(Dated: August 3, 2022)  

Primordial black holes, allegedly formed in the very early Universe, have been proposed as a possible viable dark matter candidate. In this work we characterize the expected gravitational wave signal detectable by the planned space-borne interferometer LISA and the proposed next generation space-borne interferometer \( \mu \)Ares arising from a population of primordial black holes orbiting Sgr A*, the super-massive black hole at the Galactic center. Assuming that such objects indeed form the entire diffuse mass allowed by the observed orbits of stars in the Galactic center (\( \lesssim 4 \times 10^3 M_\odot \) within a radius of \( \simeq 10^{-3} \) pc from Sgr A*), under the simplified assumption of circular orbits and monochromatic mass function, we assess the expected signal in gravitational waves, either from resolved and non-resolved sources. We estimate a small but non negligible chance of \( \gtrsim 10\% \) of detecting one single \( 1 M_\odot \) primordial black hole with LISA in a 10-year-long data stream, while the background signal due to unresolved sources would essentially elude any reasonable chance of detection. On the contrary, \( \mu \)Ares, with a \( \simeq 3 \) orders-of-magnitude better sensitivity at \( \simeq 10^{-5} \) Hz, would be able to resolve \( \simeq 140 \) solar mass primordial black holes in the same amount of time, while the unresolved background could be observable with an integrated signal-to-noise ratio \( \gtrsim 100 \). Allowing the typical PBH mass to be in the range \( 0.01-10 M_\odot \), a mass for which the number of resolvable events is indeed maximized.

I. INTRODUCTION

In recent years, partly motivated by the inconclusive results of many enterprises aimed at the detection of dark-matter particles (for a review see, e.g., [1, 3]), primordial black holes (PBHs) gained increasing attention as a possible candidate [4, 7] for such an elusive component, which accounts to 25\% of the energy density of today's Universe.

The existence of PBHs as physical objects was first proposed in 1966 by Zeldovich [8], and in 1971 Hawking similarly postulated how such objects could originate [9]. Current models trace the origin of PBHs to the collapse of large density perturbations in the early Universe, usually in the post-inflation era \( t \gtrsim 10^{-38} \text{s} \) [10, 11]. More recent work on possible formation channels include: formation by isocurvature perturbations, such as fragmentation of a real scalar field [15], resonant amplification of the curvature perturbations [16], vacuum tunneling during inflation [17], and scalaron+\( \chi \) models [18], among others.

Ref. [19] first proposed a simple relation between the typical mass of a newly formed PBH \( m_{\text{PBH}} \) and its formation cosmic time \( t \), i.e.,

\[
m_{\text{PBH}} \simeq \frac{c t^4}{G} \simeq 10^{15} \left( \frac{t}{10^{-23} \text{s}} \right) g \simeq 10^5 \left( \frac{t}{1 \text{s}} \right) M_\odot. \tag{1}
\]

Accordingly, since black holes lose mass because of Hawking radiation [9], a PBH is expected to evaporate completely in a timescale given by [20]:

\[
\tau \simeq \frac{G^2 m_{\text{PBH}}^3}{\hbar c^4} \simeq 10^{94} \left( \frac{m_{\text{PBH}}}{M_\odot} \right)^3 \text{yrs.} \tag{2}
\]

While a lower limit on the current mass of a PBH is obtained by setting the evaporation time equal to the Hubble time, i.e., \( m_{\text{PBH}} \gtrsim 10^5 \) g, no proper upper limits exist, at least on a theoretical ground. It is worth mentioning that recent theoretical arguments by [21] suggest that, under the assumption of a scale-invariant amplitude of primordial curvature fluctuations, the resulting PBH mass spectrum should show a clear peak at \( \simeq 1 M_\odot \).

In terms of energy density, a first order estimate of the current contribution of PBHs to the dark matter component of the Universe is given in [20] as

\[
f_{\text{PBH}} = \frac{\Omega_{\text{PBH}}}{\Omega_{\text{CDM}}} \simeq \left( \frac{\beta}{10^{-15}} \right) \left( \frac{m_{\text{PBH}}}{10^{15} \text{g}} \right)^{-1/2}, \tag{3}
\]

where \( \Omega_{\text{PBH}} \) and \( \Omega_{\text{CDM}} \) are the current density parameters in PBHs and in cold dark-matter, respectively, while \( \beta \) is the fraction of the Universe mass in PBHs at their formation time. A number of different techniques aimed at determining upper limits on the PBH fraction as a dark matter component have been proposed, namely gravitational lensing, dynamical effects, influence on large-scale structure, accretion and gravitational waves (see [20] for a recent review). In particular, [22] estimated the properties of a population of PBHs orbiting the supermassive variety of BHs at the center of galaxies, deriving the expected signal in gravitational waves (GWs). After limiting the analysis to the case of Sgr A*, thanks to existing scaling relations [23, 24] the authors of [22] assessed the GW signal arising from the entire cosmic population of galaxies. Further work on the detectability of a GW stochastic background from PBHs can be found in [25, 26].
In the present paper we extend and refine the analysis of [22], by improving the physical soundness of the model in many aspects. In Section II we compute the expected density profile for PBHs orbiting Sgr A* near the innermost stable circular orbit (ISCO), by considering the combined effects of two-body relaxation and GW losses, anchoring the PBH population to the one key observational constraint given by GRAVITY [27]. In particular, we adopt the upper limit of the diffuse mass allowed within the pericenter of the S2 star around Sgr A*, i.e., \( \lesssim 4 \times 10^3 \, M_\odot \) within \( r_{\text{S2}} \equiv 6 \times 10^{-4} \, \text{pc} \) from Sgr A* (i.e., about 1400 Schwarzschild Radii). In Section III we present a brief outline of the basic theoretical background of GW detection. In Section IV, through dedicated, extensive Monte-Carlo simulations, we estimate the GW characteristic strain from such constrained population of PBHs, considering observations performed by the planned space-borne interferometer LISA [28] and by the proposed next generation space-borne interferometer Ares [29]. A distinction between resolved events and stochastic background is also then carried out before calculating the corresponding signal to noise ratios. Finally, Section V is dedicated to concluding remarks.

II. DENSITY DISTRIBUTION OF PBHS AROUND SGR A*

As in [22], we assume that a population of PBHs with typical mass \( m_{\text{PBH}} = 1 \, M_\odot \) constitutes a fraction of the dark matter in the galactic center. As already pointed out, recent theoretical developments by [21] indicate indeed 1 \( M_\odot \) as the preferred mass of PBHs (still, we will relax the assumption on the mass later on). PBHs are assumed to orbit Sgr A* on purely circular orbits, and are supposed to be initially distributed according to a Navarro-Frenk-White (NFW) profile [30]. Two-body relaxation then shapes the density profile \( \rho(r) \) on a characteristic timescale given by [31]

\[
\tau_{\text{BH}} = \frac{1.8 \times 10^{-7} \, \text{yr}}{\log(M_{\text{BH}}/m_{\text{PBH}})} \left( \frac{1 \, M_\odot}{m_{\text{PBH}}} \right) \left( \frac{3 \, M_\odot \, \text{pc}^{-3}}{\rho(r)} \right)^{3} \left( \frac{v(r)}{10 \, \text{km} \, \text{s}^{-1}} \right)^{3},
\]

where \( M_{\text{BH}} \) is the mass of the central black hole, \( m_{\text{PBH}} \) is the typical mass of PBHs, and \( v(r) \) is the Keplerian mean velocity \( \sqrt{G M_{\text{BH}}/r} \). Adopting \( M_{\text{BH}} = 4.3 \times 10^6 \, M_\odot \) [27], and by assuming the PBHs to be distributed within a spherical shell comprised between \( 10^{-8} \, \text{pc} \) and \( 10^{-3} \, \text{pc} \) from Sgr A*, we found a maximum mass density of PBHs of few \( 10^{15} \, M_\odot \, \text{pc}^{-3} \) at \( \sim 3 \times 10^{-6} \, \text{pc} \) distance from Sgr A*, in agreement with [22]. To be more precise, over a relaxation time, a spike with \( \rho \propto r^{-7/3} \) is expected to form, and this is the default model that we consider here (with a cautionary \( \gamma = 1 \) power index in Eq. 1 of [22]). In the remainder of this work we will refer to this as a Spiked NFW profile. However, though neglected by [22], GW-driven inspirals and plunges of PBHs onto Sgr A* largely deplete the PBH population in the very center on a characteristic timescale given by [32]

\[
\tau_{\text{GW}} = \frac{5}{256} \frac{\varepsilon^2 r^4}{G^3 m_{\mu}^2 \mu} \approx 4 \times 10^{12} \, \text{y} \left( \frac{r}{r_{\text{S2}}} \right)^4,
\]

where \( m_{\mu} \) is the total mass of the binary and \( \mu \) is the reduced mass. The numerical value is appropriate for a 1 \( M_\odot \) PBH orbiting Sgr A* at the S2 pericenter. The above equation assumes circular orbits and quadrupole approximation. The two timescales \( \tau_{\text{BH}} \) and \( \tau_{\text{GW}} \) are shown as functions of the distance from Sgr A* in Fig. 1 as dotted and dashed lines, respectively, for the aforementioned selection of the input parameters. It is apparent how closer to Sgr A* than \( \sim 6 \times 10^{-5} \, \text{pc} \) the dynamical evolution of the PBHs population is no longer relaxation-dominated, but is driven by GW radiation losses. At such characteristic distance the time to coalescence because of GWs is \( \sim 4.2 \times 10^8 \, \text{y} \). Finally, the PBH number density distribution \( dN/dr \) (i.e., the number of objects within \( r \) and \( r + dr \) distance from Sgr A*) can be found by combining these two processes, and the resulting steady-state PBH number density profile, normalized so that the diffused mass within \( \sim 6 \times 10^{-4} \, \text{pc} \) from Sgr A* is \( \lesssim 4 \times 10^3 \, M_\odot \), is displayed in Fig. 2 for a number of plausible relaxation-driven density profiles. In the GW-domain region the PBH number density is \( \propto r^4 \), while in the outer relaxation-domain it will follow the assumed density profile. In this work we first consider the Spiked NFW density profile (solid line in Fig. 2) from [23,33], while in Section III we further study the cases for a Bahcall-Wolf (dashed line) and isothermal sphere (dotted line) density profiles. It is interesting to note how, given the similar scaling with \( m_{\text{PBH}} \) of \( \tau_{\text{BH}} \) and \( \tau_{\text{GW}} \) (Eq. 4 and Eq. 5 respectively), the location of the turning point in the distribution shown in Fig. 2 is almost independent of the actual value of \( m_{\text{PBH}} \).
III. GRAVITATIONAL WAVE SIGNALS

In this section we introduce the observables we consider in order to characterize the GW signal arising from the population of PBHs described in the previous sections. Both the frequency dependent strain amplitude \( h(f) \) and the interferometer sensitivity \( S_n(f) \) in general depend upon the position of the GW source in the sky relative to the detector. It is then useful to make the distinction between an “optimal case” and an “average case”, in terms of the orientation of the source-detector system. Following, e.g., [34], for an interferometer with non-perpendicular arms such as LISA, letting \( \alpha \) be the angle between the two arms, the detector beam pattern functions \( F_+ \) and \( F_\times \) are defined as

\[
F_+(\theta, \phi, \psi) = \sin \alpha \left[ \frac{1}{2} (1 + \cos^2 \theta) \sin(\alpha + 2\phi) \cos 2\psi \right. \\
+ \cos \theta \cos(\alpha + 2\phi) \sin 2\psi \left. \right],
\]

\[
F_\times(\theta, \phi, \psi) = \sin \alpha \left[ \frac{1}{2} (1 + \cos^2 \theta) \sin(\alpha + 2\phi) \sin 2\psi \\
- \cos \theta \cos(\alpha + 2\phi) \cos 2\psi \right],
\]

where the angles \( \theta \) and \( \phi \) define the source sky position, and \( \psi \) is the angle of the polarization plane with respect to the line of sight. The strain amplitude in the time domain \( h(t) \) is then

\[
h(t) = F_+(\theta, \phi, \psi) h_+(t) + F_\times(\theta, \phi, \psi) h_\times(t),
\]

where, in the case of circular orbits, the amplitudes for the two polarization modes are [32]

\[
h_+(t) = \frac{4}{r} \left( \frac{GM_c}{c^2} \right)^{5/3} \left( \frac{\pi f}{c} \right)^{2/3} \left( \frac{1 + \cos^2 \ell}{2} \right) \\
\times \cos(2\pi f t_\text{ret} + 2\phi_0),
\]

\[
h_\times(t) = \frac{4}{r} \left( \frac{GM_c}{c^2} \right)^{5/3} \left( \frac{\pi f}{c} \right)^{2/3} \cos \ell \\
\times \sin(2\pi f t_\text{ret} + 2\phi_0).
\]

Here \( t_\text{ret} = t - \frac{|\mathbf{x} - \mathbf{x}'|}{c} \) indicates retarded time, where \( \mathbf{x} \) and \( \mathbf{x}' \), as per the definition in Chapter 3 of [32], are, respectively, the distances at any time \( t \) from the source’s center to the detector and to a point inside the source. The “optimal orientation” case occurs when the source has angular momentum directed towards the detector, so it is face on, e.g., when \( \theta, \phi \) and \( \psi \) combine to give

\[
F_+ = 1, \\
F_\times = 0,
\]

while the “average case” is defined whenever

\[
\langle F_+^2 \rangle = \langle F_\times^2 \rangle.
\]

For further reference, see [34] and [35], or also [36]. In our work we will make use of the inclination-and-polarization averaged strain, i.e.,

\[
h = \sqrt{h_+^2 + h_\times^2}.
\]

Since we are considering sources in the Galactic center, we can ignore factors \((1 + z)\) stemming from the Universe expansion. The inclination-and-polarization averaged strain amplitude \( h \) as a function of frequency is therefore simply given by [37]

\[
h(f, d) = \frac{8\pi^{2/3} G^{5/3} f^{2/3} M_5^{5/3}}{c^4 \sqrt{10} d},
\]

where \( M_5 = m_{12}^{2/5} \) is the chirp mass and \( d \) is the distance to the source. From the strain, the signal to noise ratio of the event can be computed as

\[
\text{SNR}(f) = \frac{h(f)\sqrt{N_n(f)}}{\sqrt{f S_n(f)}},
\]

where, assuming that binaries are quasi-stationary during the observation time, the number of cycles as a function of observation time \( t_\text{obs} \) and frequency \( f \) is given by \( N_\text{cyc} = t_\text{obs} \times f \). In Eq.[16] the so-called noise spectral density \( S_n(f) \) (sometimes referred to as the noise spectral sensitivity or spectral amplitude) has units [Hz\(^{-1}\)], and quantifies the sensitivity of the GW detector. When computing the expected GW signal detectable by LISA we will adopt the noise spectral density reported in [38]. Although the sources that we consider are originated at the Galactic center, we will use the sky averaged \( S_n(f) \).
IV. RESULTS

In order to compute the GW signal arising from the population of PBHs described in the previous sections, we run a series of Monte-Carlo simulations randomly sampling the underlying distribution with 4000 PBHs of $1 M_\odot$. From the sampled population we then compute the resulting GW signal. We explicitly make a distinction between resolved events and unresolved ones, the latter combining to build-up a stochastic background. Our final results are then obtained by averaging the GW signal over a statistically significant number of simulations. In the following, we analyse the two different types of signals (resolved and background). All relevant figures are reported in Table 4.

A. Resolved events

In estimating the distribution of resolved sources, we deem an event “resolvable” whenever the two following criteria are simultaneously satisfied:

- the event has SNR $\geq 8$;
- no more than 1 event falls within a given frequency resolution bin.

As a first step, through Monte-Carlo simulations we randomly select 4000 PBHs (so as to cope with the mass constraints given by [27]) from the underlying distribution, constructing a catalog of potential sources. Then, for each source in the catalog, we compute the GW signal and its SNR according to the LISA and $\mu$ARES sensitivities. As in a typical catalog realization LISA would resolve from zero to a maximum of 1 event, in order to have a statistically significant figure we run a total of 1,000 simulations. Fig. 4 shows the probability, computed over 1,000 Monte-Carlo realizations, that a catalog contains a given number of resolved events. Regarding LISA, it is apparent how the vast majority of realizations contain no detection whatsoever, with few simulations resulting in just 1 event. Statistically, there is a $\approx 11\%$ probability that one PBH might be resolved by LISA in 10 year of data collection, with the remaining 89% probability of null detection.

---

1 Note that, given the monochromatic nature of our targets, results are essentially unaffected if the data are obtained in a continuous stream, rather than collected along a longer mission with a duty cycle of less than 100%.

2 Circular EMRIs like the ones considered here are essentially monochromatic sources featuring a waveform very similar to that of galactic white dwarf binaries, for which resolvability down to SNR = 8 has been demonstrated in early LISA mock data challenges [12].

3 The frequency resolution of the data is defined as the inverse of $t_{\text{obs}}$, so that for $t_{\text{obs}} = 10 \ (4.5) \ \text{yrs}$, the corresponding frequency resolution will be $3 \ (7) \times 10^{-9} \ \text{Hz}$.

4 Detection probabilities are only slightly modified by a change in $t_{\text{obs}}$, which in turn affects the frequency bin width and the number of cycles in the characteristic strain. For instance, halving $t_{\text{obs}}$ would reduce the SNR by a factor $\sqrt{2}$. 

FIG. 3: Sensitivities for LISA (dot-dashed line) and $\mu$ARES (dotted line) in the relevant frequency range.

While this choice is primarily driven by simplicity, it should be noted that PBHs are persistent sources and their signal will build-up in the data stream for the whole duration of the mission. Being the north ecliptic pole tilted by approximately 60° with respect to the galactic north pole and being the LISA constellation tilted by 60° with respect to the ecliptic, along the LISA orbit, the galactic center will be seen at a variable inclination, spanning a wide range essentially from being face-on to being edge-on. As for $\mu$ARES, the proposed design features two constellations in perpendicular planes, making the use of sky-averaged sensitivity a reasonable compromise in both cases.

Finally, we will add to the instrumental sensitivity curve the background noise arising from the cosmic population of white dwarf (WD) binaries [39,40]. When forecasting the GW signal in $\mu$ARES data stream, we will take $S_n(f)$ from [29], note that in this case the instrumental noise already takes into account the WD background (see also [41] for a recent take on an alternative technique to detect stochastic backgrounds in the $\mu$Hz band relying on binary resonance probes).

The observation time $t_{\text{obs}}$ (i.e., the proper “data-taking” time) for the LISA interferometer is currently set to be $\geq 45 \ \text{yrs long}$, though potentially 10 years of data could be collected, if mission operations are extended and there is no failure in the hardware. Similarly, for the proposed $\mu$ARES mission, at the time of writing a $\geq 10\text{-year long}$ mission is foreseen. In the following section, we will refer to $t_{\text{obs}} = 10 \ \text{yrs}$ for both interferometers. Fig. 3 shows the sensitivities of LISA and $\mu$ARES in the frequency range relevant to our study.
Given its much higher sensitivity at low frequencies, the outcome for \( \mu \text{Ares} \) is strikingly different, resulting in an average of \( \approx 140 \) detected PBHs in 10 years. The probability distribution, again computed over 1,000 realizations, is well fit by a Gaussian distribution with mean and standard deviation of 139.6 and 9.7, respectively. Under the assumption that the unresolved matter within the Galactic center is entirely formed by PBHs, this means that \( \mu \text{Ares} \) would have a chance of 99.9% of resolving a minimum of 110 solar-mass PBHs orbiting Sgr A*. Under our assumption of circular orbits and inclination-and-polarization averaged strain, there exist 1:1:1 relations among the radial distance of a PBH to Sgr A*, its GW frequency and the SNR of the event. From the source catalogs we can then compute frequency and SNR distributions, shown in Fig. 3. The distributions are obtained adopting a logarithmic binning in frequency, and are normalized so that the sum of the histogram heights gives the average number of resolved events, i.e., 0.11 in the case of LISA and 140 for \( \mu \text{Ares} \). Regarding LISA, all we can say is that the single one event possibly resolved during 10 years of data collection would have a higher chance to fall in the frequency range \( 3.5 \times 10^{-5} \lesssim f \lesssim 6 \times 10^{-5} \) Hz, corresponding to \( 8 \lesssim \text{SNR} \lesssim 30 \). \( \mu \text{Ares} \), instead, will produce a genuine distribution of resolved events, covering at least one decade in frequency with an SNR as large as few hundreds.

Finally, we note that the detection statistics is mainly driven by the SNR \( > 8 \) constraint, as for \( f \gtrsim 10^{-5} \) Hz there are, on average, less than 1 PBH per frequency bin anyway. This applies to both interferometers, although in the case of \( \mu \text{Ares} \) some overlap may occur in the lower frequency bins, where the number of resolvable sources is larger (Fig. 5, panel b). The figures reported here, and in next § IV C as well, would be only marginally affected by a different choice of the SNR threshold. As an example, an SNR threshold of 5 would rather produce a \( \lesssim 1\% \) increase in the chances of detection by LISA and a \( \approx 5\% \) increase in the number of sources resolvable by \( \mu \text{Ares} \).

**B. Stochastic background**

Many PBHs, if not almost all as in the case of LISA, do not satisfy the criteria for being resolvable. Still, their cumulative GW signal could well produce a background signal whose SNR would be above detection threshold. In order to estimate the amplitude of the background signal, we use Eq. (7) of \([43]\),

\[
\frac{S}{N}_\text{bkg} = t_{\text{obs}} \int \gamma(f) \frac{h_{\text{c,bkg}}(f)}{4f^2 S_n(f)^2} df, \tag{17}
\]

where again we made use of the position and polarization-averaged sensitivity \( S_n(f) \). According to Fig. 4 in \([44]\) and to \([43]\), the so-called response function is \( \gamma(f) \approx 1 \) in the relevant frequency range, while for the characteristic strain \( h_{\text{c,bkg}}^2 \) we use from \([28]\)

\[
h_{\text{c,bkg}}^2 = \sum_i \frac{h_i(f)^2 f_i}{\Delta f} = \sum_i h_i(f)^2 N_{\text{cyc}}(f). \tag{18}
\]

In the above Eq. (18) the summation is intended over the whole catalog excluding all resolved sources. As discussed in \([45]\), this is a somewhat optimistic approach, as it implicitly assumes a free-of-errors estimate of source parameters, and a optimal waveform subtraction. The monochromatic nature of the PBHs considered here makes this approach reliable. In Fig. 6a and Fig. 6b we show \( h_{\text{c,bkg}}(f) \) for all unresolved sources in a 10-year-long stream of LISA and \( \mu \text{Ares} \) data, respectively. While at the lowest frequencies the characteristic strain resembles that of a typical background noise, at higher frequencies the relatively low number of sources gives the signal a “popcorn” flavour, with frequency bins filled by more than one source interloped by empty ones. It is interesting to note how in the case of LISA, given its much lower sensitivity, many high frequency sources are counted in the

**FIG. 4: Expected probability of finding a given number of PBHs, for LISA (a) and \( \mu \text{Ares} \) (b). The latter distribution is fitted with a Gaussian with parameters mean = 139.6 and standard deviation = 9.7.**

---

**FIG. 5: Expected probability of finding a given number of resolvable sources by LISA and \( \mu \text{Ares} \). The distributions are obtained adopting a logarithmic binning in frequency, and are normalized so that the sum of the histogram heights gives the average number of resolved events, i.e., 0.11 in the case of LISA and 140 for \( \mu \text{Ares} \).**

---

**FIG. 6: Expected probability of finding a given number of resolved sources in a 10-year-long stream of LISA and \( \mu \text{Ares} \) data, respectively. While at the lowest frequencies the characteristic strain resembles that of a typical background noise, at higher frequencies the relatively low number of sources gives the signal a “popcorn” flavour, with frequency bins filled by more than one source interloped by empty ones. It is interesting to note how in the case of LISA, given its much lower sensitivity, many high frequency sources are counted in the**
non-resolved pool, and hence do contribute to the background. For \( \mu \text{Ares} \), instead, sources at high frequencies (and hence high strains) will be always resolvable, consequently the background will not extend in the \( 10^{-5} \) Hz regime. The effect is apparent also when we plot the expected probability density distribution of the background \( \text{SNR} \) (Eq. 17), shown in Fig. 7a in the case of LISA, and in Fig. 7b in the case of \( \mu \text{Ares} \). The results are again obtained averaging over 1,000 simulation runs, and refer to a 10-year-long data stream. The stochastic background in the case of LISA spans a quite large range in \( \text{SNR} \), but it still has a very low chance to be detectable during the mission lifetime. On the contrary, in the case of \( \mu \text{Ares} \) the whole of unresolved sources combine to produce a GW background which would be observable with a \( \text{SNR} \) of few hundreds.

C. Dependence upon PBH mass and density distribution

In this section we relax our assumptions regarding the typical mass of PBHs, and the details of the mass density profile, vetting how our results depend upon the specific choice of input parameters. Regarding possible PBH masses connected to GW detection, we can limit the pertaining parameter space as follows. Based on various current upper limits (see, e.g., [20]), a window exists between \( 10^{-16} \) and \( 10^{-11} \, M_{\odot} \) where 100% of dark matter could be in the form of PBHs without violating any observational constraint. However, such PBHs would be much too light to enter the GW-dominated regime. This is true up until \( \sim 10^{-4} \, M_{\odot} \), where, still according to [20], the maximum allowed dark matter fraction in the form of PBHs happens to be \( \approx 1\% \). A more operational mass limit for PBHs can be set by considering the minimum mass orbiting Sgr A* at the ISCO (i.e. at \( 1.2 \times 10^{-6} \, \text{pc} \)) whose GW losses are above the detection threshold. Such mass turns out to be \( \gtrsim 5 \times 10^{-5} \, M_{\odot} \) for the LISA sensitivity. Note that, if \( m_{\text{PBH}} \lesssim 0.01 \, M_{\odot} \),

---

5 Note that if such light PBHs do happen to exist, they would be largely evacuated from the Galactic center because of mass segregation.
An increase of 3 dex in probability distribution occurs at the largest allowed distance. This very fact and that for a Bahcall-Wolf profile the higher PBH density distribution is at the sink radius \( r_{\text{sink}} \), testing such number as a probability of detecting a single resolved event during the mission. Such probability is as large as 60% in the case of \( m_{\text{PBH}} = 0.01 \, M_\odot \) with an isothermal profile. Note also that while the Spiked NFW and isothermal cases give comparable results, the shallow Bahcall-Wolf distribution reduces the probability of detection by an order of magnitude. Rather interestingly, the median SNR of the possible detection is very similar in all tested cases.

Concerning the possibility of a LISA detection of background noise arising from the population of PBHs, though the SNR increases for lower masses, none of our models predict a statistically significant stochastic signal in the LISA data stream. For \( \mu \text{Ares} \) results are somewhat less straightforward. In this case (see Fig. 3) the sensitivity curve features a sort of plateau for \( f \gtrsim 10^{-5.5} \text{ Hz} \), basically shaped by the WD stochastic background. For large values of \( m_{\text{PBH}} \), \( N_{\text{res}} \) is determined by the steep slope of the sensitivity curve for \( f \lesssim 10^{-5.5} \text{ Hz} \). This is because in this case the GW signal is strong enough that PBHs enter the observability band well below \( 10^{-5.5} \text{ Hz} \). Reducing the typical PBH mass would then increase \( N_{\text{res}} \), because of the very same reason seen in the case of LISA. However this is true only down to a certain mass, for which PBHs start entering the observability band above \( 10^{-5.5} \text{ Hz} \), i.e., in the flat part of the sensitivity curve. Further lowering the mass would lead more and more sources to fall well below detectability threshold. The combined effects of PBH typical mass and sensitivity then creates a “sweet spot” for \( N_{\text{res}} \) happening to be just around \( m_{\text{PBH}} \sim 1 \, M_\odot \), as reported in Table I. As in the case of LISA, the shallow Bahcall-Wolf profile gives an order of magnitude less detections. Still, even in this unfavorable circumstance, only for the lowest PBH mass the number of resolved events in 10 years is

**FIG. 7**: Expected distribution of the GW background SNRs for LISA (a) and \( \mu \text{Ares} \) (b).
below unity. Finally, regarding background detectability, in all cases $\mu_{\text{Ares}}$ would produce a signal with a very high SNR.

V. DISCUSSION AND CONCLUSIONS

If a distribution of PBHs is present in our Galaxy, it might concentrate at the Galactic center, where these objects would be expected to orbit around the central massive black hole Sgr A*, thus constituting possible sources for gravitational wave detectors. Assuming a stationary distribution of PBHs subject to two-body relaxation and gravitational-wave driven infall toward Sgr A*, and complying with the mass limits posed by S2 pericenter precession [27], we have computed the expected (resolved and unresolved) GW signal detectable by future space-borne observatories such as LISA and $\mu_{\text{Ares}}$. Although simplified, our model shows that there is a $\approx 10\%$ chance for LISA to resolve a 1 $M_\odot$ primordial black hole during a 10 years observation time, while even less likely is the detection of a background signal. A solid chance of detection might instead be expected from the proposed space-borne interferometer $\mu_{\text{Ares}}$, whose higher sensitivity would allow one to resolve from several to more than one hundred PBHs, regardless of the actual typical mass or density profile, and to detect an unresolved background with a signal to noise ratio well above detection threshold.

Another important question has to do with inferring the nature of the detected sources. In other words, should LISA detect a 1 $M_\odot$ source orbiting Sgr A*, will it be possible to distinguish between a primordial black hole from an astrophysical object, such as a star, or a brown dwarf? First, we should notice that measuring the (chirp) mass of a source (and thus the mass of the PBH) is only possible if the frequency is evolving, i.e., if the source is not completely monochromatic. From the quadrupole formula, the source frequency’s rate of change is [48]

$$\dot{f} = \frac{96}{5} \pi^{8/3} \left( \frac{G M_\star}{c^3} \right)^{5/3} f^{11/3}. \tag{19}$$

The frequency resolution $\Delta f$ of an experiment is the inverse of $t_{\text{obs}}$, i.e., $\Delta f \simeq 3 \times 10^{-9}$ Hz for 10 years of observation. At the highest resolved frequency by LISA (see Fig. 3a), i.e. $f \simeq 3 \times 10^{-4}$ Hz, the time needed for the frequency to change by $\Delta f$ is 19 days. At the lowest resolved frequency by LISA (again see Fig. 3a), $f \simeq 4 \times 10^{-5}$ Hz, the time goes up to 87 years. The cutoff frequency, where it takes exactly 10 years for the frequency to change by $\Delta f$, is $7.2 \times 10^{-5}$ Hz. Should the data stream span less than 10 years, say 4.5 years, such cutoff frequency would rise to $\simeq 1.1 \times 10^{-4}$ Hz, taking into account that $\Delta f$ would change accordingly. Therefore, we do not expect the mass of the PBH candidate to be measurable for all the detected events. Even for the events with measurable mass, a possible astrophysical origin should be considered. To distinguish between a star and a PBH, one may consider tidal effects. In more detail, a star would be tidally disrupted at the tidal disruption radius $r_t = R_\star (\frac{3M_\star}{16\pi\rho})^{1/3}$ with $R_\star$ and $m_\star$ the star’s radius and mass. For a solar-type star the tidal radius is $r_{t,\odot} \approx 3.7 \times 10^{-6}$ pc, or 9 Schwarzschild radii. As can be easily understood by comparing e.g. to our Fig. 2 this is way too close to Sgr A* to prove useful for telling 1 $M_\odot$ PBHs and stars apart. For comparison, at a distance of $10^{-5}$ pc, which is well within the range of Fig. 2 the typical stars that would be tidally disrupted would be ones like S2 (i.e. a B0 star with mass $\simeq 14 M_\odot$ and radius $\simeq 7 R_\odot$). Clearly, tidal effects can be more subtle, as a deformed star, even if not disrupted, would show characteristic tidal effects in the gravitational waveforms. However, those would only be observable if the source frequency is evolving (cf. the discussion on the mass estimate right above). Even more difficult would be to distinguish a neutron star from a PBH of similar mass; only in the case of a pulsar would such distinction be easily performed.

These preliminary considerations show that, although the detection of PBHs in the GC might be feasible in the future, recognizing their PBH nature might not be at all straightforward. In future work, we will therefore study in more detail the parameter estimation capabilities of LISA and $\mu_{\text{Ares}}$, focusing on the distinctness between PBHs and stars/brown dwarfs. Additionally, we will also assess the impact of eccentric PBH orbits on our results. In fact, a relaxed isotropic cusp of PBHs in the Galactic center is expected to feature a thermal eccentricity distribution, i.e. $p(e) \propto e$. Therefore, despite GW-driven circularization, we expect the overall signal to be dominated by eccentric sources. The importance of eccentricity is twofold. On the one hand, eccentric sources emit at higher frequencies, which might significantly increase the chances of LISA to see such systems. On the other hand, eccentric sources evolve much more rapidly, thus allowing for a better determination of the source mass, therefore helping the assessment of the source nature.

In closing, we underline that, compared to LISA and $\mu_{\text{Ares}}$, thanks to their sensitivity at higher frequencies ground-based interferometers such as the next Einstein Telescope [50] will play a complementary role in the search for GWs emitted by PBHs, e.g., in the detection of binaries of such objects [51, 52]. Indeed, the prospects of genuine multi-frequency GW observations [43] will greatly increase our chances of testing the existence of such an elusive population of black holes.
TABLE I: Results for different PBH masses and density profiles (Spiked NFW (⋆), isothermal sphere (○), Bahcall-Wolf (□)).
