(March 24, 2022)

Phase fluctuations of the superconducting order parameter play a larger role in the cuprates than in conventional BCS superconductors because of the low superfluid density $\rho_s$ of a doped insulator. In this paper, we analyze an XY model of classical phase fluctuations in the high temperature superconductors using a low-temperature expansion and Monte Carlo simulations. In agreement with experiment, the value of $\rho_s$ at temperature $T = 0$ is a quite robust predictor of $T_c$, and the evolution of $\rho_s$ with $T$, including its $T$-linear behavior at low temperature, is insensitive to microscopic details.

Two classes of thermal excitations are responsible for disordering the ground state of a superconductor: fluctuations of the amplitude and phase of the complex order parameter. A consensus has not yet been reached on the relative importance of the two in the high temperature superconductors, since both are anomalous. The low superfluid density (phase stiffness) of the doped insulator implies that phase fluctuations play an unusually large role. Yet the nodes in the classical XY model of phase fluctuations in a high temperature superconductor: fluctuations of the amplitude and phase of the complex order parameter. A consensus has not yet been reached on the relative importance of the two in the high temperature superconductors, since both are anomalous. The low superfluid density (phase stiffness) of the doped insulator implies that phase fluctuations play an unusually large role.

This paper is concerned with an analytical and numerical study of the thermal evolution of the in-plane helicity modulus, $\gamma_\|/(T)$, of an anisotropic quasi two-dimensional classical XY model of phase fluctuations in a high temperature superconductor. We neglect quasiparticle fluctuations because the nodal quasiparticles are excitations of the insulating state; very little charge transport is associated with them, and their contribution to the superfluid density should be proportional to a positive power of the (small) doping concentration. We also neglect collective amplitude fluctuations associated with the quantum dynamics of the phase since, with sufficient screening, the phase fluctuations are predominantly classical down to quite low temperature.

The calculations focus on the scaled curve, $\gamma_\|/(T)/\gamma_\|/(0)$ vs. $T/T_c$, and the value of the dimensionless ratios $A_1 = T_c/\gamma_\|/(0)$ and $A_2 = T_c/\gamma_\|/(0)$, (Here $\gamma_\|/(T) \equiv d\gamma_\|/(T)/dT$.). These nonuniversal quantities turn out to be rather insensitive to microscopic details of the model, such as the strength of the interplane coupling and the exact short-distance nature of the interactions, as shown in Fig. 1 and in the tables. Figure 1 also shows that the model results agree well with experiment, when the helicity modulus of the model is related to the in-plane superfluid density, $\rho_s$ as determined by

$$\frac{\gamma_\|/(T)}{a_\perp} = \frac{\hbar^2 \rho_s/(T)}{4m^*} = \frac{(hc)^2}{16\pi^2e^2\lambda_{ab}^2/(T)},$$

where $a_\perp$ is the spacing between planes and $\lambda_{ab}$ is the London penetration depth within the CuO$_2$ planes.

There is strong empirical evidence that classical phase fluctuations determine much of the important physics in the superconducting state of the high $T_c$ superconductors, and also some properties of the normal state, especially in underdoped materials. Most notably, $T_c$ increases roughly linearly with the zero temperature superfluid density. $A_1 = T_c/\gamma_\|/(0)$ is a robust predictor of $T_c$, whereas the characteristic energy scale for pairing, $\Delta_0/2$, is both quantitatively large compared to $k_BT_c$ and decreases as the doping increases. Furthermore, ARPES and other measurements of the superconducting gap reveal that pair formation occurs at a crossover temperature well above $T_c$. It is important to note that $A_2 = T_c/\gamma_\|/(0)$ is roughly constant for various materials and doping concentrations. This implies that the fluctuations predominantly responsible for the $T$-linear dependence of the superfluid density at low $T$ are also responsible for the ultimate destruction of the superconducting state at $T_c$.

As first pointed out by Roddick and Stroud, this
behavior is characteristic of classical phase fluctuations.

The following arguments have been made against this interpretation of the data: 1) The non-universal ratio \( A_1 = T_c / \gamma_{\parallel}(0) \) should theoretically lie in the range 4-8, rather than in the experimentally observed range of 0.5 - 1. In particular, it has been argued that \( A_1 \propto n \) in multilayer materials, where \( n \) is the number of layers per unit cell. 2) For weakly coupled layers, a phase only model would yield a \( \rho_s(T) \) curve that looks like a rounded Berezinskii-Kosterlitz-Thouless (BKT) discontinuity, unlike what is seen in experiments. 3) Quantum effects suppress classical phase fluctuations [14] for temperatures below the plasma frequency. 4) If pairing occurs in a substantial range of temperatures above \( T_c \), the effects of fluctuation superconductivity should be observed, contrary to experiment.

As can be seen from the figure and the tables, our present results conclusively show that the first two assertions are incorrect; the classical XY model is quantitatively consistent with experiments. The third suggestion has been previously shown to be incorrect [3], due to screening by the substantial background normal fluid. Specifically, in a two-fluid model of a superconductor, the classical model is reliable down to a classical to quantum crossover temperature which can be well below \( T_c \): \( T_{c\text{ class}} \propto T_c / \sigma_N \), where \( \sigma_N \) is an average of the optical conductivity of the normal component in units of the quantum of conductance. The fourth point overlooks the fact that fluctuation superconductivity is only significant close to \( T_c \) where the correlation length is long. In conventional superconductors the observed fluctuations involve amplitude and phase and are Gaussian, while for the high \( T_c \) superconductors, true critical fluctuations in the XY universality class are detected in a remarkably broad range of temperatures.

A classical XY model on a tetragonal lattice will be used to study the effects of phase fluctuations in a quasi two-dimensional superconductor at wavelengths that are long enough for amplitude fluctuations to be unimportant. The in-plane unit cell area \( a_\parallel^2 \) does not enter into the evaluation of \( T_c \) or the temperature dependence of \( \gamma_{\parallel}(T) \). Here \( a_\parallel \) is a short-distance cutoff which will be discussed at the end of the paper. In general, the interaction energy, \( V \), depends on the phase difference, \( \theta_{ij} = \theta_i - \theta_j \), between nearest-neighbor sites \( <i,j> \). Because of gauge invariance and time reversal symmetry, \( V \) can be expanded in a cosine series,

\[
V(\theta_{ij}) = \sum_n A_n \cos(n\theta_{ij}).
\]  

The first harmonic, \( \cos(\theta) \), corresponds to the transfer of one pair of electrons between neighboring cells; each successive harmonic transfers a higher number of pairs. We keep only the first two terms in the cosine series for couplings within a plane, and the first cosine term for the weaker Josephson coupling between planes.

\[
H = -J_{\parallel} \sum_{<ij>\parallel} \{ \cos(\theta_{ij}) + \delta \cos(2\theta_{ij}) \} - \sum_{<kl>_\perp} \{ J_{\perp}^2 \cos(\theta_{kl}) \},
\]

where the first sum is over nearest neighbor sites within each plane, and the second sum is over nearest neighboring planes. The coupling, \( J_{\parallel} \), will be assumed to be isotropic within each plane and the same for every plane, but the coupling between planes, \( J_{\perp}^2 \), is different for crystalllographically distinct pairs of neighboring planes. It will be assumed that \( J_{\parallel}, J_{\perp}, \) and \( \delta \) are positive, since there is no reason to expect any frustration in the problem, [16] and that \( \delta \leq 0.25 \), since for \( \delta > 0.25 \) there is a secondary minimum in the potential for \( \theta_{ij} = \pi \), which is probably unphysical. The sensitivity of various computed quantities to variations in \( \delta \) in this range is a measure of the importance of “microscopic details.”

It follows from simple and general considerations that most features of the thermal evolution of the superfluid density of \( \text{YBa}_2\text{Cu}_3\text{O}_{7-\delta} \) shown in Fig. 1 are reproduced by such a model. The critical phenomena are in the same universality class as the classical 3D XY model, which is consistent with the observed behavior [3] in \( \text{YBa}_2\text{Cu}_3\text{O}_{7-\delta} \) within about 10% of \( T_c \). Furthermore, the helicity modulus is linear in the temperature, as observed in \( \text{YBa}_2\text{Cu}_3\text{O}_{7-\delta} \). Indeed, using linear spin-wave theory, it is straightforward to obtain the first terms in the low-temperature series for \( \gamma \):

\[
\gamma_{\parallel}(T) = J_{\parallel}(1 + 4\delta) - \frac{\alpha(1 + 16\delta)}{4(1 + 6\delta)} T + \mathcal{O}(T^2),
\]

where \( \alpha \) is a numerical integral which varies from \( \alpha = 1 \) in the 2d limit \((J_{\perp} \to 0)\), to \( \alpha = 2/3 \) for \( J_{\perp} \to \gamma_{\parallel}(0) = J_{\parallel}(1 + 4\delta) \) for one plane per unit cell.

A more quantitative comparison between the classical model and experimental data can be undertaken by studying various dimensionless ratios, particularly \( A_1 = T_c / \gamma_{\parallel}(0) \) and \( A_2 = T_c \gamma_{\parallel}(0)/\gamma_{\parallel}(0) \). Here, \( T_c \) is computed numerically by means of the Binder parameter [17] for systems of size up to \( 24 \times 24 \times 24 \). Errors in \( T_c \) are limited by the resolution with which the Binder crossing point is computed in each case. The quantities \( \gamma_{\parallel}(0) \) and \( \gamma_{\parallel}(0) \) are obtained from Eq. [1].

Experimentally \( A_2 \sim \frac{1}{\delta} \), and \( A_1 \) is in the range 0.6-1.3 for underdoped and optimally doped materials. Tables 1 and 2 show the ratios \( A_1 \) and \( A_2 \) for various choices of parameters in the classical XY model. Note that \( A_2 \sim \frac{1}{\delta} \) for \( \delta \) not too small, whereas \( A_2 \) is about a factor of two smaller for \( \delta = 0 \). The shape of the \( \rho_s(T) \) vs. \( T \) curves, as quantified by \( A_2 \), is remarkably robust, especially if we compare the cases of \( \delta = 0.1 \) to \( \delta = 0.25 \). The ratio \( A_1 \) is a little more sensitive to the value of \( \delta \), but it is comfortably in the experimental range for \( \delta \) between 0.1 and 0.25, and only slightly larger for \( \delta = 0 \). The relative

The nodes of the $d$-wave gap may give a $T$-linear contribution to the superfluid density, but our results suggest that this contribution is quantitatively small. This, in turn, supports the idea that there is little charge transport associated with the quasiparticles.

A much-discussed feature of the systematics of $T_c$ in the high temperature superconductors is the observed increase of $T_c$ within each family of materials with the number of planes per unit cell, $n$. Within the classical phase model, the fact that phase fluctuations lead to a particularly large suppression of $T_c$ below its mean-field value (see Table 3) leads to an increased sensitivity to even weak couplings in the third direction. This produces a strong increase of $T_c$ with $n$, although possibly not quite as strong as observed experimentally. However, it should be noted that other things may change with $n$; for example, in a three-plane material, the central plane may have a different hole concentration than the others. At the same time, since the dimensionless constant $\alpha$ in Eq. (9) is only weakly dependent on $J_\perp$, $A_2$ is an increasing function of $n$. This is to be expected as small values of $A_2$ are characteristic of low dimensional phase fluctuations. Table 3 shows the variation of $T_c$ with number of planes per unit cell for weak coupling between planes.

Table 3: Variations as a function of the number of planes per unit cell: The coupling between planes within the unit cell is $J_\perp = 0.1$, and between planes of different unit cells is $J_\perp' = 0.01$. $T_{c, MF}$ is the interplane mean-field estimate of $T_c$ obtained as described in the text.

\[
\begin{array}{cccccc}
\delta & 0 & 0 & 0 & 0 & 0 \\
n & 1 & 2 & 3 & 4 & \infty \\
d_2(0)/\rho_2 & 2.472 & 2.384 & 2.365 & 2.348 & 2.315 \\
T_c & 1.09 & 1.20 & 1.24 & 1.26 & 1.324 \\
T_{c, MF} & 1.111 & 1.287 & 1.334 & 1.361 & 1.394 \\
\delta & 0.25 & 0.25 & 0.25 & 0.25 & 0.25 \\
n & 1 & 3 & 4 & \infty \\
d_2(0)/\rho_2 & 0.6211 & 0.6092 & 0.6055 & 0.6032 & 0.5982 \\
T_c & 1.25 & 1.35 & 1.39 & 1.41 & 1.46 \\
\end{array}
\]

Mean field theory is a standard method of estimating the effects of weak higher-dimensional couplings on the critical temperature of quasi one or two dimensional systems. For instance, for one plane per unit cell ($n = 1$) this approach leads to an implicit equation for the three dimensional $T_c$:

$$\chi_{2d}(T_{c, MF})2J_\perp = 1,$$

(5)

where $\chi_{2d}(T)$ is the susceptibility of an isolated plane. For the case $\delta = 0$, we have computed the interplane
mean-field transition temperature, which is also presented in Table 3, using the Monte Carlo results of Gupta and Baillie [19] for \( \chi_2 \omega(T) \). This mean-field theory becomes exact in the limit \( J_\perp \to 0 \), and always gives an upper bound to \( T_c \).

Phase fluctuations should also have detectable effects on other equilibrium properties, such as the specific heat, the diamagnetic susceptibility, and \( \gamma_\perp \). In contrast to \( \gamma_\parallel \), these quantities depend on \( a_\parallel \). Classical systems have nonzero specific heat at \( T = 0 \), in violation of the third law of thermodynamics. The classical XY model at temperatures \( T \ll T_c \) has a specific heat per unit area in a CuO plane equal to \( C = k_B/2a_\parallel^2 \). The specific heat \( c_\perp \) at \( T = 2K \) of good crystals of optimally doped YBCO is roughly \( 5 \times 10^{-3} k_B \) per planar copper; if we assumed that all of this specific heat were due to phase fluctuations, it would imply \( a_\parallel \approx 32 \) lattice constants.

In the classical XY model \( a_\parallel \sim r_v \), where \( r_v \) is the radius of a vortex core. Recent µSR measurements [20] have found that \( r_v \) grows substantially at low fields, and tends to a zero field value which is on the order of 100\( \AA \) (26 lattice constants) and which is only weakly temperature dependent nearly up to \( T_c \). This behavior is consistent with other measurements, especially STXM in a field of 6T, [21] which have produced significantly smaller estimates of the core radius. Thus, if we estimate \( a_\parallel \) using the µSR data, it is consistent to attribute a large fraction of the low-temperature specific heat to classical phase fluctuations. The contribution of critical fluctuations to the specific heat near \( T_c \) may also be dominated by classical phase fluctuations, but a quantitative comparison of the theoretically expected (non-universal) critical amplitudes with experiment is not straightforward.

Experimentally, \( \rho_\perp/m^* \) is much more weakly temperature dependent than \( \rho_\parallel/m^* \) at low temperatures. We intend in the near future to analyze the implications of this observation for the phase fluctuation model. Specifically, since \( \gamma_\perp/\gamma_\parallel = \rho_\perp/\rho_\parallel (a_\parallel/a_\perp)^2 \), the anisotropy of the superfluid density may also contain valuable information concerning the physics of \( a_\parallel \).

Finally, we address the remarkable measurements of the frequency dependent superfluid density in BSCCO of Corson et al. [23] Without making any explicit assumptions concerning the dynamics, we can interpret these results in terms of a finite size scaling hypothesis, in which we associate a length scale, \( L(\omega) \), with the finite measurement frequency, and

\[
\gamma(T, L) \sim L^2 T^\gamma(L/\xi(T))
\]

where \( \xi(T) \) is the correlation length of the infinite system at temperature \( T \). Since BSCCO is highly anisotropic, we follow Corson et al. [23] in assuming that the finite frequency response is essentially two dimensional, in which case \( x = 0 \), and \( \xi(T) \) is infinite for all \( T < T_{BKT} \), the BKT transition temperature. This implies that \( \gamma \) is approximately frequency independent for \( T < T_{BKT} \) and vanishes exponentially as a function of \( L/\xi \) at temperatures enough above \( T_{BKT} \) that \( L > \xi(T) \). Indeed, \( \gamma(T, L) \) was computed numerically for the two dimensional XY model by Schultka and Manousakis [3] and we have repeated these calculations for anisotropic three dimensional models; the results confirm that our model nicely accounts for the observations of Corson et al. [23], with the proviso that the measured finite frequency superfluid density is interpreted as a renormalized, rather than a "bare", response function.
