table 1) 1×, 10×, and 25× increases of the reported values (Fig. 9c, d, e). Note that the 25× case is most likely an unrealistic and
Fig. 9. (a) The observed mean diurnal mixing ratio profiles of $\text{NO}_x$, $\text{NO}$, and $\text{O}_3$. Plots (b) through (e) depict the difference between the observed and simulated mean ($\Delta = \text{simulated} - \text{observed}$) diurnal cycle of the mixing ratio profiles of these gases as a function of soil NO emission for August 2008. (b) Case for “zero” soil emission. (c) Case for default soil emission ($1 \times$, $0.07 \text{ ng N m}^{-2} \text{s}^{-1}$; see Table 1). (d) Case for 10 times the default soil emission ($10 \times$). (e) Case for 25 times the soil emission ($25 \times$).

- The observed nighttime minimum of $\text{NO}_x$ seen in the data (Fig. 9a) near the forest floor points at the role of understory sinks of $\text{NO}_x$, e.g., surface deposition or chemical destruction, of a magnitude larger compared to the soil $\text{NO}_x$ source. The $0 \times$ and $1 \times$ soil NO emission flux simulations resulted in $\text{NO}_x$ profiles that are similar to each other and resemble the observed data. Apparently, $\text{NO}_x$ in the crown and above-canopy layers is rather insensitive to the magnitude of the soil NO emission flux. Even the further increases of $\text{NO}_x$. The observed nighttime minimum of $\text{NO}_x$ seen in the data (Fig. 9a) near the forest floor points at the role of understory sinks of $\text{NO}_x$, e.g., surface deposition or chemical destruction, of a magnitude larger compared to the soil $\text{NO}_x$ source. The $0 \times$ and $1 \times$ soil NO emission flux simulations resulted in $\text{NO}_x$ profiles that are similar to each other and resemble the observed data. Apparently, $\text{NO}_x$ in the crown and above-canopy layers is rather insensitive to the magnitude of the soil NO emission flux. Even the further increases of

extreme case, as it is significantly larger than what was measured (Nave et al., 2011), but it was applied here for the purpose of testing the sensitivity of the model. In addition, these simulations on the soil $\text{NO}_x$ emission influence did not include any $\text{NO}_x$ contribution by foliage emissions. In Fig. 9b–e, a positive delta value implies that the model overestimates measured mixing ratios, while a negative delta value means an underestimation in the simulated mixing ratio.
Fig. 10. Similar to Fig. 9 but for sensitivity towards foliage NO\textsubscript{x} emission. (a) The observed mean diurnal mixing ratio profiles, (b) case for “zero” foliage emission, (c) 1× case, (d) 10× case, (e) 25× case.

The NO soil flux (10× and 25×) did not produce noticeable changes to the NO\textsubscript{x} profiles, except in the understory layer. For the 1× soil NO\textsubscript{x} source, the model predicted NO\textsubscript{x} minimum mixing ratios of ∼ 0.3 ppbv in the understory layer in the early night compared to observed understory NO\textsubscript{x,MO} levels of ∼ 0.7 ppbv. This suggests that the model NO soil flux that we selected for this study – based on observed soil NO emission fluxes – appears to be too small. The 10× simulation of 0.7 ng N m\textsuperscript{-2} s\textsuperscript{-1} actually results in a better agreement between simulated and observed NO\textsubscript{x} inside the canopy.

This finding concurs with Alaghmand et al. (2011), who applied a soil NO flux at UMBS of ∼ 180 nmol m\textsuperscript{-2} h\textsuperscript{-1} (∼ 0.7 ng N m\textsuperscript{-2} s\textsuperscript{-1}) in their work. They based this number on an unpublished dataset from Carleton et al. (2003). We use NO effluxes of ∼ 0.2 µg N m\textsuperscript{-2} h\textsuperscript{-1} (or ∼ 0.07 ng N m\textsuperscript{-2} s\textsuperscript{-1}) measured around the AmeriFlux site in the summer of 2008 by Nave et al. (2011). At sunrise, the model predicted an increase in NO\textsubscript{x} mixing ratios throughout the canopy, whereas the observations showed mainly an increase in NO\textsubscript{x} above the canopy (Fig. 9a, b). Observed NO\textsubscript{x,MO} mixing ratios were as
large as 1.5 ppbv, while the model predicted above-
canopy maximum NOx mixing ratios up to ~1 ppbv,
even for the 10× soil emission case. The model pre-
dicted minimum NOx mixing ratios in the canopy layer
in the late afternoon and evening consistent with
the data from 12:00 to 18:00 EST. For the “unreasonably”
high 25× soil emission case, the model predicted levels
of NOx near the forest surface about 1 ppbv larger than
observed during the night. Yet even with this high soil
NOx flux, there was no improvement in the representa-
tion of the above-canopy early morning NOx peak.

- NO. For all soil NO flux scenarios, the daytime NO
mixing ratio profiles were slightly overestimated in the
canopy layer. The model simulated NO canopy mixing
ratios reasonably well for all soil NO emission cases
with differences of <0.05 ppbv. However, the model
underestimated the nocturnal NO mixing ratios in the
crown and above-canopy layers by >0.05 ppbv. The
25× soil emission case shows some enhancement in the
simulated NO mixing ratios in the understory layer, but
the NO increase is only confined to the understory layer,
whereas the observations showed nocturnal NO mixing
ratios of ~0.1 ppbv throughout the canopy. The simul-
ations show a similar above-canopy NO peak as seen
in the data. However, the NO maxima simulated by the
model are 0.05 to 0.1 ppbv lower than observed. During
afternoon hours, the model over-predicts NO by 0.05–
0.1 ppbv throughout the canopy. Again, the increase in
the soil NOx flux exerted little influence on the above-
canopy morning NOx peak formation.

- O3. Regardless of the changes in soil emission rates,
the model reasonably predicted absolute O3 levels, the
mixing ratio profiles of O3, and the timing of the breakup
of the nighttime O3 gradient at sunrise. The SCM underes-
timated O3 mixing ratios in the understory layer at sun-
rise (06:00–09:00 EST) and during the late evening and
nighttime (18:00–24:00 EST). This effect may be re-
lated to an overestimation of canopy sinks (e.g., foliage
or soil deposition, chemical destruction) or an under-
estimation of downward turbulent transport inside the
canopy (Fig. 7, Sect. 5.1).

5.2.2 Foliage emissions

Hanson and Lindberg (1991) compiled a report showing evi-
dence for deposition of NOx onto surfaces such as leaves,
bark, and soil. It is possible that residual NO2 could be
“trapped” in the canopy via deposition onto leaves. At sun-
rise, the deposited NO2, either as NO2 or in the form of
HONO or HNO3, would undergo photolysis to ultimately
create NO above the canopy. The sensitivity of NOx, NO,
and O3 to a foliage NOx emission flux is shown in Fig. 10.
The foliage NOx emission rates are based on leaf nitrate con-
tent reported by Zhou et al. (2011) (see Table 1), where we
assumed that photolysis of nitrate on the surface of the leaves
results in foliage NO2 and HONO emissions (hence, referred
to as foliage NOx emissions). The simulated cases include
a “zero” foliage NOx emissions flux (0×; Fig. 10b), an as-
sumed foliage NOx emissions flux based on the reported leaf
nitrate value (0.83 nmol cm−2, Table 1) (1×; Fig. 10c), and
increased foliage NOx emission fluxes based on 10 and 25
times increases in the reported leaf nitrate levels (10× and
25×, see Table 1; Fig. 10d, e). In Fig. 10b–e, a positive delta
value means that the model has overestimated the mixing ra-
tio, while a negative delta implies an underestimation in the
simulated mixing ratio value.

- NOx. The increase in foliage NOx emissions causes in-
creasing NOx mixing ratios during the sunlit daytime
hours, with most of this NOx growth seen in the under-
story layer where NOx accumulates due to slower re-
moval by transport, chemistry, and deposition. For the
10× and 25× simulation cases, resulting NOx mixing
ratios are far above the observed data. These compar-
isons do not provide evidence that foliage emission have
a determining influence on the above-canopy morning
NOx,MO peak.

- NO. NO results are similar to NOx, except that the ef-
effect on NO is not constrained to the understory layer
but is notable throughout the canopy and above-canopy
layer. Yet again, increasing the foliage NOx emission
rate above the default value yields atmospheric NO lev-
els that exceed the observations.

- O3. Increasing the foliage NOx flux had little influence
on the O3 mixing ratios. Likewise to the sensitivity of
soil NO emissions (Sect. 5.2.1), the underestimation
of O3 in the understory layer during sunrise and late
evening hours seen in the comparison between the ob-
erved and the simulated values is insensitive to changes
in foliage NOx flux.

5.2.3 Leaf-scale bidirectional exchanges of NO2

To further diagnose the contribution of the different pro-
cesses that influence the diurnal variability in NOx,MO, the
simulated process tendencies for the default conditions (ex-
pressed in ppbv hr−1) are shown for the crown layer in
Fig. 11a, and for the understory layer in Fig. 11b. From
Fig. 11a it can be inferred that changes in the crown layer
NOx mixing ratio are dominated by daytime downward tur-
bulent transport into the canopy (shown as positive turbu-
ulence tendency). This downward transport compensates for
chemical destruction and dry deposition. Figure 11b also
shows the contribution from soil emission, which provides
a constant but relatively minor contribution in the overall
net tendency. This confirms the low sensitivity of NOx at
UMBS to the soil emission source. It is interesting to see
that the net tendency after sunrise appears to be controlled
Fig. 11. Simulated August mean diurnal cycle in NOx process tendencies (ppbv h\(^{-1}\)) of emissions (red solid line), dry deposition (green long-dashed line), chemistry (blue short-dashed line), turbulent transport (maroon dashed line), and the net tendency (black solid line) (a) in the crown layer and (b) in the understory layer.

Fig. 12. Similar to Fig. 11a but showing the simulated August mean diurnal cycle in NOx process tendencies (ppbv h\(^{-1}\)) for the crown layer for an assumed NO\(_2\) compensation point of 1 ppbv.

tolysis, described in Sect. 5.2.2, which always functions as a source term (i.e. always resulting in a positive NO\(_x\) flux). The NO\(_2\) gas exchange is a pure physical process, solely driven by ambient air mixing ratio levels. The compensation point mechanism was added on top of the foliage emission flux in these simulations.

A leaf-scale NO\(_2\) compensation point of 1 ppbv was used in the simulation. This compensation point value was selected after conducting a sensitivity analysis (not shown) aiming to reproduce the observed trace gas levels throughout the day. With inclusion of this NO\(_2\) compensation point in the SCM, a relatively large NO\(_x\) foliage emissions flux, exceeding the dry deposition term, was simulated (Fig. 12). Having this compensation point reverses the net tendency at ~06:00 EST from a negative (see Fig. 11a) to a positive tendency (Fig. 12). Comparing Fig. 11a and Fig. 12, one would expect the turbulence tendency to be the same for both simulations. However, inclusion of a NO\(_2\) compensation point changes the sources and sinks; consequently, this changes the mixing ratios in the simulation. Therefore, the turbulent transport tendency (along with the concentration gradients and fluxes) will change accordingly, but the turbulent transport term, derived from the eddy diffusivity, in the SCM remained the same for the two cases. The simulated increases in atmospheric NO\(_x\) and NO mixing ratios associated with this 1 ppbv NO\(_2\) compensation point is illustrated in Fig. 13. First of all, there is an improved simulation of absolute mixing ratios with maximum increases in NO\(_x\) of ~0.3 ppbv and in NO of ~0.05 ppbv in the crown layer (Fig. 13c). Moreover, the better match in the timing of the NO\(_x\) and NO maxima associated with these changes in leaf-level NO\(_2\) exchange (i.e. the NO\(_2\) compensation point) points towards this effect having a possible important contribution to the above canopy morning NO maximum.

At this time, there are no leaf-level experimental data available from this site to further substantiate the assumption
that NO$_2$ compensation point might play an important role in the dynamics of NO$_x$ at UMBS. However, after demonstrating the significant changes in absolute mixing ratios as well as temporal variability in NO$_x$, studies of the role of this foliage source of NO$_x$, warrant further investigation.

5.3 Synthesis

Based on our air mass transport analysis, we conclude that advection and entrainment of polluted air masses in addition to local scale atmosphere-biosphere exchanges play an integral role in the observed NO$_x$ dynamics at UMBS. Advection of NO$_x$ and O$_3$ in the model was achieved by nudging the model layer above the canopy towards observation. Nudging the model allows us to assess the effects that local processes and non-local sources of pollution have on the temporal variability in NO$_x$ and O$_3$ within and below the canopy under observed conditions. As such, our study – including the presented model analysis – adds to that by Alaghmand et al. (2011), who analyzed the relative contributions of in-canopy air versus the supply of NO$_x$ and other pollutants through advection and entrainment of residual layer air masses at UMBS solely based on observations.

The 3 h lag in the NO maximum after sunrise suggests that this maximum could be associated (1) with entrainment of polluted air masses higher up in the residual layer or (2) with advection of pollution from an anthropogenic source area at an upwind distance resembling a 3 h transport time. Observed vertical gradients and meteorological data imply mixing ratios in the understory layer are depleted by chemical reaction and deposition and replenished by downward mixing of elevated mixing ratios from above the canopy. Alaghmand et al. (2011) suggested that downward mixing of localized polluted air masses did not contribute to the morning NO$_x$ maximum. Rather, they proposed that long-range transport of aged polluted air masses explain the observed NO$_x$ peak. In cases where the air mass did not flow through major sources of NO$_x$, they attributed the morning NO$_x$ maximum to local soil NO$_x$ emissions. Alaghmand et al. (2011) found that in the early morning hours (hours prior to 06:00 EST) $\sim 57\%$
of the time. NOx mixing ratios were greater below than above canopy. Thus, they postulated that there is sufficient accumulation of NOx below canopy and if this NOx was to mix upward with the breakdown of the nocturnal boundary layer, it would contribute to the observed NOx maximum at sunrise. However, our observations and simulations showed little or no accumulation of NO in the understory layer, thus providing no evidence that soil NO emissions could influence the morning NOx maximum.

Munger et al. (1996) showed that HNO3 could mix into the canopy layer at sunrise with the breakdown of the nocturnal boundary layer, but efficient deposition of total oxidized nitrogen (NOy) would prevent HNO3 to accumulate in the understory layer. If there was a sufficient amount of HNO3 (or HONO) present on the surface of the canopy leaves, then photolysis upon sunrise could account for some of the increase in NOx mixing ratios during that time. Our simulations showed that foliage emissions of NOx via nitrate photolysis alone could not explain the observed NOx maximum in the morning. In fact, it appears that the diurnal behavior is not properly represented including this foliage NOx source from nitrate photolysis. However, when considering the NO2 compensation point at the leaf-scale of the canopy, our simulated results were closer to the observed, suggesting that the NO2 compensation point mechanism may be important in explaining the dynamics of NOx at UMBS.

The below-to-above canopy O3 dynamics in August reflects the combined role of in-canopy and boundary layer photochemistry and turbulent transport resulting in entrainment of free tropospheric air masses enhanced in O3 compensating for canopy deposition. During the night, O3 titration through its reaction with NO reduces below canopy O3 levels. However, the observed NO levels below canopy were generally about two orders of magnitude smaller compared to O3 implying that other sinks, e.g., ozonolysis of very reactiveBVOCs (Kurpius and Goldstein, 2003), and dry deposition likely contribute to the apparent significant ozone sink in the understory. Bryan et al. (2012) also conducted a model study for this site and concluded that deposition was the primary sink for ozone in the canopy layer.

The simulation of dry deposition in our model is based on the selected fixed cuticular, soil and other substrate resistances according to Ganzeveld and Lelieveld (1995). Recent studies (e.g. Zhang et al., 2002; Altimir et al., 2004, 2006) have shown a potentially important role of non-stomatal uptake of O3 as a function of moisture conditions. To investigate the potential impact of such an enhanced removal by wet surfaces, we conducted an additional simulation in which we used the relative humidity (RH) of the simulated surface layer as a proxy for canopy wetness (Altimir et al., 2006) (note that the model actually calculates the wet skin fraction, i.e., the fraction of vegetation that is wetted by dewfall and rain interception). We introduced a reduced cuticular resistance scaled between the default maximum resistance of 105s−1m−1 for a RH < 70% and an assumed leaf-scale minimum cuticular resistance of 1500s−1m−1 for a RH > 95%; in between a RH of 70–95%, a linear scaling between the minimum and maximum resistance was applied. Selection of the minimum cuticular resistance is based on the reported canopy-scale VdO3 between 0.1 and 0.3 cm s−1 (Altimir et al., 2006, and references therein), resembling a canopy uptake resistance on the order of 500s−1m−1, and an LAI for this site on the order of 3–3.5 m2 m−2. Applying this substantially smaller non-stomatal uptake resistance as a function of RH resulted in simulated canopy O3 mixing ratios, that were up to ~ 13 ppbv smaller compared to the observed mixing ratios during nocturnal conditions. This indicates that this enhanced O3 removal mechanism is not a good representation for this site. However, it is known that non-stomatal ozone conductance represents over half of the total ozone flux at this site (Hogg et al., 2007). It is uncertain what drives the non-stomatal uptake of ozone. Kurpius and Goldstein (2003) suggested that this would be driven by temperature dependence in BVOC emissions in which ozone scavenging BVOCs would remove the ozone. In any case, our measurements do not allow us to partition between stomatal and non-stomatal uptake, and determining the drivers of the non-stomatal uptake is beyond the scope of this study.

Differences between the daytime August and November O3 mixing ratios could reflect the combined effect of different boundary layer dynamics (see Fig. 3), with a reduced entrainment of free troposphere air masses enriched in O3 in November compared to August. A reduced photochemistry in November is partly compensated by a reduced November O3 sink associated with a decrease in dry deposition.

In summary, the observed morning NO maximum appears to be caused by the photolysis of NO2 and leaf-level bidirectional exchanges of NO2 may contribute to the observed NOx dynamics. NO2 arises primarily from anthropogenic sources, and it is transported into the UMBS canopy by advection and entrainment.

6 Summary and conclusions

The dynamical behavior in NOx and O3 at a deciduous forest site at UMBS was investigated. We observed consistent occurrences of NO and NOx,MO diurnal maxima above the canopy during the five-month measurement period from midsummer to late-fall. These occurrences continued after leaf fall, which implies that the observed diurnal maxima of NO and NOx,MO are not controlled exclusively by biochemical processes in the canopy, but they are influenced also by processes not linked to the canopy. To determine the possible controls on the observed NO and NOx,MO diurnal maxima, we combined concentration gradient and micrometeorological measurements with a canopy-boundary layer exchange model for a detailed analysis of the role of local sources and sinks (i.e. biogenic emissions, dry deposition, and chemistry) and turbulent transport versus the role of advection.
According to our data analyses, the morning NO maximum at UMBS is associated with the increase in solar radiation after sunrise and most likely due to the photolysis of NO$_2$. The model simulations indicate that soil NO emissions are not sufficient to explain the morning NO$_x$ peak concentrations. Also, sensitivity analyses with the SCM showed that foliage NO emission located in a relatively remote area far from major urban sites, most of the NO$_x$ seen at UMBS is of anthropogenic origin and that its impact is significant on the chemistry observed at the site.

To understand the dynamics of NO$_x$ at UMBS, leaf-scale processes should be considered in addition to large scale advection, boundary layer dynamics, and entrainment. Therefore, more studies on leaf-scale processes and their effect on the biosphere–atmosphere exchange are needed for further evaluation of this question.
