INTRODUCTION

Restoration of coronary flow after an ischaemic event is mandatory in order to preserve cardiac function. However, reperfusion itself may result in mechanical, electrical and/or viability alterations in excess to that produced by ischaemia alone. The resulting tissue damage is named ischaemia/reperfusion (I/R) injury and depends mainly on the duration of
the ischaemia. If the ischaemic period is brief, I/R can cause reversible contractile dysfunction and arrhythmias (stunned heart), while in its severest form (prolonged ischaemia) I/R leads to cell death.

The endoplasmic reticulum (ER) is the main organelle involved in the proper folding and sorting of newly synthesized secretory and membrane proteins. Events occurring during I/R such as depletion of oxygen/glucose supply, Ca2+ mis-handling and reactive oxygen species (ROS) accumulation interfere with ER correct function leading to the accumulation of unfolded/misfolded proteins, a condition referred to as ER stress.2,3 ER stress triggers the unfolded protein response (UPR) consisting in various transcriptional and translational pathways which orchestrate the restoration of ER homeostasis in three distinct ways: (a) by upregulating the transcription of chaperones, (b) by attenuating the translation and therefore protein accumulation into the ER and (c) by facilitating retrotranslocation of proteins from the ER to the citosol for ubiquitin-proteasome-dependent or autophagy-lysosome-dependent degradation.2,4 However, during prolonged or overwhelming protein-folding stress, the adaptation of UPR starts to fail and a switch to pro-apoptotic signals generates the death of irreversible damaged cells.

The UPR signalling cascade relies on three independent but overlapping ER stress sensors: protein kinase RNA-like ER kinase (PERK), activating transcription factor 6 (ATF6) and inositol-requiring enzyme 1 (IRE1α).2,5 Under non-stressed conditions, these proteins are inhibited by the binding of glucose-regulated protein of 78 kDa (GRP78), an ER resident chaperone. Upon ER stress, the unfolded proteins recruit the chaperone away from the sensors leading to the activation of specific downstream pathways. PERK triggers the phosphorylation of the eukaryotic initiation factor 2 (eIF2α), which inhibits global protein synthesis, except for some specific proteins such as activating transcription factor 4 (ATF4) and GRP78. Prolonged or extreme ER stress uses ATF4 to increase CCAAT/enhancer-binding protein homologous protein (CHOP) transcription, an apoptotic signalling molecule. ATF6 is activated by cleavage after being transported to the Golgi, and then is translocated to the nucleus where it selectively increases the expression of chaperones and ER-associated degradation (ERAD) proteins, as well as X-box-binding protein 1 (XBP1). Finally, IRE1α due to its endoribonuclease activity mediates the unconventional splicing of the XBP1 mRNA for its translation into an active transcription factor, the spliced XBP1 (sXBP1), which reinforces the gene expression of chaperones and ERAD proteins. In addition, IRE1α stimulates the stress-activated c-Jun amino-terminal kinase (JNK) and activates the ER localized caspase-12, connecting ER stress with apoptosis and autophagy. Overall, the UPR controls cell survival as well as the execution of apoptosis. The fine-tuning of these processes will decide the ER stress-induced cell fate.

In the heart under severe ischaemic insult, the activation of all three branches of the UPR has been reported.6 The participation of ATF6 was demonstrated by a substantial amount of research using both pharmacologic and genetic approaches in in vitro and in vivo studies.7-10 Overall, the evidence supported a cardioprotective role of this pathway against I/R damage mediated not only by inducing genes that encode ER resident chaperones and components of the ERAD machinery,11,12 but also through the ATF6-induced expression of SERCA2a and antioxidant genes, allowing a link between ER stress and oxidative stress and Ca2+ handling.13,14 Regarding the PERK branch, Miyazaki et al showed that I/R activates the phosphorylation of eIF2α and increases CHOP gene expression.3 Moreover, they demonstrated that hearts from CHOP-deficient mice exhibited markedly reduced reperfusion injury when compared with wild-type mice, associated to a decreased number of apoptotic cardiomyocytes, suggesting a deleterious effect of CHOP-mediated pathway on the development of I/R injury. Finally, the specific role for the IRE1α signalling was addressed in gain- and loss-of-function studies of its downstream component sXBP1. Wang et al15 demonstrated that sXBP1 expression is necessary and sufficient to protect the heart from I/R injury. Although it is known that persistent stress can cause the activation of pro-apoptotic pathways of the IRE1α cascade,16,17 this has not yet been clarified in the context of myocardial I/R injury.

All these studies confirmed that UPR is triggered in the myocardium under those ischaemic challenges that lead to cell death. However, there is still a gap for the occurrence of ER stress in an ischaemic condition not associated with irreversible cell damage. This prompted us to investigate whether UPR is activated in the stunned heart and to examine the signalling pathways involved. In addition, we evaluated the functional impact of the ER stress response in the post-ischaemic cardiac performance of the stunned heart.

![FIGURE 1](image-url) mRNA expression of ER stress markers in the stunned heart. Total results of mRNA expression levels of sXBP1, total-XBP1, GRP78 and CHOP in non-ischaemic hearts (Control) and hearts subjected to I/R 20/30 or I/R 30/60. Data represent means ± SE of 7-14 hearts/group. *P < .05 respect to Control. #P < .05 vs I/R 30/60
RESULTS

2.1 ER stress in the stunned heart

To ascertain whether UPR is triggered in the stunned heart, the relative abundance of mRNA encoding several ER stress markers (sXBP1, total-XBP1, GRP78 and CHOP) was analysed by real-time quantitative RT-PCR (Figure 1). Compared with non-ischaemic hearts, hearts subjected to I/R 20/30 showed a significant increase in sXBP1, total-XBP1 and GRP78 mRNA levels. This enhancement was similar to that detected in hearts subjected to I/R 30/60. However, the levels of CHOP mRNA, which were significantly elevated in hearts with irreversible I/R damage, showed no increase in stunned hearts when compared with non-ischaemic hearts. To test whether this lack of increase in CHOP mRNA levels was due to the reperfusion time point at which the analysis was performed, a group of hearts was subjected to a prolonged reperfusion period of 60 minutes following the 20 minutes of ischaemia. Once again, the expression of CHOP mRNA levels remained unchanged with respect to non-ischaemic hearts, while mRNA levels of the adaptive UPR genes were comparable to those obtained after I/R 20/30 (Figure S1). These results suggest that the intensity of the ischaemic insult, and not the reperfusion time, what determines the outcome of the ER stress response. Taken together, the results at the level of mRNA indicate that the UPR is triggered in the stunned heart, with signalling pathways belonging to the adaptive cascades for cell survival. The main difference between the UPR induced by the two I/R protocols was that in hearts with severe I/R injury, the adaptive UPR signals were concurrently activated with the transcriptional induction of CHOP, a key pro-apoptotic component of the ER stress response.

Since prolonged simulated ischaemia alone has been shown to efficiently activate certain ER stress response genes in neonatal rat cardiac myocytes,7,9 we investigated if 20 minutes of ischaemia were sufficient to upregulate the expression of GRP78 and sXBP1 in the ex vivo perfused heart. As depicted in Figure S2, ischaemia elicited an increase in GRP78 but not in sXBP1 mRNA levels. These results support the concept that UPR pathways have different temporal dynamics. Our findings do not allow us to conclude if more time of ischaemia alone or conditions provided by reperfusion, are required for the induction of sXBP1.

We then studied proteins involved in the initial phase of ER stress response18: the phosphorylation of eIF2α, associated to the rapid halt in protein translation and the activation of JNK and caspase-12, components of the ER stress-mediated apoptotic pathway (Figures 2A and 2). The phosphorylation of eIF2α increased in stunned hearts with respect to non-ischaemic hearts. No changes were detected in total eIF2α (Figure S3A and C). The phosphorylation of JNK increased in both I/R groups, with values significant higher in the I/R 20/30 than in the I/R 30/60. Finally, caspase-12 was similarly activated under mild and severe I/R injuries compared to the non-ischaemic group.

The results obtained at the protein level in the stunned heart demonstrate the activation of an early marker of the adaptive UPR branch (eIF2α phosphorylation) and unexpectedly, the
**FIGURE 3** Assessment of cell apoptosis in hearts subjected to I/R. (A) Representative images of TUNEL (red dots) to denote the apoptotic cells, DAPI (blue dots) to mark the nuclei and the merging of both in a bright field image obtained from left ventricular sections of non-ischaemic hearts (Ctrl) and hearts at the end of I/R protocols. Yellow arrows highlight TUNEL-positive nuclei. (B) Quantitative analysis of TUNEL-positive nuclei. Data represent means ± SE of 4–8 hearts/group.

**FIGURE 4** Assessment of permanent cardiac damage in hearts subjected to I/R. (A) Representative images of TTC-stained rat heart sections obtained from non-ischaemic hearts (Control, Ctrl) and hearts subjected to I/R 20/30 or I/R 30/60 and total results of the infarct size expressed as percentage of total ventricle area. (B) Total results of lactate dehydrogenase (LDH) release measured in Pre-Ischemia (Pre-Isch) and after 10 minutes of reperfusion in I/R protocols. Data represent means ± SE of 4–10 hearts/group. *P < .05 vs Control. #P < .05 vs I/R 30/60.
simultaneous activation of two proteins generally related to pro-apoptotic cascades of the UPR (JNK and caspase-12).

2.2 | I/R-induced injury

To assess whether the activation of pro-apoptotic cascades was leading to cell death in hearts subjected to I/R 20/30, we performed TUNEL staining of left ventricular sections obtained at the end of the protocol. Figures 3A and 3 showed that the number of myocytes undergoing apoptosis (TUNEL-positive nuclei) were not different from non-ischaemic hearts, even when the reperfusion period was extended to 60 minutes following the 20 minutes of ischaemia. Meanwhile, TUNEL-positive nuclei significantly increased in hearts subjected to I/R 30/60. Permanent cardiac damage was examined by TTC staining. The results showed an infarct size of 58.2 ± 6.3% in hearts subjected to the severe I/R injury, while the necrotic area was negligible in stunned and non-ischaemic perfused hearts (Figure 4A). Additionally, cell cytotoxicity was evaluated by LDH release assay. As depicted in Figure 4B, the increase in LDH levels in the perfusate obtained at 10 minutes of reperfusion, attained statistical significance only in those hearts subjected to the protocol of irreversible I/R injury. These results were in agreement with the TTC staining findings and are consistent with the generally accepted understanding that in rats an ischaemic period up to 20 minutes causes minimal tissue damage.1

In the absence of detectable apoptosis, the overall results suggest that the UPR maladaptive pathways triggered by the stunned heart are either ineffective or overwhelmed by the pro-survival pathways.
2.3 Functional impact of UPR in the stunned myocardium

To establish the functional impact of the ER stress on the post-ischaemic recovery of the stunned myocardium, we used the chemical chaperone, TUDCA. We first tested the ability of TUDCA to alleviate the activation of the UPR in our experimental condition by measuring the expression of ER stress-related genes in hearts subjected to I/R 20/30 in the presence of the chaperone. As shown in Figure 5A, TUDCA significantly prevented the increase in sXBP1 and GRP78 mRNA levels detected in I/R-untreated hearts, confirming the effectiveness of TUDCA as a UPR inhibitor. Figures 5B-D shows the time course of different mechanical parameters used to characterize left ventricular function during I/R. TUDCA treatment significantly improved the post-ischaemic recovery of contractility, measured by the maximum rate of pressure development (+dP/dt) and accelerated relaxation, evidenced by the shortening of half-relaxation time (t1/2), compared with the untreated hearts (Figures 5B and 5). In addition, TUDCA mitigated the reperfusion-induced contracture, as indicated by the reduction of left ventricular end diastolic pressure (LVEDP, Figure 5D). To confirm the cardioprotective role of ER stress inhibition in the stunned heart, we studied the effects of another chemical chaperone, 4-PBA. As shown in Figures 6A-D, the prevention of I/R-induced enhancement of UPR markers by 4-PBA occurred in association with increased contractile performance, accelerated relaxation and decreased reperfusion-induced contracture. Neither TUDCA nor 4-PBA affected basal mechanical function (Table 1 in Supporting Information).

Since TUDCA and 4-PBA have been reported to show cytoprotective actions by reducing the oxidative stress, we evaluated their effects on the I/R-induced oxidative stress. Lipid peroxidation products (thiobarbituric acid-reactive substances, TBARS) were measured as a marker of oxidative injury. As shown in Figure 6E, the amount of TBARS significantly increased after I/R in the untreated group with respect to non-ischaemic hearts, and this was unaltered by TUDCA or 4-PBA administration. Overall, the results indicate that inhibition of the UPR can improve the post-ischaemic recovery of cardiac mechanical function. Moreover, the protection exerted by TUDCA and 4-PBA against I/R-associated mechanical dysfunction seems to be independent of the oxidative stress.

3 DISCUSSION

Brief periods of myocardial ischaemia not causing irreversible damage may nevertheless result in a transient impairment of contractile function and in the appearance of lethal arrhythmias upon reperfusion. The molecular mechanisms that have been proposed to underlie this potentially serious deterioration of myocardial performance include reactive oxygen species (ROS) generation and intracellular Ca2+ overload. These two cellular perturbations are also known to interfere with ER proper function triggering the UPR. In the context of severe I/R injury, evidence has been presented that ER stress can either mitigate or cause myocardial damage. However, there have been no studies examining the ER stress response and the cellular processes regulated by ER stress in the stunned myocardium. The data presented here demonstrated that an ischaemic insult of 20 minutes in perfused rat hearts is sufficient to trigger the UPR. Analysis of mRNA and protein levels of different ER stress effectors allowed us to suggest that all three branches of the UPR are activated in the stunned heart: increased phosphorylation of eIF2α is a molecular readout of PERK activation; overexpression of unspliced XBP1 is a specific marker of ATF6 activity and elevated sXBP1, the consequence of IRE1α endoribonuclease activity. Furthermore, IRE1α pathway could also be involved in elevation of both, JNK phosphorylation and cleavage of caspase-12. Finally, increased GRP78 mRNA level, a well characterized biomarker of ER stress, could not be attributed to a specific UPR branch since it is a target gene of all the three axes. Most of these UPR downstream signals are involved in events that target cellular protective responses. However, at first sight it seems contradictory that caspase-12 and JNK, two molecules initially linked to ER-induced apoptosis, appeared activated in an I/R injury with minimal or no myocardial damage. Different experiments using cells lacking caspase-12 or in caspase-12 deficient mice demonstrated that the ER-resident caspase does not actively contribute to apoptosis. Caspase-12 appears to have very limited enzymatic activity and specifically directed towards its own proenzyme and not to any other caspase of the apoptotic cascade. Thus, caspase-12 processing may constitute just an epiphenomenon of the UPR. Nevertheless, it is still often used as a marker for ER-stress. The role of JNK activation in the ER stress response has also been reconsidered. JNK signalling is currently accepted to have functionally distinct phases with opposing effects in the ER stress response. In contrast to the pro-apoptotic late phase, the early and transient phase of JNK activation has been reported to protect ER-stressed cells from executing apoptosis. The mechanisms involved in this pro-survival signalling response include the JNK-induced expression of anti-apoptotic genes and the JNK-mediated induction of autophagic flux. Taken together, these reported results allow us to speculate that under the sub-cytotoxic ER stress induced by the stunned heart both, caspase-12 activation and JNK-phosphorylation, are either not playing any role in apoptosis or leading to protective cascades during the ER stress response.

with genetic manipulation of UPR central genes or by the use of pharmacological tools such as the chemical chaperones, 4-phenylbutyric acid (4-PBA) and tauroursodeoxycholic acid (TUDCA). 46,47 In perfused rat hearts submitted to a severe I/R injury (ischaemic period of 30 minutes or longer), the inhibition of the UPR by 4-PBA or TUDCA, decreased the number of apoptotic myocytes and diminished the infarct size, alleviating the deterioration of cardiac contractile function.19,36-39 In some cases, these beneficial effects were associated to a reduction in the oxidative stress.19 The present results show for the first time that during a mild I/R injury, with minimal or no cell death, the inhibition of the ER stress response is also cardioprotective, suggesting that the UPR is contributing to the decline of the post-ischaemic mechanical performance of the stunned heart. Since the TUDCA and 4-PBA-induced contractile improvement occurred despite not having any effect on the I/R-induced oxidative stress, it is tempting to speculate that UPR inhibitors are ameliorating the intracellular Ca2+ mishandling occurring upon reperfusion.

Previous studies from our group performed in Langendorff-perfused mouse hearts subjected to an I/R-stunned protocol showed a sarcoplasmic reticulum (SR) Ca2+ depletion coupled to a decreased Ca2+ transient occurring upon reperfusion.40 The findings suggest that this SR Ca2+ leak is responsible at least in part for the cytosolic Ca2+ overload at the onset of reflow and thus, to the contractile dysfunction described for the stunned heart. Moreover, thapsigargin or tunicamycin, two well-known ER stressors, have been reported to induce the release of Ca2+ from the ER in different cell lines.41-43 Therefore, it is interesting to speculate that the I/R-induced ER stress is contributing to the SR/ER Ca2+ loss and in consequence to the intracellular Ca2+ alterations and contractile impairment upon reperfusion. At this respect, it has been suggested that the translocon, one of the ER Ca2+ leak mechanisms,44 mediates the ER Ca2+ unloading that occurred in response to ER stress inducers.41,43 The translocon is a protein complex involved in protein transport that under non-stress conditions is sealed from the luminal side by GRP78 but when the chaperone is recruited by the unfolded proteins, it behaves as a Ca2+ channel.41,43,45 Whether the translocon is present in cardiac muscle and whether it plays a functional role during the I/R-induced ER stress, remains to be determined.

In conclusion, our results showed that ER stress is triggered in the stunned heart and contributes to the contractile dysfunction. Furthermore, our data suggest that prevention of the ER stress by the use of chemical chaperones could be a therapeutic tool to limit the deterioration of the contractile function in clinical settings such as spontaneous reperfusion after revascularization therapies or after thrombolysis subsequent to acute myocardial infarction.46

4 | MATERIALS AND METHODS

4.1 | Animals

The experiments were performed in male Wistar rats (200-300-g body weight). Animals were inbred and maintained in our animal facilities in accordance with the Guide for the Care and Use of Laboratory Animals (NIH, 2011). The protocols were approved by the Institutional Animal Care and Use Committee (CICUAL) of School of Medicine, National University of La Plata, Argentina (Nro T05022014).

4.2 | Ex vivo experiments: Intact hearts

During this study, animals were anaesthetized by intraperitoneal injection of Ketamine/Xylazine (75/10 mg/kg). The dose was sufficient to produce a surgical level of anaesthesia (loss of pedal withdrawal reflex) without profoundly affecting the cardiovascular function. Central thoracotomy and heart excision were performed immediately after phase III of anaesthesia was reached. Isolated hearts were perfused at constant temperature (37°C), heart rate (4 Hz) and flow (14 mL/min) with physiological bicarbonate buffer solution (BBS) composed by (in mM): 128.3 NaCl, 4.7 KCl, 1.35 CaCl2, 20.2 NaHCO3, 0.4 NaH2PO4, 1.1 MgSO4, 11.1 glucose and 0.04 Na2EDTA. This solution was equilibrated with 95% O2-5% CO2 to give a pH of 7.4, as described.47 The mechanical activity of the heart was assessed by introducing into the left ventricle (LV) a balloon connected to a pressure transducer (AD Instruments MLT 0380, CO, USA) and filled with aqueous solution to achieve a left ventricular end-diastolic pressure (LVEDP) of approximately 5-10 mmHg. LV contractility was evaluated using the developed pressure (LVDP) and the maximal rate of pressure development (+dP/dt). Relaxation was assessed by half relaxation time (t1/2), the time from peak developed pressure to 50% of decay of developed pressure.47

4.3 | Perfusion protocols

Two experimental groups were performed: I/R 20/30 (hearts subjected to 20-min global ischaemia followed by 30-min reperfusion) and I/R 30/60 (hearts subjected to 30-min global ischaemia followed by 60-min reperfusion). At the end of reperfusion, hearts were freeze-clamped and stored at −80°C for biochemical determinations. When drugs were used, they were perfused only during the reperfusion period [3 mM 4-phenylbutyrate (4-PBA) and 30 μM tauroursodeoxycholic acid (TUDCA)]. A group of hearts perfused but not submitted to I/R protocol, was used as control.

4.4 | LDH determinations

Lactate dehydrogenase (LDH) concentration was measured with a Boehringer commercial kit (Boehringer Mannheim,
4.5 | Measurement of lipid peroxidation

Generation of ROS in the isolated rat heart was evaluated indirectly by measuring the formation of thiobarbituric acid reactants (TBARS), as an index of lipid peroxidation. Powered ventricular tissue from each heart was homogenized in 5 vol. of a buffer solution containing 140 mM KCl and 20 mM KH₂PO₄ (pH 7 at 4°C) and then centrifuged at 1000× g for 10 minutes. The supernatant was used for the assay. The formation of TBARS was quantified according to Buege and Aust.

4.6 | Electrophoresis and Western Blot

Pulverized frozen ventricles were homogenized using a handheld homogenizer (Kinematica Polytron 1200 PT E) in five volumes of the following: 20 mM Tris-HCl, 5 mM EDTA, 2.5 mM EGTA, 10 mM NaCl, 300 mM sucrose, 1% IGEPAL, 0.1% SDS, 25 mM NaF, 1 mM PMSF, 1 mM Benzamidine, 10 μg/mL Leupeptin, 1 μg/mL pepstatin, 1 μg/mL E64 [trans-Epoxyseccinyl-t-leucylamido(4-guanidino)butane]. The homogenate was sedimented at 13 000× g for 10 minutes, and the supernatant was fractionated in small aliquots, frozen in liquid N₂ and stored at −80°C. Protein concentration was measured using the Bradford method with bovine serum albumin (BSA) as the standard. 50 μg of homogenate protein was electrophoresed per gel lane in 10%-12% acrylamide gels according to Laemmli. Proteins were transferred to PVDF membranes (Immobilion-P, Millipore). Blots were blocked with Tris-buffered saline (TBS) (50 mM Tris, 150 mM NaCl, pH 7.4) with or without the addition of 0.1% Tween (TBST) and 5% skim milk or BSA, as indicated for each antibody, and then incubated with the following primary antibodies: phospho-JNK (1:1000 in TBST 5% BSA), JNK (1:1000 in TBST 1% milk), Santa Cruz Biotechnology, caspase-12 (1:1000 in TBST 1% milk) Sigma-Aldrich, phospho-eIF2α (1:1000 in TBST 5% BSA) Cell Signaling Technology, eIF2α (1:1000 in TBST 1% milk) Invitrogen, GAPDH (1:10 000 in TBST 1% milk) Millipore. The membranes were incubated with the appropriate horseradish peroxidase-conjugated secondary antibody (Santa Cruz Biotechnology, 1:10 000 in 1% milk TBST) and developed using an enhanced chemiluminescence reagent (Millipore). The signals emitted for chemiluminescence were detected using Chemidoc Imaging system (Bio-Rad) and analysed with ImageJ software (NIH). The results were normalized to corresponding densitometry signal of unphosphorylated protein or GAPDH.

4.7 | Real-time qPCR

RNA was extracted from hearts using TRIzol reagent (Life Technologies, Carlsbad, Calif). cDNA was generated by reverse transcriptase reaction using M-MLV RT (Promega, Madison, Wis). Real-time quantitative PCR was performed on cDNA using the SYBR Select Master Mix (Life Technologies, Carlsbad, Calif) and iCycler iQ (Bio-Rad, Hercules, Calif). The following primers were used:

| Gene                  | Sense (5’ to 3’)       | Antisense (5’ to 3’)  |
|-----------------------|------------------------|-----------------------|
| XBP1 (unspliced and spliced forms) | AGAAACAGCA             | AGCAAGAAGAT           |
|                       | ACCTGAGGGG             | TCCATCAAGCAT          |
| CHOP                  | TACACCCACCA            | GCTAGGGGATGC          |
|                       | CACCTGAAAGC            | ACGGTCAAG             |
| GRP78                 | TGATTCGCAG             | GTTATTTGTTC           |
|                       | GAACACTGTGG            | TTTCAGGGG             |
| Spliced XBP1          | GAGTCCGCA              | GTTCAACTTG            |
|                       | GCAGGTCG               | TCAGAATGC             |
| GAPDH                 | GGTTGTGGA              | CCACAGTCTTC           |
|                       | CCACGAGAAT             | TGAGTGGA              |

Relative abundance of RNA was calculated by the ΔΔCt method. Primers were designed using Primer-Blast (NCBI, NIH). All primers were between 90% and 110% efficient, as assessed by standard curve, and all displayed only one dissociation peak.

4.8 | TUNEL technique

The terminal deoxynucleotidyl transferase dUTP nick end labelling (TUNEL) technique was employed to study apoptosis, using the Tunel In situ Cell Death Detection Kit, TMR red (Roche, Indianapolis, IN, USA), as previously described. Briefly, sections were deparaffinized, dehydrated and incubated with proteinase K for antigen retrieval. After washing with PBS containing 0.5% Tween 20 (Merck, Schuchardt OHG, Hohenbrunn, Germany), slides were incubated with the reaction mixture containing modified nucleotides (TMR-dUTP) and the enzyme terminal deoxynucleotidyl transferase (TdT) that catalyses the template-independent polymerization of deoxyribonucleotides to the 3′-end of single- and double-stranded DNA. After washing, nuclei were counterstained with 5 μg/ml of DAPI (6-diamidino-2-phenylindole; Invitrogen Life Technologies, Eugene, OR, USA) following the manufacturer’s protocol. Cover slips were mounted on slides using the aqueous medium Reagent FluoroSave (Calbiochem, La Jolla, CA, USA) and then examined under confocal microscopy (FV1000, Olympus Co., Tokyo, Japan). The TUNEL reaction mixture replaced by the label solution of the kit was used as a negative control.
4.9 | Infarct size

After the reperfusion period, hearts were perfused with 1% triphenyltetrazolium chloride (TTC) in phosphate buffer (pH 7.4) for 7 minutes and immersed in this solution for another 7 minutes. The hearts were frozen at −20°C for 1 hour and then cut into six transverse slices (2 mm thick) along the long axis of the LV, from apex to base. Infarct areas were enhanced by storage in 10% formaldehyde solution for 48 hours before measurement. The quantification was performed on digital photographs by manually outlining the margins of the differentially coloured areas: pale (infarcted) and red (viable tissue) using Image J (NIH). Infarct weight was determined as follows: (A1 × W1) + (A2 × W2) + (A3 × W3) + (A4 × W4) + (A5 × W5) + (A6 × W6), where A is the average infarct area of both sides of the slice and W the weight of the respective section. The weight of the area at risk (total ventricle area) was calculated in a similar fashion. Infarct size was expressed as the weight of infarct area/weight of ventricle area × 100.

4.10 | Statistics

Data are expressed as mean ± SEM. Statistical significance was determined by Student’s t-test for paired or unpaired observations as appropriate, and ANOVA when different groups were compared. The Newman-Keuls test was used to examine statistical differences observed with the ANOVA. A P value <.05 was considered statistically significant.

ACKNOWLEDGEMENTS

We wish to thank Dr. Mariano Di Carlo for his initial collaboration with this project. B.R. is currently at the Department of Pathology, Johns Hopkins University, Baltimore, MD, United States. We would like to thank Dr. Mariana Bollo for the generous gift of total eIF2α antibody. This work was supported by Agencia Nacional de Promoción Científica y Tecnológica, Argentina (PICT # 2073 to L. Vittone and PICT # 0856 to M. Said) and by Consejo de Investigaciones Científicas y Técnicas (CONICET), Argentina (PIP # 0507 to C. Mundiña-Weilenmann).

CONFLICT OF INTEREST

No conflicts of interest, financial or otherwise, are declared by the authors.
