Abstract
Luminescence spectroscopy experiments were realized for single colloidal quantum dots CdSe/ZnS in a broad temperature range above room temperature in a nitrogen atmosphere. Broadening and shifts of spectra due to the temperature change as well as due to spectral diffusion processes were detected and analyzed. A linear correlation between the positions of maxima and the squared linewidths of the spectra was found. This dependence was explained by a model that takes into account the slow variation of the electron-phonon coupling strength.

I. Introduction
Colloidal semiconductor quantum dots (QDs) are very interesting objects because of their unique optical properties such as a wide absorption spectrum, a narrow emission line, a size-tunable emission wavelength, high photostability, and high fluorescence quantum yield. The very first spectroscopic measurements of single CdSe quantum dot photoluminescence revealed interesting phenomena such as long-term fluctuations of the emission intensity (blinking) and very slow spectral diffusion (SD) with characteristic time scales of up to hundreds of seconds. It was shown that at cryogenic temperatures, the observed emission spectrum linewidth of single QDs depends on the signal accumulation time due to spectral shifts, while the linewidths and the peak positions of the spectra are correlated.

Spectral diffusion at higher temperatures was observed by Muller et al. in single CdSe QDs capped by a CdS rodlike shell. The linewidth and the peak position of the emission spectrum are found to be correlated at 5 K, 50 K, and room temperature. These correlations at all temperatures were explained by the motion of the net surface charge, which induces a Stark shift of the emission energy depending on the distance to the CdSe core, while the spatial jitter of the charge density causes spectral line broadening. Gomez et al. noted that this hypothesis does not apply to the spherically symmetric QDs. Besides, it should lead to variations of the linewidth with a change in the dielectric properties of the medium. A series of spectroscopic experiments were performed on single spherical QDs spin-coated on top of thin films of various polymer matrices at room temperature. It was shown that there is a correlation between the linewidth and the peak position of the emission spectrum in these particles without a significant dependence on the dielectric permittivity of the matrix. Based on this, it was concluded in Ref. 9 that the mechanism responsible for the correlated broadening and the peak position shift...
of the emission spectra in the PL has to be intrinsic to the QD core.

Note that the broadenings of single QD emission spectra at 5 K and at room temperature are different in nature. At 5 K, the zero-phonon line is observed and its width is much smaller than the longitudinal optical (LO) phonon energy. The linewidth at room temperature becomes greater than the energy of the LO phonons, which means that the multiphonon nature of the broadening should be taken into account. While the electron-phonon coupling and spectral diffusion contributions to the spectra of chromophore molecules in solid matrices have been studied in detail, the same contributions in QDs are still of much interest. Here, we present an in-depth experimental and theoretical study of the discussed spectral characteristics of single colloidal semiconductor QDs CdSe/ZnS in the context of their feasible relation to electron-phonon coupling.

II. EXPERIMENT

We performed a set of spectroscopic experiments with single QDs, including measurements with slow heating and cooling of a sample. Fluorescence images and spectra of single quantum dots were recorded using a home-built fluorescence microscope equipped with a prism spectrometer. Two optical schemes—a wide-field scheme and a scanning confocal one (see Fig. 1)—were combined in the microscope in order to simplify the procedure of single quantum dot preliminary searching (by using fluorescence image processing and antibunching identification) and to perform sequential measurements of the fluorescence spectra of the selected QD. Quantum dots (CdSe/ZnS from Sigma-Aldrich with the fluorescence peak at 620 nm) were dispersed in a toluene solution of polyisobutylene of low concentration and then spin coated onto a cover glass. The thickness of the polymer films with single quantum dots varied within the range of several tens of nanometers. The sample was placed onto the piezo-driven stage (NanoScan Technology), which allowed one to move the selected QD to the laser spot position with high (nanometer) precision. Between the sample and the piezo-driven stage, a thermoinsulating (fluoroplastic) substrate a few millimeters thick was placed, with a hole in the center allowing the microscope objective to approach the plane of the sample at the required distance. The thermoinsulating substrate contained a temperature sensor that had good thermal contact with the sample. On top of the sample, a three-stage thermoelectric module was pressed, which was used to heat or cool the sample. This optical scheme (including the piezo-driven stage with the sample, the microscope objective, and the thermoelectric module) was mounted inside a special home-built chamber, allowing measurements both in a vacuum and in a gas nitrogen/helium atmosphere. In this particular case, the measurements were performed in a nitrogen atmosphere. The sample temperature was controlled by using a LakeShore temperature controller. A tunable dye laser (Coherent CR599) or solid state laser Coherent Verdi was used to excite quantum dots at the wavelength of 580 nm (near the quantum dot absorption band edge) or at 532 nm, respectively. The excitation laser intensity (~100 W/cm² in a focused spot) was attenuated by neutral spectral density filters (Standa) and controlled by using a Newport power meter. A set of interference filters (Semrock and Thorlabs) was used for the separation of the QD fluorescence signal from the scattered laser radiation. Two highly sensitive cooled electron multiplying charge-coupled device (EMCCD) cameras were utilized to record single quantum dot images (Andor Luca) and spectra (Andor Ixon Ultra). The Hanbury Brown and Twiss scheme with broadband 50% splitter (Thorlabs) and two identical single-photon avalanche diode (SPAD) detectors (EG&G SPCM-200PQ, time resolution 1.3 ns, dead time 200 ns, QE 65%) was used to measure the autocorrelation function for QD fluorescence intensity. Each fluorescence spectrum from a single quantum dot was measured with an exposure time of 200 ms and a spectral resolution of 0.7 nm, which was sufficient to achieve a good signal-to-noise ratio.
FIG. 2. Spectral traces (left panel) where the peak position is shown by the red line, time dependencies of the normalized PL intensity (central panel), and the linewidth (right panel) for two different single CdSe/ZnS quantum dots (a) and (b) measured at room temperature.
III. RESULTS

In the experiments at room temperature for each studied single QD, we registered 2500–3000 emission spectra with 200 ms accumulation time. The presence of both blinking and spectral diffusion processes can be clearly seen. Spectral traces for two QDs are shown in Fig. 2.

Each spectrum was fitted with a Gaussian function

$$G(\epsilon) = \frac{G_0}{\sqrt{2\pi}\sigma} \exp\left\{ \frac{-(\epsilon - \epsilon_0)^2}{2\sigma^2} \right\} + b,$$

whose four parameters were peak emission photon energy \(\epsilon_0\), linewidth \(\sigma\), amplitude \(G_0\), and background level \(b\). An example of a typical spectrum fitting is shown in Fig. 3.

The correlation between the peak energy and the linewidth was found for all studied QDs. As seen in Fig. 4, the peak energy dependence of the linewidth squared can be fitted by the linear function

$$\sigma^2 = \alpha kT(E_0 - \epsilon_0),$$

where \(T\) is the absolute temperature, \(k\) is the Boltzmann constant, \(E_0\) is the energy gap for particular QD, and the parameter \(\alpha\) is the linear dependence coefficient between the squared line width and peak energy in the units of \(kT\). The values of \(\alpha\) are found to be in the range from 0.48 to 0.63 for varied QDs at room temperature.

In order to characterize the shift of the spectra, we found a squared peak energy displacement of a typical single QD emission spectrum

$$D^2(\tau) = \langle (\epsilon_0(t) - \epsilon_0(t + \tau))^2 \rangle$$

as a function of time \(\tau\) following Ref. 17. As can be seen in Fig. 5, the averaged spectral shift squared \(D^2\) is less than the \(\sigma^2\) of a typical single QD spectrum for all delay times, but more importantly, it is much smaller than linewidth squared when \(\tau\) is equal to the signal accumulation time \(\tau = 200\) ms. Thus, we can conclude that the observed linewidth is not related to the spectral shifts during this time period.
IV. THEORY AND DISCUSSION

Such a large value of the linewidth can be explained by multi-phonon excitation.11,12 Let us consider the following Hamiltonian of the QD electronic system interacting with $N$ phonon modes:

$$\hat{H} = \hat{H}_0 + A \sum_{i=1}^{N} \hat{q}_i (a_i |e\rangle \langle e| + b_i |g\rangle \langle g|),$$

where

$$\hat{H}_0 = \sum_{i=1}^{N} \frac{\hat{p}_i^2}{2} + \frac{\omega_i^2}{2} \hat{q}_i^2 + E_0 |e\rangle \langle e|,$$

$E_0$ is the energy gap, and $|g\rangle$ and $|e\rangle$ are the ground state and excited electronic state of the QD, respectively. The parameter $A$ characterizes the electron-phonon interaction strength. $\hat{q}_i$ and $\hat{p}_i$ are the coordinate and momentum operators of $i$th phonon mode, characterized by the frequency $\omega_i$. Both the excited state and the ground state are connected with the photon modes in the model. The interaction of the excited state and the ground state with the $i$th phonon is described by the dimensionless coefficients $a_i$ and $b_i$, correspondingly.

The emission spectrum at a given value of $A$ has a Gaussian form with the following parameters (see details of the derivation in the Appendix):

$$\epsilon_0 = E_0 - A^2 \sum_{i=1}^{N} a_i (a_i - b_i) \frac{1}{\omega_i^2},$$

$$\sigma^2 = kTA^2 \sum_{i=1}^{N} (a_i - b_i)^2 \frac{1}{\omega_i^2}.$$  

Equations (4) and (5) give the linear dependence of Eq. (1) where

$$\alpha = \left[ \sum_{i=1}^{N} a_i (a_i - b_i) \right] \frac{1}{\sum_{i=1}^{N} \omega_i^2}.$$  

As seen in Fig. 4, the parameter $\alpha$ varies from one QD to another, as well as $E_0$. The model predictions are consistent with the experimental results of Gomez et al.7 since the electron-phonon interaction in QDs is not related to the dielectric properties of the environment.

In order to check the theory at various temperatures, the spectroscopic experiment on one quantum dot was performed with heating and cooling of the sample. Twenty spectra were measured sequentially at each selected temperature in the range from 305.5 K to 353.6 K. It was found that all the data can be well fitted by Eq. (1), provided that the energy gap $E_0$ depends on temperature and keeps constant, as seen in Fig. 6. The $E_0$ value proves to decrease with temperature rise. The changes in the effective band gap presumably occur due to thermal expansion. Importantly, this result does not depend on the process which led the system to that temperature (heating or cooling). Note that this dependence of the “pure” energy gap $E_0$ on temperature is not due to the electron-phonon interaction as is usually considered.20–22

Therefore, the suggested model explains the fluctuations of the linewidth of a single QD emission at temperatures 300 K and above, but at the same time, it predicts the spectral shifts correlated with the linewidth.

What is the mechanism of the variations in the magnitude of the electron-phonon interaction? The estimate shows that at a given excitation intensity of 100 W/cm$^2$, the average time between the absorption of photons of one QD is about 1 $\mu$s. Thus, the effect of multie exciton states can be excluded from consideration. An increase in the temperature of a single QD after absorption of photons does not exceed 2 K, as estimated by Kuno et al.23 while thermal relaxation is of the order of 10 ps. This means that local heating can also be excluded from the possible causes of the phenomenon.

![FIG. 5. Time dependence of $D^2$ function for a single QD at room temperature (black diamonds). The red line is $-\tau^6$. The value of $\beta$ is 0.003.](image)

![FIG. 6. The peak energy vs the linewidth squared for a single QD at various temperatures (points). The solid lines indicate the theoretical prediction at four different temperatures. Parameter $\alpha = 0.03$.](image)
Plakhontnik et al. showed that the squared energy displacement of a single QD emission at cryogenic temperatures has an anomalous (sublinear) behavior at short times $D^2 \sim \tau^\beta$, where $\beta < 1$. It was explained by introducing a number of stochastic two-level systems (TLSs) having a wide distribution of flipping rates. The squared energy displacement calculated with the use of our experimental data at room temperature also shows a similar sublinear time dependence (Fig. 5). This means that the TLS based model can be used to describe the fluctuations of the electron-phonon interaction value at high temperatures as well. A possible microscopic origin of the conformation change in the TLS could be due to the jumps of the surface or interface atom between two quasistable positions. Note the general interest regarding the microscopic nature of the SD processes that were observed for most single quantum emitters: single organic dye molecules, single light harvesting complexes and proteins, color centers in diamonds, and single rare-earth ions in crystals. In many cases, SD has been attributed to the tunneling processes in an emitter and/or its local surroundings. At the same time, the relation between SD and phonon-assisted optical dephasing was always under discussion.

Empedocles and Bawendi observed changes in the electron-phonon interaction parameter upon application of an external electric field. It can be assumed that the shift of the peak of the spectrum in an external electric field is partially determined by a change in the electron-phonon interaction parameter upon application of an external electric field. It can be assumed that the shift of the peak of the spectrum and the emission intensity of a single quantum dots with nanometer spatial resolution is developed under support of the Russian Science Foundation (Project No. 17-72-20266, head I. Yu. Eremchev).

APPENDIX: DERIVATION OF EQUATIONS (4) AND (5)

Potential energy of the excited electronic state is given by the following formula:

$$U_e(q) = \sum_{i=1}^{N} \left( \frac{\omega_i^2}{2} q_i^2 + A q_i a_i \right).$$

In the classical limit $\hbar \omega_0 \ll kT$, the probability distribution function of the coordinates is given by the Boltzmann distribution,

$$P(q) = \frac{1}{Z} \exp \left\{ -\frac{1}{kT} \sum_{i=1}^{N} \left( \frac{\omega_i^2}{2} q_i^2 + A q_i a_i \right) \right\}, \quad (A1)$$

where $Z$ is the partition function,

$$Z = \int dq_1 \int dq_2 \cdots \int dq_N \exp \left\{ -\frac{1}{kT} \sum_{i=1}^{N} \left( \frac{\omega_i^2}{2} q_i^2 + A q_i a_i \right) \right\}. \quad (A1)$$

It is assumed that the thermal relaxation is much faster than the variations of the parameter $A$. The energy of the emitted photon at given values of the phonon coordinates is equal to the difference between the energies of the excited and ground states,

$$\epsilon = E_0 + A \sum_{i=1}^{N} (a_i - b_i) q_i. \quad (A2)$$

Equation (A1) is a multidimension Gaussian distribution, and Eq. (A2) is a linear function of the coordinates $q_i$. Consequently, the distribution of $\epsilon$ is also Gaussian,

$$p(\epsilon) = \frac{1}{\sqrt{2\pi}} \exp \left\{ -\frac{(\epsilon - \epsilon_0)^2}{2\sigma^2} \right\},$$

where the parameters $\epsilon_0$ and $\sigma^2$ can be found by averaging over the distribution (A1),

$$\langle \epsilon \rangle = \bar{\epsilon} = E_0 + A \sum_{i=1}^{N} (a_i - b_i) \langle q_i \rangle, \quad (A3)$$

$$\sigma^2 = \left\langle (\epsilon - \bar{\epsilon})^2 \right\rangle = A^2 \sum_{i=1}^{N} (a_i - b_i)^2 \left\langle (q_i - \bar{q}_i)^2 \right\rangle. \quad (A4)$$

The mean values for the coordinates can be easily found by integration over distribution (A1)

$$\langle q_i \rangle = \frac{a_i}{\omega_i^2}, \quad \langle (q_i - \bar{q}_i)^2 \rangle = \frac{kT}{\omega_i^2},$$

Substituting these expressions into Eqs. (A3) and (A4) gives Eqs. (4) and (5).
