(Dated: February 2, 2021)

We investigate the effects of two electronic bands at the negative electronic compressibility (NEC) in a two-dimensional electron gas (2DEG). We use a simple homogeneous model with Coulomb interactions and first-order multi-band coupling to examine the role of effective mass and relative permittivity in relation to the critical carrier density, where compressibility turns negative. We demonstrate that the population of a second band, along with the presence of inter-band coupling, can dramatically change the cross-over carrier density. Given the difficulty in determining and confirming multi-band electronic systems, this model provides a potential method for identifying multi-band electronic systems using precise bulk electronic properties measurements. To help illustrate this method, we apply our results to the observed NEC in the 2D electron gas at the interface of LaAlO$_3$/SrTiO$_3$ (LAO/STO) and determine that, for the known parameters of LAO/STO, the system is likely a realization of a two-band 2D electron gas. Furthermore, we provide general limits on the inter-band coupling with respect to the electronic band population.

I. INTRODUCTION

Complex oxides heterostructures have provided an exciting platform for various physical phenomena for over two decades, demonstrating the fascinating interplay between competing states depending on composition, doping, substitution, and structure[1, 2]. Highly tunable electron-electron interactions at interfaces have been shown to host states with charge, spin, and orbital orderings[3–8] that emerge from the two-dimensional electron gas (2DEG) at the interface.[9–14]

While there are many interesting properties of the 2DEG, we focus on the observations of negative electronic compressibility (NEC). NEC is produced through electron-electron interactions, where the exchange and Coulomb energies outweigh the overall kinetic energy of the electronic system[15–17]. Electronic compressibility is typically negative for dynamic, open 2D systems[18–22] in non-equilibrium states, although recently, 3D NEC systems have been discussed[23].

The 2DEG state of the complex oxide heterostructure LaAlO$_3$/SrTiO$_3$ (LAO/STO) exhibits a NEC. Over the last decade, measurements of the quantum capacitance have shown that the LAO/STO interface displays a large NEC around a carrier density of $10^{13}$ cm$^{-2}$[24–26]. Aside from NEC, LAO/STO interfaces were shown to host the possibly unconventional superconducting states at $T_c \sim 0.2$ K[27–29], which has led to fundamental questions about the nature of the superconducting state and its relation to the nature of the normal state[30–35]. It is also known that superconductivity can be enhanced to 0.3–0.4 K by applying an electric field[30, 31] and is observed to increase with strain[36–37]. Therefore, there is an exciting possibility that NEC and superconductivity might be related.

Observations point to the very robust superconducting interactions in STO that are controlled by doping and dimensionality. Literature has shown that the electron mobility observed at the interface is related to the electronic states within STO alone and is not dependent on the adjacent material[26, 32, 34, 35, 38–42]. Furthermore, recent experiments have also found strong evidence that the maximum $T_c$ in the heterostructures is achieved once an extra electron band becomes occupied[35]. Currently, there are a few proposals that the superconductivity in LAO/STO may be a realization of a multi-band system[26, 32, 40, 43], where band structure calculations have illustrated the role of split bands in electronic transport as a function of doping[44]. However, this is not without controversy, as some reports indicate that the claim of multi-band electronic structure still need to be looked at carefully[35].

The determination of a multi-band superconducting state is quite complicated as the multi-band phenomenon’s conclusive evidence can take decades due the difficulty in resolving the small energy gap between bands which is not well resolved by most techniques. However, not long after the theoretical basis[45], multi-band superconductivity was discovered in transition-metal superconductors, including Nb-doped STO[39, 46, 47]. In the case of Pb superconductors, the theory suggested that two-band superconductivity was possible in 1965[48], but it was not experimentally confirmed until 2000[49], despite earlier experimental evidence[50]. Detailed ab-initio calculations supporting the multi-band scenario were performed in 2009[51].

This paper aims to examine the differences in electronic compressibility between one- and two-band models and hopes to provide clarity and guidance for understanding the nature of collective electronic states at 2D interfaces (i.e., multi-band superconductivity). Therefore, in this study, we examine the one and two-band models of a 2DEG and investigate the onset of negative...
compressibility. Using a homogeneous 2D electron model and a two-band description of the electron interactions, we examine the dependence of the negative compressibility crossover point with respect to the carrier density. In general, we find the increases in effective mass leads to the rise in critical carrier density for NEC. In contrast, an increase in the relative permittivity of the 2DEG leads to a decrease in the critical carrier density. Furthermore, the addition of a second band lowers the overall carrier density, where the presence of inter-band coupling will dramatically reduce the polarizability of the 2DEG. The analysis presented in this work establishes features in the bulk electronic properties that allow for the possible identification of multiple bands in 2DEG systems. Additionally, through the comparison with previous experimental results for LAO/STO[24–26, 42], we find that the NEC of LAO/STO is consistent with a two-band model of the 2DEG, which provides further evidence that the LAO/STO interface electron states may be a realization of a multi-band system. Our findings also provide a straightforward method for the identification of electron band populations and coupling between the bands.

The structure of the paper is as follows: after the Introduction, we discuss the general attributes of the negative compressibility state in Sec II. In Sec. III, we revisit the electron gas free energy calculation for the multi-band case. In Sec IV, we discuss our results in the context of LAO/STO interface and conclude in Sec. V with a summary of the results.

II. ELECTRONIC COMPRESSIBILITY

Electronic compressibility, the response of the chemical potential to changes in the carrier density, is given by

$$\kappa = \left( n^2 \frac{d\mu}{dn} \right)^{-1}$$  \hspace{1cm} (1)

where \( \mu \) is the chemical potential and \( n \) is the carrier density. Typically, an increase in the carrier density produces a positive increase of the chemical potential[18–23]. Because of standard thermodynamic constraints, electronic compressibility tends to be positive. However, if the system is interacting, in some cases, the compressibility shift is negative, resulting in the so-called negative electronic compressibility[52]. NEC is typically found in 2D materials due to topological effects[18–19, 21, 22]. Recently, it has also been suggested in 3D materials[23].

If we assume a two-band model with simple parabolic dispersion (as shown in Fig. 1), then as the chemical potential increases to \( \mu / \mu_c = 1 \), the second band becomes populated and the carrier density will increase. At a critical density, one will see a dramatic increase in the Density of States (DOS) \( D(E_F) \) (shown in Fig. 1(c)) as a result of second band being populated.

We start with inverse compressibility \( \kappa^{-1} \) being proportional to \( d\mu/dn \), and can be written as

$$\frac{d\mu}{dn} = \frac{d\mu}{dD(E_F)} \frac{dD(E_F)}{dn}.$$  \hspace{1cm} (2)

where \( dD(E_F)/dn \) is essentially \( \delta(D(E_F) - n) \). Given a standard experimental width, \( dD(E_F)/dn \) will resemble Fig. 1(d).

For a two dimensional electron gas (2DEG) at \( T = 0 \), the chemical potential is equivalent to the Fermi Energy \( E_F \). Using a standard parabolic dispersion,

$$\mu = E_F = \frac{\hbar^2 k_F^2}{2m^*}.$$  \hspace{1cm} (3)

where \( k_f \) is the Fermi wavevector and \( m^* \) is the effective electron mass. For a 2D system, the number of states per unit area \( N = \frac{k_F^2}{2\pi} \). Thus the DOS is well known as

$$D(E_F) = \frac{dN}{dE_F} = \frac{m^*}{\pi \hbar^2}.$$  \hspace{1cm} (4)

From this relationship, we can infer that

$$\frac{d\mu}{dD(E_F)} = \frac{d\mu}{dm^*} = -\frac{\pi \hbar^4 k_F^2}{2m^*2}.$$  \hspace{1cm} (5)

This result provides an important clue about the origin of a negative contribution to the compressibility: negative sign appears as chemical potential decreases with the effective mass per same carrier density. Therefore, to gain an understanding of when the electronic compressibility

FIG. 1. (Color Online) Illustration of the two-bands with the (a) \( \mu < \mu_c \) and (b) \( \mu > \mu_c \). (c) The DOS as a function of \( n \) for the two-band system. (d) \( dD(E_F)/dn \) as function of \( n \).
for a two-band system becomes negative, we need to understand the free energy of electron gas in the system.

Chemical potential is defined as the change in free energy over the change in the number of electrons $N_e$,

$$\mu = \frac{dF}{dN} = \frac{df}{dn},$$  \hspace{1cm} (6)

where $f = F/A$ is the free energy divided by the area. One can relate the chemical potential to the density by normalizing the system by the area $A$, which allows us to define the electronic compressibility in terms of the free energy and the carrier density since $d\mu/dn = d^2f/dn^2$,

$$\kappa = \left(n^2 d^2f/dn^2\right)^{-1}. \hspace{1cm} (7)$$

Since most experimental measurements examine the $d\mu/dn$, we will use inverse compressibility $\kappa^{-1}$ to discuss the crossover between positive and negative compressibility.

It is important to note that, in many systems, the effective mass and Fermi wavevector are direction dependent. Here, we assume a simplified isotropic model.

III. 2D ELECTRON GAS FREE ENERGY

Focusing on carrier density dependence of the free energy, we decompose $f$ into kinetic, exchange, and Coulomb components ($f = f_k + f_{ex} + f_c$) using an analytic model, and examine each component individually for each band. Based on a homogeneous 2D electron model,

$$f_k = \sum_i \frac{\pi n_i^3 \hbar}{2 m_i^*},$$

$$f_{ex} = -\sum_i \sqrt{\frac{2 n_i^3}{\pi}} \frac{e^2}{3 \pi \epsilon_{eff}},$$

$$f_c = \sum_i n_i^2 \frac{\alpha_B \epsilon}{2 \epsilon_{eff}} - \sum_i \sqrt{\frac{n_i^3}{\pi}} \frac{e^2}{2 \epsilon_{eff}},$$

where the Coulomb or electrostatic term is broken into in-plane and out-of-plane components. Here, $\epsilon_{eff} = \epsilon_r \epsilon_0$ (the effective dielectric constant), and $\epsilon$ is the electron charge, $\alpha_B$ is the effective distance between layers, $a_B$ is the Bohr radius $4\pi \epsilon_0 \hbar^2/m^* e^2$ and $\alpha$ is a tuning parameter for the out-of-plane electrostatic part of free energy. The out-of-plane electrostatic confinement term is needed for 2DEG materials with strong polarization. Overall, the full free energy is summed over $i$ bands, where $i = 2$ is the specific case we consider. This free energy is a general analytic model and is meant to examine the general nature of the 2DEG in the absence of more complicated interactions. Therefore, we are using this model to detail qualitative features understand the differences between one- and two-band systems.

FIG. 2. (Color Online) The inverse electronic compressibility for the one-band model plotted as a function of carrier density for various effective masses and out-of-plane electrostatic parameters $\alpha = 0$ (a), 0.1 (b), and 0.5 (c). The quoted relative permittivities are given a the permittivity needed for the crossover carrier density to be $n_c = 1 \times 10^{13}$ cm$^{-2}$.

A. One-band model

Using the free energy for a one-band 2DEG, the inverse electronic compressibility can be shown to be

$$\kappa^{-1} = n^2 \left( \frac{\pi \hbar^2}{m^*} + \frac{16 \alpha \pi^2 \hbar^2}{m^* \epsilon_r} - \frac{3e^2}{8 \sqrt{n \pi \epsilon}} - \sqrt{\frac{2}{n \pi^3}} \frac{e^2}{\epsilon_{eff}} \right). \hspace{1cm} (9)$$

where the effects of the parameters are shown in Fig. 2. Here, we present the inverse electronic compressibil-
density as a function of the carrier density for various effective electron masses and relative permittivities as well as with and without the presence of out-of-plane electrostatic confinement. Here, we have chosen parameters for the effective mass and relative permittivity that will provide a crossover carrier density of 1.0 \times 10^{13} \text{cm}^{-2} for various values of out-of-plane electrostatic parameter \( \alpha \). The crossover points indicate carrier densities where electronic compressibility switches from positive and negative. These densities correspond to regime where which provides the general a second band is populated. When compared to experimental results, it is not just the value of crossover carrier density value but also the line’s overall slope through the point that also matters. The slope of the electronic compressibility through the critical point appears to be greatest when effective masses and permittivities are lowest, which indicates a greater increase in chemical potential with carrier density.

Since the inverse electronic compressibility is proportional to the change in the chemical potential with regards to \( n \), we can determine the critical crossover carrier density \( n_c \) for the one-band model by solving \( d\mu/dn = 0 \), and show that

\[
n_c = \frac{m^{*2}e^4}{64\pi^5\hbar^4\epsilon_0^2 (16\pi\alpha + \epsilon_r)^2} \left( 12\pi\sqrt{2} + 9\pi^2 + 8 \right).
\]

Here, the crossover carrier concentrations depend on the square of the effective mass over relative permittivity for the 2DEG. The addition of an out-of-plane electrostatic confinement field lowers the carrier density for negative electronic compressibility (shown in Fig. [3], where it is demonstrated that the crossover carrier density is controlled by effective mass, relative permittivity, and \( z \)-axis electrostatic potential. Within the general understanding of electrodynamics, an increasing effective mass will increase the number of states at the Fermi level, lowers the overall kinetic energy of the electronic system, and increases the critical carrier density for the transition.

Figure [3] shows that an increase in the relative permittivity leads to the decrease the critical carrier density. We interpret this effect being due to a decrease in the exchange and Coulomb interactions. This effect is also accompanied by increase of the out-of-plane electrostatic confinement.

These changes in the permittivity with carrier density are consistent with the general understanding of electronic structure. The lower the carrier density, the more insulating the material becomes, resulting in enhanced polarizability for the material. It is also shown that increasing the effective mass will also increase the needed permittivity due to the reduction in the conductivity, which will localize charge and allow for higher polarizabilities.

**B. Two-band Model**

Since the crossover carrier density of 2DEG is a measure of band population, there should be distinct differences in the effects of a one-band system regarding a two-band system. Therefore, we generalize the previous analysis to a two-band case and slightly alter the model by adding the first-order coupling between bands.

Assuming a two-band model \((i = 1, 2)\), we have:

\[
f = \left( \frac{\pi\hbar^2}{2} + \frac{8\pi^2\alpha\hbar^2}{\epsilon_r} \right) \left( \frac{n_1^2}{m_1^*} + \frac{n_2^2}{m_2^*} \right) - \sqrt{\frac{2}{\pi}} \frac{e^2}{\epsilon_{\text{eff}}} \left( \frac{1}{3} + \frac{1}{\sqrt{2}} \right) \left( n_1^2 + n_2^2 \right) + \frac{\lambda\pi\hbar^2}{2\sqrt{m_1^*m_2^*}} n_1n_2,
\]

where \( \lambda \) provides a first-order coupling between the two bands within a Ginzburg-Landau approximation, where this term is considered isotropic to help reduce the overall number of parameters. Since the interaction can be either repulsive or attractive, \( \lambda \) can be either positive or negative. Here, the total interaction energy between two bands can be expanded as an ordered series of terms. We are considering only the first-order term, which is linear in both \( n_1 \) and \( n_2 \). Higher-order terms and other interactions could also be included, but they are typically system-specific and move us away from this more general model.

From the free energy model, the inverse electronic compressibility \( \kappa^{-1} \) can now be written as

\[
\kappa^{-1} = \frac{n^2}{\epsilon_{\text{eff}}} \left[ \frac{\pi\hbar^2}{2} + \frac{16\alpha\pi\hbar^2}{\epsilon_r} \right] \left( \frac{\eta^2}{m_1^*} + \frac{(1 - \eta)^2}{m_2^*} \right) - \frac{e^2}{4\epsilon_{\text{eff}}\sqrt{n}} \left( \sqrt{\frac{2}{\pi}} + \frac{1}{2\sqrt{2}} \right) \left( \eta^2 + (1 - \eta)^2 \right) + \frac{\lambda\pi\hbar^2}{\sqrt{m_1^*m_2^*}} \left( \eta - \eta^2 \right).
\]

Here, we define the total carrier density \( n = n_1 + n_2 \) and relative population factor \( \eta \), where \( n_1 = \eta m_1 \) and \( n_2 = (1 - \eta) m_2 \).
FIG. 4. (Color Online) The inverse electronic compressibility as a function of carrier density for the 2-band system with various coupling interactions $\lambda = -1, 0$ and 1 and density ratios $\eta = 0.25, 0.50, \text{ and } 0.75$. Within each plot, the inverse electronic compressibility is plotted for different effective masses. The out-of-plane electrostatic factor and the relative permittivity has been selected to make $n_c = 1.0 \times 10^{13}$ cm$^{-2}$ ($\alpha = 0.0$) or $0.5 \times 10^{13}$ cm$^{-2}$ ($\alpha = 1.0$).

As shown for the one-band model, Fig. 4 shows the inverse electronic compressibility as a function of the 2D carrier density for the two-band system with various coupling interactions $\lambda$, density ratios $\eta$, and effective masses. To illustrate the effect of $\alpha$, the data with critical crossover points at $1.0 \times 10^{13}$ cm$^{-2}$ have a value of $\alpha = 0$, while $0.5 \times 10^{13}$ cm$^{-2}$ have a value of $\alpha = 1$.

Similar to the one-band model, the lower effective masses produce a sharper slope of the curve through the critical points. The addition of a second band enhances the slope further as $\lambda$ or $\alpha$ are increased, where the dramatic increase in slope requires a lower effective dielectric constant. A general effect of the two-band model the need for lower overall polarizability to achieve the same crossover carrier density, which leads to the suggestion that the combination of effective mass and dielectric measurements can help distinguish between one- or two-band systems.

To examine these effects further, we focus on the crossover carrier density for the inverse electronic compressibility, given by

$$n_c = \frac{27(\eta^2 - \eta) + 9 - 18\sqrt{\eta(\eta - 1)^3} \left(\frac{a_3 + a_4}{8\epsilon_{eff}}\right)^{1/2}}{\left(\frac{a_1 m_1^* + a_1 m_2^* - \lambda a_2}{\sqrt{m_1^* m_2^*}}\eta + a_1 m_2^*\right)^2},$$

where $a_1 m_1^* = \frac{\pi h^2}{2 m_1^*} + \frac{a_8^2 h^2}{m_1^* \epsilon_{eff}}, a_2 = \frac{\pi h^2}{2 \sqrt{m_1^* m_2^*}}, a_3 = \frac{2}{9\pi} e^2$, and $a_4 = \frac{e^2}{2\sqrt{\pi}}$. In a similar manner as the one-band
model, Fig. 5 shows the critical carrier density as a function of \( \epsilon_r \) and \( m_2^* \) for different values of \( \lambda \) and \( \eta \). Here, the first band’s effective mass is set to 0.5 and \( \alpha = 0 \). Larger critical carrier density occurs in systems with larger effective masses and lowers relative permittivities. Fig. 5 illustrates the effect of \( \lambda \) and \( \eta \) on the critical carrier density as a function of \( \epsilon_r \) and \( m_2^* \).

In Fig. 6, the effects of \( \eta \) and \( \lambda \) on the crossover carrier density with \( m_2^* = 0.5 \) and \( m_2^* = 1.0 \) and \( \alpha = 0.0 \) and 1.0 are detailed. Here, \( m_1^* \) is held at 0.5 and \( \epsilon_r = 50 \), and shows that the sharing of carrier density between the bands increases the critical carrier density. This effect is illustrated best when the effective masses are equal. Here, the critical carrier density is symmetric about \( \eta = 0.5 \), and \( \eta \) results in shifting of electrons towards one band regime and produces higher carrier density regions with increasing effective mass.

From Eq. 13, we see some overall trends: i) as the density ratio is shifted from the equal point of \( \eta = 0.5 \), the electronic system requires an overall increase permittivity and becomes more apparent with a negative \( \lambda \). ii) as \( \lambda \) increases in value, the needed relative permittivity is decreased. While the overall dependence of the critical carrier density from the effective permittivity and masses is similar to the one-band model, examining the combination of measured parameters can help determine the likelihood of either a one- or two-band system.

By looking at the \( \eta = 0.5 \) and \( \lambda = 0 \) case in Fig. 4 the critical carrier density response is quite similar to that of the one-band model. If one includes band interactions the crossover points shift depending on the type of interaction and strength: for increasing \( \lambda \), the critical point shifts as the required permittivity decreases.

To further examine the effects of multi-band interactions, we focus on the example of the LAO/STO interface, where some experiments have indicated that the system is possibly in the multi-band regime[39, 43, 58].

FIG. 5. (Color Online) The critical carrier density as a function of \( \epsilon_r \) and \( m_2^* \) for different values of \( \lambda \) and \( \eta \) with \( m_1^* = 0.5 \) and \( \alpha = 0 \). The color scales for each row of plots are set by the \( \lambda = -1 \) column to detail the shift in carrier density.
FIG. 6. (Color Online) The effects of $\eta$ and $\lambda$ on the crossover carrier density with $m^*_2$ = 0.5 and 1.0 and $\alpha$ = 0.0 and 1.0. Here, $m^*_1$ is held at 0.5 and $\epsilon_r = 50$.

IV. RELEVANCE TO LAO/STO INTERFACES

The interface of LaAlO$_3$ (LAO) and SrTiO$_3$ (STO) has become a textbook example of the emergence of complex phenomena at complex oxides’ interfaces where two band insulators produce a 2DEG, which becomes superconducting at 200-300 mK[27,29]. Studies into the nature of the superconducting state at the LAO/STO interface has revealed the potential for a multi-band electronic system[26,32,40,41,44]. On the other hand, measurements of the relative permittivity and effective mass of LAO/STO are performed. Within our model we conclude that for the known LAO/STO parameters does not fall within the predicted behavior of a one-band model.

Electron-doped n-type STO exhibits a distinct transition into a superconductor with a peak $T_c$ = 200 mK. Moreover, theoretical and experimental studies have shown that the superconducting transition can be dramatically enhanced under pressure[30,37]. In Fernandes et al. [32] we described multi-band aspects of this superconductivity and discussed the similarities between bulk STO and the LAO/STO interface. In the present work we adopt this two-band model for general case of normal state 2DEGs to LAO/STO interface to determine the most relevant features.

To make a relevant comparison we would need to determine values of dielectric constant for interfaces. For the bulk systems, LAO has a measured dielectric constant of about 18-24[63,64]. In contrast, STO can have a dielectric constant upwards of 25000 at zero electric fields, and drops to around 300 (with an electric field or at high temperatures) [68,69]. Since the 2DEG exists in the STO layer with a typical depth of 5-7 nm[69], the results of the analysis of the two-band model depend greatly on the measured value of the dielectric constant and the effective mass. To be specific, we assume a range of dielectric constants between about 70 and 150[6,7,42,67–73] and an estimated effective masses for the LAO/STO range from 0.5$m_e$-0.7$m_e$ for the first band and 5.0-14$m_e$ for the second band[67].

In LAO/STO, the critical carrier density is very device-dependent and seems to fall between 0.5 and 1.0 $\times$ 10$^{13}$ cm$^{-2}$[24]. With these ranges in mind, Fig. 7 shows the carrier density as a function of relative permittivity and effective mass for two different electrostatic parameters for the one-band model. The parameter ranges for LAO/STO have been shaded in grey. Through the middle, the brown contour shows the permittivity and effective mass range for the general critical carrier density range of LAO/STO. In Fig. 7(a), the measured LAO/STO parameters come very close to falling into the carrier density range for $\alpha = 0$. However, suppose one includes an out-of-plane electrostatic energy (Fig. 7(b)), which is needed for the polar heterostructure of LAO/STO. In that case, the parameters become even further apart. Therefore, given the wide range of device-specific measurements, it seems that the one-band model is not applicable.

Figure 8 shows the carrier density as a function of relative permittivity and effective mass for two different electrostatic parameters for the two-band model. The main issue is that we do not know the relative population of...
FIG. 8. (Color Online) The critical cross-over carrier density is plotted as a function of $\lambda$ and $\eta$ for the closest LAO/STO parameters ($\epsilon_r = 70$, $m_1^* = 0.7$, and $m_2^* = 14$) for the two-band model with $\alpha = 0$ (a) and 1.0 (b). The blue/brown cone region denotes the LAO/STO critical carrier density region and provides a multi-band parameter space for experimentalists to investigate the presence of the two-band electronic states in these devices.

the bands nor the coupling constant. Therefore, by using the closest parameters from the one-band model ($\epsilon_r = 70$ and $m_1^* = 0.7 m_e$) and instituting a second-band effective mass of $14 m_e$, we show the range of $\eta$ and $\lambda$ needed to provide critical carrier density of between 0.5 and $1.0 \times 10^{13}$ cm$^{-2}$ for $\alpha = 0.0$ and 1.0 (without and with electrostatic confinement).

We conclude that the band filling never falls on $\eta = 1$ or 0, hence we assume that a two-band model is needed to account for the measured electronic parameters of LAO/STO. Furthermore, our model provides a useful tool for experimentalists to investigate the multi-band model.

Our approach demonstrates that effective masses for the 2DEG must be reasonably small for the first band to produce a similar compressibility slope and dielectric constant. We find more flexibility with the inter-band coupling and variable carrier density within a two-band model.

Overall, the proposed two-band 2DEG model demonstrates that stronger inter-band coupling lowers the required $\epsilon_r$ for the system. The coupling of the bands produces less electron screening. It makes the system less metallic, consistent with Fernandes et al. [32], where it was shown that a weakly interacting two-band model adequately describes the 2D STO system. Our analysis indicates that, within the 2DEG model, a two-band or multi-band system is adequately describing the LAO/STO interface [32, 39]. We also mention multiple experimental observations suggesting multiband nature of 2DEG [26, 30, 32].

V. CONCLUSIONS

In this paper, we provide a general method for determining the effects of multi-band interactions on a two-dimensional electron gas through electronic compressibility. Using a 2D electron gas model with a first-order inter-band coupling between the carrier densities, we examine the dependence of negative compressibility of the 2D electron gas on critical carrier density, dielectric constant, and effective mass and compare the results to the interface of LaAlO$_3$/SrTiO$_3$. Our calculations show that the presence of inter-band coupling has an effect on the polarizability and the critical carrier density of the 2DEG. Furthermore, we find that the bands’ effective masses have a distinct and dramatic effect on the negative compressibility.

Given recent suggestions that the LAO/STO interface is a multi-band electron system [26, 32, 40, 41], we relate the negative compressibility to inter-band and intra-band interactions and to the effective electron masses in the bands. We find that a one-band model does not reproduce the LAO/STO interface’s critical carrier density. On the other hand, using a two-band model, we find the critical carrier density for the negative compressibility crossover of LAO/STO within the parameter range that consistent with the observations.

Among future applications of the model presented here, we mention the effects of dynamics on electronic properties like transport and compressibility. For example, the role of dynamics and pumping in producing transient negative compressibility regime in multi-band 2DEG would be an interesting problem to pursue. We also point to the important questions about the nature of the superconducting state, seen in LAO/STO, in the presence of two coupled electronic bands.
