Abstract
AIM: To explore dysregulation of cyclin E in malignancies, and to further investigate the role of cyclin E in Helicobacter pylori (H. pylori)-induced gastric precancerosis.

METHODS: Four-week-old specific pathogen-free male Mongolian gerbils were employed in the study. 0.5mL 1×108 cfu·L-1 suspension of H. pylori NTCC11637 in Brucella broth was inoculated orally into each of 20 Mongolian gerbils, and a further 20 gerbils were inoculated with Brucella broth as controls. 10 of the infected gerbils and 10 of the non-infected control gerbils were sacrificed at 25, 45 wk after infection. The expression of cyclin E was analyzed by RT-PCR and immunohistochemical studies with monoclonal antibody to cyclin E in Mongolian gerbil of H. pylori-induced gastric precancerosis.

RESULTS: H. pylori was constantly detected in all infected animals throughout the study. At 25 wk after infection of H. pylori, ulcers were observed in the antral and body of stomach (n=6). Histological examination showed that all animals developed severe inflammation and multifocal lymphoid follicles appeared in the lamina propria and submucosa of gastric antrum. At 45 wk after infection of H. pylori, severe atrophic gastritis (n=10), intestinal metaplasia (n=8) and dysplasia (n=6) could be observed. Cyclin E mRNA levels were significantly more at 25 wk after infection of H. pylori (1.27±0.26), and at 45 wk after infection of H. pylori (1.82±0.39) than control-animals (0.59±0.20, P<0.01). cyclin E mRNA levels were evaluated by 2.2-fold at 25 wk (P<0.01) and 3.1-fold at 45 wk (P<0.01) precancerosis induced by H. pylori, when compared with control gastric epithelium of Mongolian gerbil. Immunohistochemical staining revealed exclusive nuclear staining of cyclin E. Furthermore, there was a sequential increase in cyclin E positive cells from normal epithelium to precancerosis.

CONCLUSION: Overexpression of cyclin E occurs relatively early in gastric tumorigenesis in this model.

Yao YL, Xu B, Song YG, Zhang WD. Overexpression of cyclin E in Mongolian gerbil with Helicobacter pylori-induced gastric precancerosis. World J Gastroenterol 2002;8(1):60-63

INTRODUCTION
Gastric cancer is a major health problem[1-3] and remains the second most common cancer in the world[4,6]. Although epidemiological studies have indicated that H. pylori infection plays a crucial role in gastric carcinogenesis in humans[7-24], there is no direct proof that H. pylori is actually associated with gastric carcinogenesis[13,25-26]. The purpose of this study was to elucidate the relationship between H. pylori infection and gastric carcinogenesis by using an animal model of long-term H. pylori infection, and explore the role played by cyclin E in gastric tumorigenesis[27-29].

Cyclins are positive regulators of cell cycle progression. They function by forming a complex with and activating a class of protein kinases which are essential for cell cycle transitions. As the major regulatory events leading to cell proliferation occur in the G1 phase of the cell cycle, altered expression of cyclins involved in the G1 phase may be an important step in oncogenesis[26-31]. Among G1 cyclins, an accumulating body of evidence suggests that over expression and rearrangement of cyclin E is associated with malignancy. Over expression of cyclin E has also been found in mouse mammary tumors and is associated with tumor development; altered expression of cyclin E can accelerate occurrence and early progression of colorectal cancer, and plays an important role in occurrence of breast cancer[34-37]. But cyclin D1, over expression in esophageal cancer and breast cancer, has no over expression in gastric cancer, which suggests expression of cyclins has specificity of organs. To gain a further understanding of the role played by cyclin E in gastric tumorigenesis, the study investigates the role of cyclin E in H. pylori-induced gastric precancerosis[38,39].

MATERIALS AND METHODS

Animals and preparation
Four-week-old specific pathogen-free male Mongolian gerbils, weighing (20±5)g, were employed in the study. They were housed in individual metabolic cages in a temperature conditioned room (23±2)℃ with a 12 h light-dark cycle, allowed access to standard rat chow (provided by Experimental Animal Center, First Military Medical University) and water ad libium, and acclimatized to the surrounding for 7 d prior to the experiments. H. pylori(NTCC11637) was obtained from American Type Culture Collection and cultured on Brucella agar plates containing 70 mL·L-1 goat blood in a microaerobic condition (volume fraction; N2:85%, O2:5%, CO2:10%, in aerobic globe box) at 37℃ for 3 d. The strain was identified by morphology, Gram’s stain, urease production and so on.

Experimental protocol
Suspension 0.5 ML 1×108 cfu·L-1 of H. pylori NTCC11637 in Brucella broth was inoculated orally into each of 20 Mongolian gerbils which had been fasted overnight, for 14 d continuously. A further 20 gerbils were inoculated with Brucella broth as controls. 10 of the infected gerbils and 10 of the non-infected control gerbils were sacrificed at 25, 45 wk after infection. The stomach of each animal which had been fasted overnight, for 14 d continuously. A further 20 gerbils were inoculated with Brucella broth as controls. 10 of the infected gerbils and 10 of the non-infected control gerbils were sacrificed at 25, 45 wk after infection.
formalin and processed by standard methods that embedded in paraffin, sectioned and stained with haematoxylin for analyzing histological changes, Giemsa stain for detecting for *H. pylori* and Alcian blue (AB)/PAS stain for examining intestinal metaplasia.

**RNA isolation and RT-PCR analysis**

Using TriPure isolation reagent (Boehringer Mannheim, Germany), total cellular RNA was isolated from previously frozen tissues according to the manufacturer’s instruction. All RNA samples were analyzed for integrity of 18s and 28s rRNA by ethidium bromide staining on 0.5% agarose-formaldehyde gels. RT-PCR analysis was performed as follows. RNA was incubated at 60°C for 10 min and chilled to 4°C immediately before being reverse transcribed. Reverse transcription of 1µg total RNA using antisense primers was performed in a volume of 20µL for 40 min at 50°C, containing 200 U MMLV reverse transcriptase, 1× buffer RT, 1 MU·L⁻¹ Rnasin, 0.5 mmol·L⁻¹ dATP, dGTP, dCTP and dTTP respectively and 0.2 µmol·L⁻¹ antisense primers including cyclin E and β-actin respectively. The samples were heated to 99°C for 5 min to terminate the reverse transcription reaction. By using a Perkin-Elmer DNA Thermocycler 4800 (Perkin-Elmer, Norwalk, CT), the reaction mixture was first heated at 94°C for 1.5 min, followed by an incubation for 7 s at 99°C immediately before being reverse transcribed. The amplification reaction mixture consisted of 10×buffer 5µL, 0.2 mmol·L⁻¹ dATP, dGTP, dCTP and dTTP respectively, 2.5 U Taq DNA polymerase, and 0.2 µmol·L⁻¹ each of sense and antisense primers in a final volume of 50µL. The reaction mixture was first heated at 94°C for 2 min and amplification was carried out for 29 cycles at 94°C for 0.5 min, 53°C for 1 min, 70°C for 1.5 min, followed by an incubation for 7 s at 70°C. The number of amplification cycles was previously determined to keep amplification in the linear range to avoid the “plateau effect” associated with increased numbers of PCR cycles. The PCR primers used were: cyclin E, sense 5′-TAT GGC GAC ACA AGA AAA TG-3′ and antisense 5′-AGG GTA CAT GGT GGT GCC GCC AGA C-3′; β-actin, sense 5′-CCA AGG CCA GAA GAC AGA CAA CG-3′; β-actin, sense 5′-CCA AGG CCA ACC GCG AGA AGA TG-3′ and antisense 5′-AGG GTA CAT GGT GGT GCC GCC AGA C-3′. The length of PCR products for cyclin E and β-actin was 770 bp and 587 bp. PCR products were run on a 15% agarose gel in 0.5×TBE buffer and then analyzed by gel image analysis system. The level of cyclin E was reflected with the ratio of cyclin E/β-actin.

**Immunohistochemical staining**

Four micrometers paraffin-embedded tissue sections were deparaffinized and rehydrated. Endogenous peroxidase activity was ablated with 10 mL·L⁻¹ hydrogen peroxide in methanol. The immunostaining for cyclin E was conducted using the StreptAvidin-Biotin-enzyme Complex kit (Boster, Wuhan). Immunostaining by replacing primary antibody with PBS was also conducted as a negative control. The staining was evaluated semiquantitatively on the basis of the percentage of positive cells, and classified as follows⁴⁰: diffusely positive (+++) when positive cells accounted for more than 70% of the total cells, partially positive (+ +) when positive cells were 35%-70%, partially positive (+) when positive cells accounted for 5%-35%, and negative (-) when positive cells accounted for less than 5%.

**Statistical Analysis**

Experimental results were analyzed with Chi-square Tests and K Related Samples Test by SPSS software. Statistical significance was determined at *P*<0.05.

**RESULTS**

*Histopathological findings*  
*H. pylori* was detected in gastric antrum and gastric body of all infected animals throughout the study, and more in gastric antrum than gastric body. By the 25th wk after infection of *H. pylori*, ulcers were observed in the antral and body of stomach (*n*=6). Histological examination showed that all animals developed severe inflammation in the area close to ulcers; multifocal lymphoid follicles appeared in the lamina propria and submucosa; and there were mild atrophic gastritis in all infected animals. By the 45th wk after infection of *H. pylori*, severe atrophic gastritis (*n*=10), intestinal metaplasia (*n*=8) and dysplasia (*n*=6) could be observed. Those metaplastic glands appeared more atypical than the surrounding nonmetaplastic and hyperplastic glands. Severe atrophic gastritis, intestinal metaplasia and dysplasia were gastric precancerosis. In the uninfected animals, there were no significant changes throughout the study.

**RT-PCR analysis of cyclin E mRNA expression**

There were cyclin E mRNA expression in gastric antrum mucosa of control-animals. cyclin E mRNA levels were significantly more at 25 wk after infection of *H. pylori* (1.27±0.26), and at 45 wk after infection of *H. pylori* (1.82±0.39) than control-animals (0.59±0.20, *P*<0.01); Cyclin E mRNA levels were evaluated by 2.2-fold at 25 wk (*P*<0.01) and 3.1-fold at 45 wk (*P*<0.01) precancerosis induced by *H. pylori*, when compared with control gastric epithelium of Mongolian gerbil (Figure 1-3).

Immunohistochemical analysis of cyclin E protein expression
To examine whether increased cyclin E mRNA expression was accompanied by increased expression of cyclin E protein, immunohistochemical analysis was performed. Cyclin E protein expression lied in nuclei and cytoplasm. Cyclin E protein expressions were evaluated significantly at 25 wk ($P < 0.01$) and at 45 wk ($P < 0.01$) precancerosis induced by \textit{H. pylori}, when compared with control gastric epithelium of Mongolian gerbil (Figure 4 and Table 1).

**DISCUSSION**

\textit{H. pylori} infection is now known as a major cause of acute and chronic active gastritis, peptic ulcer disease and atrophic gastritis and is also suspected to be involved in the genesis of gastric adenocarcinoma and mucosa-associated lymphoid tissue lymphoma[41-46]. In 1994, the International Agency for Research on Cancer (IRAC), a branch of the World Health Organization (WHO), convened experts from 11 countries to examine the evidence linking a number of infectious agents with human cancer. Although there is no direct proof that \textit{H. pylori} is actually associated with gastric carcinogenesis, epidemiological studies have indicated that \textit{H. pylori} infection plays an important role in gastric carcinogenesis in humans; \textit{H. pylori} was designated as a definite carcinogen (group I) to the human stomach based on prospective case-control studies reported in 1991. Several experiments were conducted in Japan that demonstrated that chronic \textit{H. pylori}-infection models of Mongolian gerbils developed gastric carcinoma. These results will be extremely significant to elucidate the mechanism of gastric carcinogenesis due to \textit{H. pylori} infection[5,50]. Apoptosis, a programmed cell death, was ignored, just like \textit{H. pylori}, only to reappear recently. However, the number of current publications dealing with apoptosis of \textit{H. pylori} has increased exponentially. Although gastric epithelial apoptosis is a programmed physiological event in the superficial aspect of the mucosa and is important for healthy cell turnover, \textit{H. pylori} infection reportedly promotes such a cell death sequence[51-52]. Because apoptosis regulates the cycle of cell turnover in balance with proliferation, dysregulation of apoptosis or proliferation evoked by \textit{H. pylori} colonization would be linked to the gastric carcinogenesis[53-56].

Cyclins are positive regulators of cell cycle progression, initially identified in early cleavage embryos of marine invertebrates as proteins that accumulated during interphase and were degraded at mitosis. Cyclins are now known to be positive regulatory subunits of a class of protein kinase termed cyclin-dependent kinases. These protein kinases have been shown in a number of diverse eukaryotic systems to be the master regulators of major cell cycle transitions[57-59]. Cyclin E is essential for the G1/S phase transition in the cell cycle. Cyclin E gene amplification and altered expression has been reported in a variety of human cancers[60-61]. Now Cyclin E gene has been detected as oncogene[62]. Cyclin E was synthesized in the mid-term of the cell cycle, expressed the highest level when entering S phase, and degraded through S phase. The level of cyclin-dependent kinase2 kept constant during the cell cycle. Cyclin E, cyclin-dependent kinase2 and cyclin-dependent kinase inhibitor regulated G1/S phase transition by two-way at late stage of G1 phase. Cyclin E accelerated G1/S phase transition by composing and activating cyclin-dependent kinase2.

In the present study, to explore dysregulation of cyclin E in malignancies, and to further investigate the role of cyclin E in \textit{H. pylori}-induced gastric precancerosis, cyclin E mRNA level was measured by quantitative RT-PCR analysis in Mongolian gerbil gastric antrum mucosa. In addition, the expression and localization of protein product was analyzed by immunohistochemistry. Sample size requirement for obtaining sufficient amounts of RNA for RT-PCR analysis did not allow detection of either cyclin E mRNA level in any specific type of preneoplastic lesions. However, using immunohistochemical technique, cyclin E protein expression in preneoplastic lesions was observed from paraffin-embedded tissue sections. Cyclin E mRNA levels were increased 2.2-fold at 25 wk and 3.1-fold at 45 wk precarcinosis induced by \textit{H. pylori}, when compared with normal gastric epithelium of Mongolian gerbil. Immunohistochemical staining revealed exclusive nuclear staining of cyclin E. Furthermore, there was a sequential increase in cyclin E positive cells from normal epithelium to precancerous lesions. The present study indicated that expression of cyclin E increased from normal epithelium to precancerous lesions, dysregulation of cyclin E expression occurred relatively early in gastric tumorigenesis in this model and might participate in tumor progression. These findings suggested that \textit{H. pylori}-induced gastric precancerosis was associated with dysregulation of gastric epithelial cell cycle. Further studies were needed to delineate the mechanism of these alterations.
