Origin of the Mobile Di-Hydro-Pteroate Synthase Gene Determining Sulfonamide Resistance in Clinical Isolates

Miquel Sánchez-Osuna1, Pilar Cortés1, Jordi Barbé** and Ivan Erill**

1 Departament de Genètica i de Microbiologia, Universitat Autònoma de Barcelona, Bellaterra, Spain, 2 Department of Biological Sciences, University of Maryland, Baltimore County, Baltimore, MD, United States

Sulfonamides are synthetic chemotherapeutic agents that work as competitive inhibitors of the di-hydro-pteroate synthase (DHPS) enzyme, encoded by the folP gene. Resistance to sulfonamides is widespread in the clinical setting and predominantly mediated by plasmid- and integron-borne sul1-3 genes encoding mutant DHPS enzymes that do not bind sulfonamides. In spite of their clinical importance, the genetic origin of sul1-3 genes remains unknown. Here we analyze sul genes and their genetic neighborhoods to uncover sul signature elements that enable the elucidation of their genetic origin. We identify a protein sequence Sul motif associated with sul-encoded proteins, as well as consistent association of a phosphoglucosamine mutase gene (glmM) with the sul2 gene. We identify chromosomal folP genes bearing these genetic markers in two bacterial families: the Rhodobiaceae and the Leptospiraceae. Bayesian phylogenetic inference of FolP/Sul and GlmM protein sequences clearly establishes that sul1-2 and sul3 genes originated as a mobilization of folP genes present in, respectively, the Rhodobiaceae and the Leptospiraceae, and indicate that the Rhodobiaceae folP gene was transferred from the Leptospiraceae. Analysis of %GC content in folP/sul gene sequences supports the phylogenetic inference results and indicates that the emergence of the Sul motif in chromosomally encoded FolP proteins is ancient and considerably precedes the clinical introduction of sulfonamides. In vitro assays reveal that both the Rhodobiaceae and the Leptospiraceae, but not other related chromosomally encoded FolP proteins confer resistance in a sulfonamide-sensitive Escherichia coli background, indicating that the Sul motif is associated with sulfonamide resistance. Given the absence of any known natural sulfonamides targeting DHPS, these results provide a novel perspective on the emergence of resistance to synthetic chemotherapeutic agents, whereby preexisting resistant variants in the vast bacterial pangenome may be rapidly selected for and disseminated upon the clinical introduction of novel chemotherapeutics.

Keywords: sulfonamide, resistance, antibiotic, phylogeny, mobile element, integron, plasmid
INTRODUCTION

Antibiotic resistance is a pressing problem in modern healthcare (Carlet et al., 2014; Rossolini et al., 2014). Bacterial cells present several mechanisms to cope with exposure to antibiotics or chemotherapeutic agents, which may be acquired through mutation or, most frequently, via lateral gene transfer on mobile genetic elements (Davies and Davies, 2010). These mechanisms include modification of the antimicrobial target, degradation or chemical modification of the antimicrobial molecule, targeted reduction of antimicrobial uptake, active export of the antimicrobial through efflux pumps and use of alternate pathways and enzymes (Davies and Davies, 2010).

It is widely accepted that many antibiotic resistance genes present today in pathogenic bacteria originated from homologs evolved over eons in either the microbes that naturally produce the antibiotics or their natural competitors (Aminov and Mackie, 2007). When coupled with the high plasticity of bacterial genomes and their co-existence with a large variety of genetic mobile elements, the availability of a readily evolved pool of antibiotic resistance genes set the stage for the rapid proliferation of multi-resistant strains in the clinical setting shortly after the commercial introduction of antibiotics (Aminov and Mackie, 2007). In contrast, the origins of resistance against chemotherapeutic agents are harder to pinpoint. Since these were designed in vitro, it seems unlikely that a large pool of genes conferring resistance to chemotherapeutic agents existed before their introduction. After their discovery in the 1960’s, resistance to quinolones was initially rare and limited to chromosomal mutations in DNA gyrase, topoisomerase IV or efflux pumps (Hooper, 1999). However, in the early 2000’s plasmid-borne qnr genes were first detected and spread rapidly to clinical pathogens. Qnr is a member of the pentapeptide repeat family and was shown to confer resistance by binding to DNA gyrase and limiting the effect of quinolone drugs. The origin of plasmid-borne qnr genes has been traced to environmental homologs and these are thought to have derived from genes originally targeting antibiotics, such as microcin B17 (Tran and Jacoby, 2002).

Aryl sulfonamides are synthetic antibacterial compounds presenting a structure similar to para-amino benzoic acid (PABA), and containing a sulfonamide group linked to an aromatic group. Commonly referred to as sulfonamides or sulfa drugs due to their clinical relevance, synthetic aryl sulfonamide function as competitive inhibitors of the di-hydro-pteroate synthase (DHPS) enzyme, encoded in bacteria by the folP gene (Sköld, 2000). DHPS participates in folate synthesis using PABA as a substrate, and the competitive inhibition of DHPS by sulfonamides results in growth arrest (Mitsuhashi, 1993; Sköld, 2000). Experiments in mice in the 1930’s demonstrated the effectiveness of sulfonamide against bacteria, and sulfonamide became the first antibacterial chemotherapeutic to be used systemically (Domagk, 1935; Aminov, 2010). It remained in use throughout World War II, but by the end of the 1940’s resistant strains started to emerge and sulfonamides were rapidly displaced in favor of the newly discovered antibiotics (Sköld, 2000; Davenport, 2012).

Resistance to sulfonamide through increased production of PABA was reported in the early 1940’s (Landy et al., 1943), but the most commonly reported mechanism of sulfonamide resistance are mutations to the chromosomal folP gene (Huovinen et al., 1995; Sköld, 2000). Mutations to the chromosomal folP gene have been shown to provide varying degrees of trade-off between resistance and efficient folate synthesis, decreasing DHPS affinity for sulfonamide while maintaining or increasing its affinity for PABA (Sköld, 2000). These mutations have occurred independently in multiple bacterial genera and target multiple conserved areas of the DHPS protein (Sköld, 2000). However, similar mutational profiles, such as two-amino acid insertions in Neisseria meningitidis and Streptococcus pneumoniae, have been reported (Rådström et al., 1992; Haasum et al., 2001), and in both these genera there is evidence of extensive recombination within folP genes (Fermer et al., 1995; Swedberg et al., 1998).

In spite of the multiple instances of chromosomal folP resistant variants, clinical resistance to sulfonamides is predominantly plasmid-borne and mediated by sul genes encoding alternative sulfonamide-resistant DHPS enzymes (Sköld, 2000). Four different sul genes have been described to date, with sul1 and sul2 being the predominant forms in clinical isolates (Rådström et al., 1991). The sul1 gene is typically found in class 1 integrons and linked to other resistance genes (Rådström et al., 1991), whereas sul2 is usually associated to non-conjugative plasmids of the IncQ group (Enne et al., 2001) and to large transmissible plasmids like pPB1 (Treeck et al., 1981). The sul3 gene was characterized in the Escherichia coli conjugative plasmid pVP440. It was shown to be flanked by two copies of the insertion element IS15A/26 and to be widespread in E. coli isolates from pigs in Switzerland (Perreton and Boerlin, 2003). Recently, a sul4 gene was identified in a systematic prospection of class 1 integron-borne genes in Indian river sediments, but this sul variant has not yet been detected in clinical isolates. Genomic context analyses revealed that the sul4 gene had been recently mobilized and phylogenetic inference pinpointed its putative origin as part of the folate synthesis cluster in the Chloroflexi phylum (Razavi et al., 2017).

Despite the importance of sulfonamides in human and animal therapy, the putative origin of the three sul genes that account for the vast majority of reported clinical resistance to sulfonamide remains to be elucidated. In this work we leverage comparative genomics, phylogenetic analysis and in vitro determination of minimal inhibitory concentrations (MIC) of sulfamethoxazole to unravel the origin of the sul1, sul2, and sul3 genes. Our analysis indicates that chromosomally encoded folP genes conferring resistance to sulfonamide originated in members of the Leptospiraceae family and were transferred to the Alphaproteobacteria Rhodobiales family more than 500 million years ago. These isolated sources of chromosomally encoded sulfonamide-resistant DHPS were mobilized independently, leading to the broadly disseminated sul1, sul2, and sul3 resistance genes. Our results hence indicate that resistance to synthetic chemotherapeutic agents may be available in the form of chromosomally encoded variants among the extremely diverse bacterial domain, and can be rapidly disseminated upon the release of novel synthetic drugs.
MATERIALS AND METHODS

Data Collection

FolP, GlmM, and Sul-3 homologs were identified in complete GenBank sequences (GenBank, RRID:SCR_002760) through BLASTP (BLASTP, RRID:SCR_001010) (Altschul et al., 1997) using the E. coli FolP (WP_000764731) and GlmM (WP_000071134) proteins as the query. Putative homologs were detected as BLASTP hits passing stringent e-value (<1e−20) and query coverage (75%) thresholds. FolP and GlmM chromosomally encoded proteins were identified on a representative genome of all bacterial orders with complete genome assemblies on RefSeq (RefSeq, RRID:SCR_003496), of each bacterial family for the Proteobacteria, of any bacterial species where chromosomally encoded sulfonamide resistance mutants had been reported, and on all available complete genomes for clades of interest (Rhodobacteraeae, Spirochaetes, and Chlamydiaceae) (Supplementary Table S1). All protein coding gene sequences for these genomes were downloaded for %GC analysis. Sul proteins encoded by mobile sul genes were identified on complete plasmid, transposon, and integron GenBank sequences (GenBank, RRID:SCR_002760).

Identification and Visualization of Sul-Like Signatures in FolP Sequences

To identify sequence motifs associated with Sul proteins, we performed a CLUSTALW alignment (Clustal Omega, RRID:SCR_001591) using a non-redundant (<99% identity) subset of the Sul-3 homologous sequences detected previously and FolP sequence sampled from each bacterial clade. Following visual inspection of the resulting alignment, a Sul-like motif conserved in several chromosomally encoded FolP proteins was visualized using iceLogo (iceLogo, RRID:SCR_012137) (Colaert et al., 2009) and a consensus motif was derived and encoded into a PROSITE-format pattern (PROSITE, RRID:SCR_003457). The inferred PROSITE pattern was used to seed a Pattern Hit Initiated BLAST (NCBI PHI-BLAST; RRID:SCR_004870) search against the NCBI non-redundant Protein database (Protein, RRID:SCR_003257) using as a query the protein sequences of Sul-3 reported in the literature (WP_001336346, WP_010890159, and WP_000034420) and conservative e-value (<1e−20) and query coverage (75%) limits. Only chromosomal hits with the identified signature characteristic of sul gene products were retained for further analysis.

Multiple Sequence Alignment and Phylogenetic Inference

For phylogenetic inference, multiple sequence alignments of identified FolP/Sul-3 and GlmM homologous sequences were performed with CLUSTALW (Clustal Omega, RRID:SCR_001591) (Thompson et al., 1994) using variable (5, 10, and 25) gap opening penalties. These alignments were then integrated with local LALIGN alignments with T-COFFEE (T-Coffee, RRID:SCR_011818) (Notredame et al., 2000), and the resulting alignment was trimmed using the “less stringent selection” parameters of the Gblocks online service (Castresana, 2000; Dereeper et al., 2008). Bayesian phylogenetic inference on trimmed alignments was performed with MrBayes (MrBayes, RRID:SCR_012067) (Ronquist and Huelsenbeck, 2003). Four Metropolis-Coupled Markov Chain Monte Carlo runs with four independent chains were carried out for 30,000,000 generations, and the resulting consensus tree was plotted with FigTree (FigTree, RRID:SCR_008515).

DNA Sequence Analyses

Analysis of %GC in synonymous and non-synonymous patterns and Ks/Ka divergence were performed according to the Nei–Gojobori computation method (Nei and Gojobori, 1986) and the standalone PAL2NAL program for codon-based alignments (Suyama et al., 2006), using custom Python scripts for pipelining. Analyses of %GC content were performed on all sampled bacterial genomes, computing genome-wide %GC statistics and comparing them to folP estimates. Analyses of Ks/Ka divergence were performed on pair-wise alignments of the N- and C-terminal ends of the glmM gene sequence of all sampled bacterial groups. One-sided Mann-Whitney U-tests were performed using GraphPad Prism (GraphPad, RRID:SCR_002798) to determine whether differences between folP and chromosomal %GC content were significantly different in the presence and absence of Sul-like signature motifs, and whether the N- and C-terminal regions presented different mutational profiles. The scripts used for the analysis are available at the GitHub ErillLab repository. Nucleotide sequence identities percentages were computed on gapless positions of PAL2NAL codon-based alignments using a custom Python script. Amelioration times were estimated using the Ameliorator program (Lawrence and Ochman, 1997) under different selection modes. Ks and Ka values were estimated from pairwise alignments of orthologs between the Parvibaculum lavamentivorans and Leptospira interrogans genomes as determined by the OMA Orthology database (OMA Orthology database, RRID:SCR_016425) (Altenhoff et al., 2018) and species divergence times were inferred from published molecular clock phylogenies (Battistuzzi et al., 2004).

Cloning, Transformation and Complementation of the folP Gene for Broth Microdilution Assays

The L. interrogans serovar Lai strain 56601 folP and Chlamydia trachomatis D/UW-3/CX folKP gene were synthesized and adapted to E. coli codon usage at ATG-biosynthetics GmbH, Germany; whereas P. lavamentivorans DS-1 (DSMZ 13023) and Rhodobacter sphaeroides 2.4.1 (gently provided by Professor S. Kaplan; Health Science Center. University of Texas) folP genes were amplified from genomic DNA. The sul2 gene was amplified from the RSF1010 plasmid (Kushner, 1978; Honda et al., 1991) and used as a positive control. The folP/sul genes were amplified using suitable primers (Supplementary Table S2), purified PCR products were then digested with NdeI and BamHI (New England Biolabs, RRID:SCR_013517) and cloned into a dephosphorylated pUA1108 vector (Mayola et al., 2014), previously cut with the same restriction enzymes. The
ligation was introduced by transformation into competent *E. coli* DH5α cells and recombinant plasmids were extracted with the NZYMiniprep kit (NZYTech, RRID:SCR_016772), sequenced (Macrogen, RRID:SCR_014454) and introduced by transformation in competent *E. coli* K-12 (CGSC 5073) (CGSC, RRID:SCR_002303). Susceptibility to sulfamethoxazole (Sigma-Aldrich, RRID:SCR_008988) for the strains containing the folP/sul genes was determined using broth microdilution tests in Mueller-Hinton broth (MH) with half serial dilutions of sulfamethoxazole ranging from 512 to 0.125 mg/L, following the CLSI guidelines (Clinical and Laboratory Standards Institute, 2003). Colonies were grown on Luria-Bertani (LB) agar for 18 h and then suspended in sterile 0.9% NaCl solution to a McFarland 0.5 turbidity level. These suspensions were diluted at 10⁻² in Mueller-Hinton (MH) broth, and 50 µL (5 × 10⁴ cells) were inoculated onto microtiter plates containing 50 µL of MH broth supplemented with 1024–0.250 mg/L of sulfamethoxazole. To determine growth, absorbance at 550 nm was measured after 24 h incubation at 37°C (Sunrise plate reader; Tecan Life Sciences, RRID:SCR_016771).

**RESULTS**

**Identification of Putative Chromosomal Origins for sul1-3 Genes**

To identify putative chromosomal homologs of *sul1*-3 genes, we performed a multiple sequence alignment including any protein sequences with at most 90% similarity to those encoded by *sul1*-3 genes reported in the literature and by chromosomal *folP* genes from a representative of each bacterial order. Inspection of the resulting alignment ([Figure 1A](#) and [Supplementary Data 1](#)) revealed the presence of a two-amino acid insertion in proteins encoded by *sul1*-3 genes that is not present in those encoded by *sul4* or the analyzed chromosomal *folP* genes. This two-amino acid insertion is located in a conserved region of the *FopP* protein (residues R171-N211 of the *E. coli* *FopP* protein [WP_000764731]) that presents other signature changes in *sul1*-3 genes. This search identified several proteins encoded by *Rhodobiacaeae* family members that presented a similar insertion pattern. BLASTP (BLASTP, RRID:AB_141607) searches with these *Rhodobiacaeae* *FopP* sequences matched proteins in several members of the *Leptospiroseae* and the Chlamydiae. However, analysis of the resulting multiple sequence alignment showed that only the *Leptospiroseae* *FopP* protein sequences displayed the identified two-amino acid insertion pattern ([Supplementary Data 3](#)). Heretofore, we refer to these chromosomally encoded *FopP* proteins containing the signature Sul motif as *FopP*⁺, and to their encoding gene as *folP*⁺.

In order to gain further insight into the possible chromosomal origins of *sul* genes, we performed tBLASTX searches against the NCBI RefSeq Genome Database (RefSeq, RRID:SCR_003496) using the genetic surroundings (3,000 bp) of *sul1*, *sul2*, and *sul3* genes with at most 90% similarity to those reported in the literature ([Supplementary Table S3](#)). This search did not return consistent results for the *sul1* and *sul3* genetic surroundings, but it identified a conserved gene fragment encoding the N-terminal region of the phosphogluconoclastic mutase GlmM protein downstream of *sul2* in multiple plasmids harboring this resistance gene. These *sul2*-associated GlmM sequences lack the entire GlmM C-terminal region, including three of its functional domains (Mehra-Chaudhary et al., 2011), and it can therefore be safely assumed that they are not functional as phosphogluconosamylases. This genetic arrangement has been reported previously as a feature of *sul2* isolates (Kchenberg and Schwarz, 2005; Hu et al., 2016), and it is strongly conserved in the genomic surroundings of chromosomal *folP* genes in the Gammaproteobacteria, the Betaproteobacteria and several Alphaproteobacteria lineages ([Figure 1C](#)). Analysis of the *folP* genetic surroundings in complete genomes of the Spirochaetes and the Alphaproteobacteria shows clear differences between the genes coding for the identified *Rhodobiacaeae* and *Leptospiroseae* *FopP*⁺ proteins harboring the two-amino acid insertion pattern and those without it ([Figure 1C](#)). The *Leptospiroseae* show a conserved arrangement with *folP*⁺ flanked by a peptidoglycan-associated lipoprotein and a tetratricopeptide repeat-containing domain protein, whereas in most other Spirochaetes *folP* is flanked by a 1-deoxy-D-xylulose-5-phosphate synthase and a diadenylate cyclase. In contrast, the Alphaproteobacteria yield several distinct syntenic regions for *folP*. In the *Rhodobiacaeae*, *folP*⁺ is flanked by genes coding for either a FtsH-family metallopeptidase or a TetR-family transcriptional repressor and the phosphogluconosamylase mutase glmM. In the Rhodobacterales, *folP* is flanked by a dihydropeptiderin aldolase and *glmM*, but in the *Rhizobiaceae* it is flanked by a Zn-dependent protease and the dihydropeptiderin aldolase. This last arrangement, in which the dihydropeptiderin aldolase is followed by a 2-amino-4-hydroxy-6-hydroxymethylidihydropteridine diphosphokinase is also part of the genetic surroundings of *folP* in most Actinobacteria ([Figure 1C](#)).

**Phylogenetic Analysis of sul/folP and glmM Genes**

The presence of a signature two-amino acid insertion characteristic of *sul* gene products in chromosomally encoded FolP⁺ proteins and the identification of a genetic environment for *sul2* genes that is conserved in multiple bacterial genomes suggested that it might be possible to pinpoint the evolutionary origin of *sul* genes. To further investigate this possibility, we performed a rigorous phylogenetic analysis of FolP/Sul protein sequences. We sampled a representative genome of all bacterial orders with complete genome assemblies, of each
bacterial family for the Proteobacteria and all available complete genomes for clades of interest (Rhodobacterales, Spirochaetes, and Chlamydiaceae), and we identified chromosomally encoded FoP homologs in each of these genomes using BLASTP (BLASTP, RRID:SCR_001010) with the *E. coli* FolP protein as a query. We used a distance tree generated with CLUSTALW (Clustal Omega, RRID:SCR_001591) to identify and discard a set of protein sequences from duplicated *folP* genes in the Actinobacteria (Supplementary Data 4), and we performed multiple sequence alignment and Bayesian phylogenetic reconstruction of the remaining FoP/Sul sequences with T-COFFEE (T-Coffee, RRID:SCR_011818) and MrBayes (MrBayes, RRID:SCR_012067) (Supplementary Data 5).

The resulting tree (Figure 2) provides strong support for the hypothesis that *sul*-3 genes originated in the Rhodobacterales and Leptospiraceae families. In particular, the topology inferred by MrBayes suggests that the *Leptospiraceae folP* gene gave rise to both *sul3* and the *folP* gene encountered in the *Rhodobacterales*, most likely through a lateral gene transfer event in an ancestor of this Alphaproteobacteria family. According to the reconstructed FoP phylogeny, the *Rhodobacterales folP* gene was subsequently mobilized as *sul2*, and later evolved into the
The fact that the *Leptospiraceae* FolP* sequences branch independently of other Spirochaetes sequences and immediately after the Chlamydiae suggests that the *Leptospiraceae* folP* gene might have originated as a result of lateral gene transfer event from the Chlamydiae, and that it subsequently incorporated the signature two-amino acid insert present in sul-encoded DHPS proteins. Importantly, the trimmed multiple sequence alignment used for FolP/Sul Bayesian phylogenetic inference (Supplementary Data 5) does not incorporate the two-amino acid insertion of the Sul motif, indicating that the joint branching of Sul1-3 sequences with chromosomally encoded *Rhodobiaceae* and *Leptospiraceae* FolP proteins is based on sequence similarity beyond this insertion and its immediate vicinity (Figures 1A,B).

The existence of a genetic environment for sul2 genes conserved in bacterial chromosomes provides the means to independently assess the likelihood of the evolutionary scenario inferred from the FolP phylogeny. Using the same sampling methods utilized for sul/folP protein products, we collected protein sequences for phosphoglucosamine mutase (GlmM) homologs and performed Bayesian phylogenetic inference on the aligned N-terminal regions. The resulting GlmM tree (Figure 3) provides further support for a *Rhodobiaceae* origin of the sul2 gene, with the sul2-associated GlmM sequences branching with the *Rhodobiaceae* GlmM protein sequences deep within an otherwise monophyletic Alphaproteobacteria clade. Taken together, the consistent branching with the *Rhodobiaceae* of the protein sequences encoded by both sul2 and its accompanying glmM gene fragment firmly establish this Alphaproteobacteria family as the chromosomal origin for the sul2 gene. The phylogenetic evidence thus indicates that the sul2 gene was excised with the N-terminal fragment of the glmM gene during the mobilization event that led to their incorporation into plasmid vectors. Given that the folP-glmM arrangement is only seen in the Proteobacteria, this also excludes the possibility that the sul2 gene was mobilized directly from a *Leptospiraceae* background, where the folP gene presents an unrelated, yet conserved, genomic environment (Figure 1C).

**Analysis of sul/folP and glmM Gene Sequences**

The phylogenetic analysis of FolP and GlmM sequences puts forward an evolutionary scenario wherein the *Leptospiraceae* folP* was transferred to the members of the *Rhodobiaceae* family before being mobilized independently into the sul3- and sul1/2-harboring mobile genetic elements reported in sulfonamide-resistant clinical isolates. To further investigate this hypothesis, we undertook a systematic analysis of folP and glmM coding sequences. We compiled folP gene sequences for all the FolP proteins included in the phylogenetic analysis (Figure 2), as well as any sul gene sequences with less than 90% identity to those reported in the literature and any chromosomal folP* genes encoding a DHPS with the signature Sul motif (Figure 1A) for which there were at least 1 Mbp of whole genome shotgun sequence data (Supplementary Data 6). We computed the overall and codon-position %GC content on both the folP/sul coding sequences and all the available coding sequences in their respective genome assembly (Supplementary Table S4). The %GC content data (Figure 4A)
reveals that sul1/2 sequences have a high %GC content (60.76 SD ± 1.42) that is consistent with their origin as mobilized Rhodobiaceae folP∗ sequences (%GC content: 62.02 SD ± 2.22). Similarly, sul3 sequences display a %GC content (38.14 SD ± 0.55) consistent with their mobilization from a Leptospiraceae folP∗ background (39.39 SD ± 4.17). This similarity in %GC content precludes the dating of these mobilization events through analysis of DNA amelioration rates. However, examination of DNA sequence similarity (Table 1) reveals identity values of 50–60% between the posited chromosomal donors and their mobile counterparts. These values are in the lower range of sequence identities for previously described mobilization events (Table 1), and hence point to an early mobilization of folP∗ genes that is consistent with the almost universal association of sul genes with class 1 mobile integrons (Lévesque et al., 1995). Together with the phylogenetic inference results, these data provide strong support for an independent mobilization of sul1/2 and sul3 genes from, respectively, Rhodobiaceae and Leptospiraceae family chromosomal backgrounds.

The independent mobilization of sul1/2 and sul3 is underpinned by a preceding lateral gene transfer of folP∗ from the Leptospiraceae into a Rhodobiaceae ancestor. In this context, the substantial divergence in %GC content between the chromosomal folP∗ genes of both clades indicates a long process of amelioration. In fact, statistical analysis of the differences in codon position %GC content between folP genes and all available coding sequences in their respective genomes shows that Leptospiraceae and Rhodobiaceae folP∗ genes encoding proteins with the Sul motif cannot be distinguished from other folP genes (one-sided Mann–Whitney U-test p > 0.05 for GC1, GC2, and GC3) (Figure 4B) (Supplementary Table S4). We used Ameliorator (Lawrence and Ochman, 1997) to estimate the time required for the observed amelioration via forward simulation from Leptospiraceae codon position %GC values. Even under assumptions of fast evolutionary change, the software provides a lower bound of 476 million years for the observed amelioration of the Leptospiraceae folP∗ gene into the Rhodobiaceae one. Statistical analysis of synonymous and non-synonymous mutation patterns in the N- and C-terminal regions of the glmM gene also shows that mutation patterns in each region of the Rhodobiaceae glmM gene are indistinguishable from those observed in other glmM genes (one-sided Mann–Whitney U-test p > 0.05). Since the glmM gene fragment associated to
sul2 genes is likely to be non-functional and subject to genetic drift, the absence of diverging substitution patterns between the N- and C-terminal regions of Rhodobiales glmM sequences indicates that the glmM and sul2 genes were transferred from the Rhodobiales to sul2-harboring vectors, and not vice versa (Supplementary Table S5). Lastly, given that gene loss is much more likely than gain (Kannan et al., 2013), the absence of glmM fragments in sul1 isolates supports in turn the notion that sul1 derived from sul2. This is consistent with the branching pattern observed in the FolP/Sul tree (Figure 2) and the observed DNA identity values (Table 1), which define a scenario of independent mobilization of sul3 from the Leptospiraceae and sul2 from the Rhodobiales, with the subsequent uptake of sul1 by class 1 integrons.
**Sulfonamide Resistance of Chromosomal folP Genes**

Phylogenetic and sequence analysis results indicate that chromosomal *folP* genes encoding proteins with the signature Sul motif were independently mobilized into the *sul1*-harboring mobile elements found in sulfonamide-resistant clinical isolates, but they do not address whether the presence of this motif is associated with sulfonamide resistance. To investigate this possibility, we cloned the *folP* gene coding for DHPS in the *Rhodobacteraceae* *P. lavamentovorans* DS-1 (WP_012111048), the *Leptospiraceae* *L. interrogans* serovar Lai str. 56601 (WP_000444207), the *Rhodobacteraceae* *R. sphaeroides* 2.4.1 (WP_011337038) and the *Chlamydiae* *C. trachomatis* D/UW-3/CX (WP_009871981). Following Clinical and Laboratory Standards Institute (CLSI) guidelines (Clinical and Laboratory Standards Institute, 2003), we then performed broth microdilution assays to determine the minimal inhibitory concentration (MIC) of sulfamethoxazole. The results shown in **Table 2** reveal that both *P. lavamentovorans* and *L. interrogans* chromosomal *folP* genes confer resistance to sulfamethoxazole in an *E. coli* strain sensitive to sulfonamides. These data are in agreement with previous reporting of sulfonamide resistance in multiple *L. interrogans* strains (Chakraborty et al., 2010, 2011; Wuthiekanun et al., 2015), and suggest that the observed resistance was likely due to mutations in the *Leptospiraceae* chromosomal *folP* gene rather than to the presence of plasmid-borne *sul* genes. Moreover, our results show that complementation with *folP* genes from another Alphaproteobacteria family lacking the Sul motif, the *Rhodobacteraceae*, does not confer resistance to sulfamethoxazole. These results reveal that the chromosomal *folP* genes that gave rise to *sul* genes are capable of conferring resistance to sulfonamide in *E. coli*. In contrast with the *Leptospiraceae* and the *Rhodobacteraceae* *folP* genes, the chromosomal *folKP* gene of the *Chlamydiae*, which encodes a DHPS lacking the Sul motif, does not confer resistance to sulfamethoxazole (**Table 2**). This is in agreement with abundant reports of sulfonamide susceptibility in several *Chlamydia* species (Hammerschlag, 1982; Fan et al., 1992; Sandoz and Rockey, 2010; Marti et al., 2018). Since the *Chlamydiae* *folKP* gene is the most closely related chromosomal *folP* gene to the cluster encompassing the *sul* genes and the *Leptospiraceae* and the *Rhodobacteraceae* *folP* (**Figure 2**), the lack of resistance in *Chlamydiae* *folKP* genes strongly suggests that changes in the region encompassing the Sul motif may be responsible for the observed resistance. This region is located in a connector loop within the N-terminal ‘pole’ of the eight-stranded α/β barrel of DHPS, which is involved in sulfonamide recognition (Rådström and Swedberg, 1988; Morgan et al., 2011). The two-aminoc acid insertion might hence result in decreased affinity for sulfonamide by locally disrupting folding, as has been proposed previously for similar insertions in chromosomal *folP* genes (Achari et al., 1997).

**DISCUSSION**

**Prevalence of Sulfonamide Resistance in Ancestral Bacteria**

The evidence presented here converges toward an evolutionary scenario in which *sul1*-3 genes from clinical isolates derive from ancestral chromosomal mutations in the *folP* gene of the *Leptospiraceae* and the *Rhodobacteraceae* (**Figure 5**). The emergence and maintenance of a sulfonamide-resistant *folP* gene in the
TABLE 2 | Broth microdilution assays.

| Species                  | Sulfamethoxazole (mg/L) |
|--------------------------|-------------------------|
| Escherichia coli CGSC5073| 8                       |
| Escherichia coli CGSC5073 pUA1108 | 8                  |
| Escherichia coli CGSC5073 pUA1108::folP<sub>E</sub> | >512                |
| Escherichia coli CGSC5073 pUA1108::folP<sub>R</sub> | 512                  |
| Escherichia coli CGSC5073 pUA1108::folP<sub>St</sub> | 4                    |
| Escherichia coli CGSC5073 pUA1108::folP<sub>R</sub> | 8                    |
| Escherichia coli CGSC5073 pUA1108::sul2 | >512                  |

Minimum inhibitory concentrations (MICs) of sulfamethoxazole in wild-type Escherichia coli CGSC5073 carrying different versions of pUA1108::folP; Pl, Parvibaculum lavamentivorans; Li, Leptospira interrogans; Ct, Chlamydia trachomatis; Rs, Rhodobacter sphaeroides.

Leptospiraceae and its subsequent transfer to the Rhodobiacaeae suggests that it might have conveyed some selective advantage prior to the introduction of sulfonamides, but the advent of mutations providing significant resistance to sulfonamide and their subsequent spread could also have been fortuitous. In both scenarios, formally variants of an evolutionary exaptation process (Gould and Vrba, 1982), a resistance-causing mutation may arise and be maintained in the population in the absence of direct antibiotic selection. Upon the clinical introduction of the relevant antibiotic, selection favors the rapid spread of the resistance determinant.

The emergence and maintenance of resistance against synthetic chemotherapeutic agents prior to their clinical deployment may hence reside in the evolution of resistance as a side-effect of mutations providing some other fitness benefit. A case in point is the evolution and rapid mobilization via plasmid-borne qnr genes of resistance to quinolones (Nordmann and Poirel, 2005). Qnr proteins bind to DNA gyrase, the target of quinolones, early in the gyrase catalytic cycle and decrease binding of quinolones to the enzyme-DNA complex (Tran et al., 2005). Other members of the pentapeptide repeat family are known to bind DNA gyrase and provide some level of quinolone resistance (Hege et al., 2005). Conversely, qnr-encoded proteins can provide cross-protection against naturally occurring antibiotics and synthetic agents targeting DNA gyrase (Hooper and Jacoby, 2016). The likely chromosomal origins of qnrA and qnrS genes have been traced to water-borne isolates of, respectively, Shewanella algae and Vibrio splendidus (Cantón, 2009) (Table 1). It has been hypothesized that these ancestral qnr genes and other pentapeptide repeat family members may have evolved to provide resistance against other compounds targeting DNA gyrase, such as the plasmid-borne microcin B17 (Heddle et al., 2001), as elements facilitating or modulating the normal function of DNA gyrase (Aminov and Mackie, 2007) or as functional components of the adaptation of Shewanella species to cold environments (Kim et al., 2011). In this context, the sequence determinants associated with chromosomal folP<sup>*</sup> genes may have originally enhanced PABA binding or another aspect of folate biosynthesis (Sköld, 2000), provided protection against hitherto unknown antibiotics targeting DHPS, or fulfilled an unrelated function.

The emergence and persistence of mutations conferring resistance against chemotherapeutic agents prior to their discovery may also have taken place in the absence of selection for the resistance-conferring mutations. The appearance of sulfonamide-resistance mutations in chromosomal folP genes has been amply documented (Huovinen et al., 1995; Sköld, 2000), and these were in fact the primary drivers of sulfonamide resistance following the introduction of sulfa drugs (Sköld, 2000). Furthermore, it has been documented that the presence of sulfonamide resistant DHPS does not necessarily impose a fitness cost on bacteria (Ènne et al., 2004). Structural studies have suggested that most sulfonamide resistance mutations act by modulating accessibility of sulfonamides to the PABA-binding pocket without hindering PABA binding (Baca et al., 2000; Morgan et al., 2011). It is hence conceivable that naturally occurring mutations conferring resistance to sulfonamide might not be selected against in the absence of this chemotherapeutic agent. Subsequent complementary changes to adjust the affinity for PABA of the altered DHPS molecule may have resulted in fixation of the original mutations conferring resistance to sulfonamide (Andersson, 2006).

Alternatively, sulfonamide resistance mutations in folP may have arisen and persisted in response to naturally occurring sulfonamides produced by competing organisms. Sulfonamides are rare in nature, with only eight known natural sulfonamides reported to date (Petkowski et al., 2018). Of these, only two naturally occurring sulfonamides are aryl sulfonamides, produced in very small amounts by recombinant Streptomyces species harboring the complete xiamycin biosynthesis gene cluster (Baunach et al., 2015). Although these sulfonamides show potent antimicrobial activity, their bulky substitution pattern suggests that their mode of action and molecular target are likely different from synthetic aryl sulfonamides (Baunach et al., 2015).

Mobilization of Ancestral Resistance Reservoirs

The phylogenetic inference and genomic analysis results reported in this work uphold an evolutionary scenario wherein chromosomally encoded sulfonamide resistant folP variants were independently mobilized from Leptospiraceae and Rhodobiacaeae backgrounds, and that mobile folP<sup>*</sup> genes subsequently spread very rapidly following the clinical introduction of synthetic aryl sulfonamides, giving rise to the sul1/2 and sul3 genes routinely detected in clinical isolates (Figure 5). The rapid mobilization and dissemination of genes conferring resistance to antibiotic and chemotherapeutic agents upon the clinical or agricultural use of these compounds has been amply documented (Aminov and Mackie, 2007; Stokes and Gillings, 2011). Mobilization and spread may be mediated by plasmids encoding transposons and integrons, as well as integrative and conjugative elements, mobile pathogenicity islands and bacteriophages, but the common tenet is that sustained exposure of bacterial populations to antibiotics or chemotherapeutic agents induces a strong selective pressure to elicit the mobilization of resistance determinants (Stokes and Gillings, 2011).
Together with penicillin and tetracycline, sulfonamides have been the antibacterial agents most frequently used at sub-therapeutic levels in livestock production (Franco et al., 1990), and it has been reported that sulfonamides have higher mobility, lower removal efficiency and deeper environmental penetration than most other antibacterial agents (Kumar et al., 2005). The widespread and intensive use of sulfonamides in agriculture, aquaculture and animal husbandry since the mid 1960's, and their persistence in soil, sediments and subterranean aquatic communities where *Leptospiraceae* and *Rhodobiaceae* abound, provides an ample window of opportunity for the spread of chromosomally encoded or already
mobilized \( \text{folP}^* \) genes within these bacterial communities and the subsequent transfer of these mobile resistance determinants to other bacterial clades.

Recent mobilization from a Chloroflexi chromosomal \( \text{folP} \) background has been postulated as the likely origin of the \( \text{sul} 4 \) gene (Razavi et al., 2017), and this result is in agreement with the phylogenetic analysis reported here (Figure 2). In the case of the chromosomal \( \text{folP}^* \) genes identified here and their mobilization into \( \text{sul} \)-harboring resistance vectors, several sources of evidence provide additional support for the frequent mobilization of chromosomal \( \text{folP}\) genes. For instance, phylogenetic evidence (Figure 2) indicates that the \( \text{Rhodobacteraceae folP}^* \) was incorporated at some point by the Actinobacterium \( \text{Amycolatopsis} \), which harbors three \( \text{folP} \) orthologs (Supplementary Data 7). Similarly, a plasmid broadly distributed among \( \text{Azospirillum} \) isolates (e.g., AP010951, FQ311873), a member of the \( \text{Rhodospirillaceae} \) Alphaproteobacteria family, contains a \( \text{folP} \) gene flanked by genes coding for a flagellar export pore protein (FlhB) and the full length phosphoglucomutase (GlmM) (Supplementary Data 7). This \( \text{folP} \) does not contain the signature two-amino acid insertion, indicating that its mobilization occurred independently of those leading to \( \text{sul} 2/2 \) genes.

More significantly, a partial genomic sequence from a \( \text{Pseudomonas aeruginosa} \) isolate (LLMY1000073.1) harbors a \( \text{folP}^* \) gene with high sequence and genetic neighborhood similarity to the \( \text{Rhodobacteraceae P. lavamentivorans} \) DS-1 (van Belkum et al., 2015). The genes immediately upstream and downstream of this \( \text{P. aeruginosa folP}^* \), which contains the \( \text{Sul} \) motif, encode a TetR family regulator and a partial phosphoglucosamine mutase (GlmM) (Supplementary Data 7). These three genes are flanked by \( \text{IS91} \) and \( \text{ISL3} \) family transposases. Importantly, the \( \text{IS91} \) transposase contains similar sequence motifs and shares termini identity with ISCR elements, which are present in both \( \text{sul1} \) and \( \text{sul2} \)-harboring plasmids (Toleman et al., 2006; Toleman and Walsh, 2011). Moreover, this \( \text{P. aeruginosa folP}^* \) presents 72.76% nucleotide identity with the \( \text{P. lavamentivorans folP}^* \), which is significantly higher than the one observed between \( \text{P. lavamentivorans folP}^* \) and \( \text{sul2} \) (Table 1). It is hence highly likely that the \( \text{P. aeruginosa folP}^* \) represents an intermediate step or an independent mobilization of the \( \text{Rhodobacteraceae folP}^* \).

Taken together, the protein sequence phylogeny and genomic context evidence (Figures 1–3), the absence of \( \text{Sul} \)-containing motifs in any other chromosomal \( \text{folP} \) genes (Figure 1), the tight alignment in \%GC content between the different chromosomal \( \text{folP}^* \) and mobile \( \text{sul} \) genes (Figure 4), and the identification of multiple \( \text{folP} \) mobilization events consistently point toward an independent mobilization from \( \text{Leptospiraceae} \) and \( \text{Rhodobacteraceae} \) chromosomal backgrounds that gave rise to, respectively, \( \text{sul3} \) and \( \text{sul2/1} \) genes. The close similarity in \%GC content between the putative donor and mobilized sequences (Figure 4), and the lack of suitable models for sequence evolution in mobile elements make it difficult to estimate precisely the timing of this mobilization using sequence analysis methods. The relatively low nucleotide sequence identity between the \( \text{Leptospiraceae} \) and \( \text{Rhodobacteraceae} \) chromosomal \( \text{folP}^* \) genes and \( \text{sul} \) genes (Table 1) suggests that \( \text{folP}^* \) genes were mobilized and diversified long before the clinical introduction of sulfonamides. Nonetheless, extensive recombination and unusual selection pressures on mobile elements could in principle also account for the observed sequence divergence within a shorter timescale. What seems abundantly clear is that shortly after the clinical introduction of sulfonamides, \( \text{sul} \) genes spread rapidly on a variety of mobile elements, as attested by the well-established association between \( \text{sul} \) genes and integrons (Lévesque et al., 1995; Davies, 2007).

Metagenomics analysis and prospective studies of preserved ancient environments, such as permafrost and remote cave habitats, have largely displaced the notion that antibiotic resistance emerges in response to anthropogenic antibiotic use (D’Costa et al., 2011; Bhullar et al., 2012; Perron et al., 2015; Crofts et al., 2017). These studies have conclusively shown that antibiotic resistance predated the use of antibiotics by humans, and that it is widely distributed across the bacterial pangenome. In a few isolated cases, resistance determinants for synthetic chemotherapeutic agents that predate or have rapidly arisen upon human use has been documented, but their existence can be attributed to cross-resistance to naturally occurring antibiotics [e.g., microcin B17 for quinolones (Tran and Jacoby, 2002), sisomicin for amikacin (Perron et al., 2015)]. The identification in this work of ancient chromosomal mutations in \( \text{folP} \) conferring resistance to sulfonamide as the likely origins of the \( \text{sul1} \)-\( \text{3} \) genes present in sulfonamide-resistant clinical isolates puts forward an alternative scenario. Given the absence of known naturally occurring aryl sulfonamides targeting DHPS, our results suggest that resistance to novel synthetic chemotherapeutic agents may be already available in the vast microbial pangenome, and that its global dissemination can take place in a very short amount of time upon the clinical introduction of novel chemotherapeutic compounds.

DATA AVAILABILITY STATEMENT

The datasets used in this study can all be freely accessed at the NCBI GenBank/RefSeq databases (https://www.ncbi.nlm.nih.gov/). All scripts used for analysis can be obtained at the GitHub ErillLab repository (https://github.com/ErillLab/).

AUTHOR CONTRIBUTIONS

MS-O and IE performed the \textit{in silico} analyses. MS-O and IE developed scripts for genomic analyses and ran phylogenetic inference methods. MS-O and PC performed the \textit{in vitro} analyses. IE and JB conceived the experiments and coordinated the research. IE and MS-O drafted the manuscript. All authors discussed the findings and interpreted the results.

FUNDING

This work was supported by grant BIO2016-77011-R from the Spanish Ministerio de Economía y Competitividad to JB.
ACKNOWLEDGMENTS

The authors wish to thank Joan Ruiz and Susana Escrivano for their technical support during some of the experimental procedures, as well as Júlia López for her continued support.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fmicb.2018.03332/full#supplementary-material
