Abstract
We consider the logarithmic negativity of a finite interval embedded in an infinite one dimensional system at finite temperature. We focus on conformal invariant systems and we show that the naive approach based on the calculation of a two-point function of twist fields in a cylindrical geometry yields a wrong result. The correct result is obtained through a four-point function of twist fields in which two auxiliary fields are inserted far away from the interval, and they are sent to infinity only after having taken the replica limit. In this way, we find a universal scaling form for the finite temperature negativity which depends on the full operator content of the theory and not only on the central charge. In the limit of low and high temperatures, the expansion of this universal form can be obtained by means of the operator product expansion. We check our results against exact numerical computations for the critical harmonic chain.

1. Introduction

Entanglement is the key characteristic distinguishing quantum and classical mechanics. Since the birth of quantum mechanics this phenomenon has been attracting a continuous interest in the physics community. However, only during the last decade has a systematic study of the entanglement in extended quantum systems been initiated (see e.g. [1] as reviews). This study allowed a more precise characterization of many-body quantum systems both in and out of equilibrium. In particular, it has been shown that when one considers the entanglement between...
two extended parts in an extended quantum system, universal scaling forms arise, e.g. close to a quantum critical point or in systems displaying topological order (see again [1] as reviews).

The entanglement between two extended parts in a pure quantum state is measured by the famous entanglement entropy, defined as follows. Let $\rho$ be the density matrix of an extended quantum system taken in a pure quantum state $\Psi \rangle |\Psi\rangle$. Let us consider a spatial bipartition of the system in two parts $A$ and $B$ such that the Hilbert space can be written as a direct product $\mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_B$. $A$’s reduced density matrix is $\rho_A = \text{Tr}_B \rho$ and from this the (von Neumann) entanglement entropy is defined as

$$S_A = -\text{Tr} \rho_A \ln \rho_A.$$  

(1)

For a one-dimensional critical system whose scaling limit is described by a conformal field theory (CFT), in the case when $A$ is an (extended) interval of length $\ell$ embedded in an infinite system, the asymptotic large $\ell$ behaviour of the entanglement entropy is $[2-5]$

$$S_A = \frac{c}{3} \ln \frac{\ell}{a} + \text{const},$$  

(2)

where $c$ is the central charge of the underlying CFT [6] and $a$ the inverse of an ultraviolet cutoff (e.g. the lattice spacing).

One can then wonder if and how these nice universal results extend to finite temperature entanglement and whether it is possible by studying entanglement measures to describe the crossover/transition from quantum to classical world which is expected to take place as we ‘warm up’ a quantum system. Indeed this problem has been extensively studied (see again [1] as reviews) at the level of few microscopic constituents (e.g. the entanglement between two spins in a very long spin-chain or the entanglement between few spins and the remainder of the system), but here we are genuinely interested in the entanglement between two extended parts at finite temperature, a problem which has been little studied [7-9] because of a series of technical difficulties. In this case, the entanglement entropy is no longer a good entanglement measure since it clearly mixes up quantum and classical correlations (but still shows very interesting features [3, 10, 11]). A measure of entanglement for bipartite mixed states is instead the so-called entanglement negativity introduced in a seminal series of papers [12–16]. In order to define it, let us divide an extended quantum system in two parts which we call $A_1$ and $A_2$ (it is often very useful to think to a mixed state as obtained by tracing out the degrees of freedom of a larger system in a pure state which has been tripartite in $A_1, A_2$ and $B$ —a procedure called purification—). Let us denote by $|e^{(1)}_i\rangle$ and $|e^{(2)}_j\rangle$ two bases in the Hilbert spaces corresponding to $A_1$ and $A_2$ respectively. Let us define the partial transpose with respect to $A_2$ degrees of freedom as

$$\left\langle e^{(1)}_i | e^{(2)}_j \right\rangle_{\rho^{T}_{A_1 \cup A_2}} = \left\langle e^{(1)}_i | e^{(2)}_j \right\rangle_{\rho_{A_1 \cup A_2}} \rho^{T}_{A_1 \cup A_2} \left| e^{(1)}_i \right\rangle \left\langle e^{(2)}_j \right|,$$  

(3)

and from this the logarithmic negativity as

$$E \equiv \ln \| \rho^{T}_{A_1 \cup A_2} \| = \ln \text{Tr} \left| \rho^{T}_{A_1 \cup A_2} \right|,$$  

(4)

where the trace norm $\| \rho^{T}_{A_1 \cup A_2} \|$ is the sum of the absolute values of the eigenvalues of $\rho^{T}_{A_1 \cup A_2}$. In this expression $A_1 \cup A_2$ does not have to coincide with the entire system. The negativity has the important property of being basis independent and this makes it calculable by means of quantum field theory (QFT) and in particular CFT in which we are interested here. Recently [17, 18] we developed a systematic method to calculate the negativity in QFT and many-body systems in general. This method has been so far extensively used to calculate the entanglement between two parts $A_1$ and $A_2$ of an extended system in a pure state in which
a third part $B$ has been previously traced out. This method allowed the description of ground-states of CFTs [17–22], systems with topological order [23, 24] and also some non-equilibrium situations [25–27]. These studies also allowed a refined understanding of numerical and analytic computations [28–39].

The manuscript is organized as follows. In section 2 we discuss the general CFT approach to entanglement entropy and negativity. In section 3 we report a first naive derivation of the negativity between a single interval and the rest of the system at temperature. This naive derivation provides a wrong result and we explain what is going wrong in this apparently innocuous computation. In section 4 we fix the previous error and we provide a general scaling form for the negativity at finite temperature. Finally, in section 5 we report explicit numerical computation of the finite temperature negativity in the harmonic chain, showing perfect agreement with the previous universal result, but after all the various lattice effects are properly taken into account. In section 6 we draw our conclusions and discuss generalizations.

2. General CFT approach to entanglement entropy and negativity

A very powerful way to calculate the entanglement entropy in a general QFT is based on a replica approach [3, 5]. The overall idea is simply to compute the moments of the reduced density matrix $\Tr \rho_A^n$ with $n$ integer or, equivalently, the Rényi entropies

$$S^{(n)}_A = \frac{1}{1 - n} \ln \Tr \rho_A^n. \quad (5)$$

The computation of these moments in 1+1 dimensional quantum field theories is made possible by the fact that they correspond to partition functions on $n$-sheeted Riemann surfaces with branch points at the boundaries between regions $A$ and $B$ [3]. The partition function on the $n$-sheeted surface can be casted in the form of correlation functions on the complex plane of particular operators termed branch-point twist fields [3, 5, 40]. For example, in the case when $A = \bigcup_{i=1}^N [u_i, v_i]$ consists of $N$ disjoint intervals, we have

$$\Tr \rho_A^n = \left\langle T_n(u_1) \overline{T_n(v_1)} \cdots T_n(u_N) \overline{T_n(v_N)} \right\rangle_C. \quad (6)$$

At this point, if the expression for $\Tr \rho_A^n$ is analytically continuable to general complex $n$, the entanglement entropy is just given by the $n \to 1$ limit of the Rényi entropies. Furthermore, the knowledge of the Rényi entropies for arbitrary $n$ provides also the full spectrum of the reduced density matrix [41].

Although this approach has general validity in one spatial dimension, it is particularly useful in CFT because the twist fields turned out to behave like primary operators with scaling dimension [3, 42]

$$\Delta_n = \frac{c}{12} \left( n - \frac{1}{n} \right). \quad (7)$$

When this relation is specialized to an interval $A$ of length $\ell$ in an infinite system, we obtain the moments

$$\Tr \rho_A^n = \left\langle T_n(u) \overline{T_n(v)} \right\rangle = c \left( \frac{\ell}{a} \right)^{-c/6(n-1)/n}, \quad (8)$$

which can be straightforwardly analytically continued to get the von Neumann entropy (2). The calculation of the entanglement entropy for many disjoint intervals $A = \bigcup_{i=1}^N [u_i, v_i]$ is
much more complicated. Global conformal invariance fixes the scaling form

\[ \text{Tr} \rho_A^n = c_n \left( \prod_{i<j} (u_{kj} - v_{ij}) (v_{kj} - u_{ij}) \right)^{(c/6)(n-1/n)} F_{n,N}(\{x\}) . \] (9)

Here \( \{x\} = \{x_1, x_2, ..., x_{2N-3}\} \) stands for the collection of \( 2N - 3 \) independent ratios that can be built with \( 2N \) points. The functions \( F_{n,N}(\{x\}) \) are universal, but they depend on the full operator content of the CFT—not only on the central charge—and so they should be calculated case by case. Their calculation is a real tour de force which has been performed explicitly only in few instances [43–52] (exploiting old results of CFT on orbifolds [53–56]) and agree with some explicit numerical and analytical computations [43, 44, 48, 49, 52, 57–62]. We mention that these universal functions \( F_{n,N}(\{x\}) \) have very cumbersome analytic forms which prevented the analytic continuations to \( n \to 1 \), with the notable exception of the free un-compactified boson [45] which is the only exactly known entanglement entropy for two disjoint intervals. Some results for two disjoint regions in higher dimensional CFTs are also known [63–65].

### 2.1. The entanglement negativity in CFT

Moving now to the entanglement negativity, we start by reviewing the general situation studied by CFT in [17, 18] in which a one-dimensional system (which can be either infinite, finite, semi-infinite etc) is divided into three parts, two of which are finite intervals \( A_1 \) and \( A_2 \) of length respectively \( \ell_1 \) and \( \ell_2 \) and the part \( B \) represents the remainder of the system. We will denote with \( \rho_A \) the reduced density matrix of \( \cup \equiv A \cup A \cup B \), i.e.

\[ \rho_A = \text{Tr}_{AB} \rho_A^T \]

The QFT approach to negativity is also based on a replica trick [17, 18]: one considers the traces \( \text{Tr} (\rho_A^T)^n \) of integer powers of \( \rho_A^T \) and notices that \( \text{Tr} (\rho_A^T)^n \) have a different functional dependence on \( |\lambda_i| \) according to the parity of \( n \) (\( \lambda_i \) being the eigenvalues of \( \rho_A^T \)). Indeed, for \( n \) even and odd (that we denote as \( n_e \) and \( n_o \) respectively), the traces of integer powers of \( \rho_A^T \) are

\[ \text{Tr} (\rho_A^T)^{n_e} = \sum_i |\lambda_i|^{n_e}, \quad \text{Tr} (\rho_A^T)^{n_o} = \sum_i |\lambda_i|^{n_o} - \sum_i |\lambda_i|^{n_e}. \] (10)

If we set \( n_e = 1 \) in equation (10) we formally obtain \( \text{Tr} |\rho_A^T| \), which is the quantity we are interested in, according to equation (4). Instead, setting \( n_o = 1 \) in equation (11) gives the normalization \( \text{Tr} \rho_A^T = 1 \). This means that the analytic continuations from even and odd \( n \) are different and, in particular, the trace norm that we want to compute is obtained by considering the analytic continuation of the even sequence at \( n_e \to 1 \), i.e.

\[ \mathcal{E} = \lim_{n_e \to 1} \ln \text{Tr} (\rho_A^T)^{n_e}. \] (12)

Since in the QFT representation of the density matrix a transposition has the effect to exchange lower and upper edges of the open cut [17, 18] (see also next section), the traces of integer powers of the partial transpose for two disjoint intervals are partition functions on \( n \)-sheeted Riemann surfaces or, equivalently, the correlation functions of four twist fields [18]
\[ \text{Tr} \left( \rho_A^{\Delta_2} \right)^n = \left\langle T_n(u_1) T_n^2(u_2) T_n^2(v_2) \right\rangle, \] (13)

i.e. the partial transposition has the net effect of exchanging two twist operators compared to \( \text{Tr} \rho_A \), see equation (6) for \( N = 2 \).

Equation (13) is generically valid, but it simplifies when specialized to the case of two adjacent intervals, obtained by letting \( v_1 \rightarrow u_2 \), leading to the three-point function

\[ \text{Tr} \left( \rho_A^{\Delta_2} \right)^n = \left\langle T_n(u_1) T_n^2(u_2) T_n(v_2) \right\rangle. \] (14)

A further simplification occurs when specialising to a pure state by letting \( B \rightarrow \emptyset \) (i.e. \( u_2 \rightarrow v_1 \) and \( v_2 \rightarrow u_1 \), when dealing with the CFT on the plane) for which \( \text{Tr} \left( \rho_A^{\Delta_2} \right)^n \) becomes a two-point function

\[ \text{Tr} \left( \rho_A^{\Delta_2} \right)^n = \left\langle T_n^2(u_2) T_n^2(v_2) \right\rangle. \] (15)

As explained in more details in [18], as a partition function on an \( n \)-sheeted Riemann surface, this expression depends on the parity of \( n \) because \( T_n \) connects the \( j \)th sheet with the \((j + 2)\)th one. For \( n = n_r \) even, the \( n_r \)-sheeted Riemann surface decouples in two independent \((n_r/2)\)-sheeted surfaces. Conversely for \( n = n_o \) odd, the surface remains an \( n_o \)-sheeted Riemann surface. In formulas, these observations are

\[ \text{Tr} \left( \rho_A^{\Delta_2} \right)^{n_r} = \left( \left\langle T_n^{n_r/2}(u_2) T_n^{n_r/2}(v_2) \right\rangle \right)^2 = \left( \text{Tr} \rho_{A_r^{n_r/2}} \right)^2, \] (16)

\[ \text{Tr} \left( \rho_A^{\Delta_2} \right)^{n_o} = \left\langle T_n(u_2) T_n(v_2) \right\rangle = \text{Tr} \rho_{A_o^{n_o}}. \] (17)

Hence, for a bipartite system, \( \text{Tr} \left( \rho_A^{\Delta_2} \right)^n \) can be generically written as a function of \( \text{Tr} \rho_{A_r^{n_r/2}} \) with \( m \) being either \( n \) or \( n_r/2 \). In particular, taking the limit \( n_r \rightarrow 1 \), we obtain that the logarithmic negativity equals the Rényi entropy of order \( 1/2 \), a well known result for bipartite states [12].

Equations (16) and (17) are simply specialized to the CFT case by plugging into them the general formula for \( \text{Tr} \rho_{A_r^{n_r/2}} \) in equation (8), obtaining [17, 18]

\[ \text{Tr} \left( \rho_A^{\Delta_2} \right)^{n_r} = \left( \left\langle T_n^{n_r/2}(u_2) T_n^{n_r/2}(v_2) \right\rangle \right)^2 = \left( \text{Tr} \rho_{A_r^{n_r/2}} \right)^2 = c_{n_r/2} \left( \frac{\ell}{a} \right)^{-c/(n_r/2-2/n_r)} , \] (18)

and

\[ \text{Tr} \left( \rho_A^{\Delta_2} \right)^{n_o} = \left\langle T_n(u_2) T_n(v_2) \right\rangle = \text{Tr} \rho_{A_o^{n_o}} = c_{n_o} \left( \frac{\ell}{a} \right)^{-c/(n_o-1/n_o)} . \] (19)

This simple result shows an important feature of the negativity in CFT, i.e. the operator \( T_n \) and \( T_n^2 \) have scaling dimension \( \Delta_n^{(2)} \) which depends on the parity of the replica index as

\[ \Delta_n^{(2)} \equiv \begin{cases} \Delta_n & \text{odd } n, \\ 2\Delta_{n/2} & \text{even } n. \end{cases} \] (20)

The constants \( c_{n_r,n_o} \) are non-universal, but they are the same as in the Rényi entanglement entropies (8), so that we can write

\[ \text{Tr} \left( \rho_A^{\Delta_2} \right)^{n_r} = c_{n_r}^{(2)} \left( \frac{\ell}{a} \right)^{-\Delta_n^{(2)}}, \quad \text{Tr} \left( \rho_A^{\Delta_2} \right)^{n_o} = c_{n_o}^{(2)} \left( \frac{\ell}{a} \right)^{-\Delta_n^{(2)}}. \] (21)

In the replica limit \( n_r \rightarrow 1 \), we have \( \Delta_{n_r} \rightarrow 0 \) and \( \Delta_n^{(2)} \rightarrow -c/4 \). Thus, performing the analytic continuation, we have
\[ \| \rho_A^{T_n} \| = \lim_{n \to 1} \text{Tr} \left( \rho_A^{T_n} \right) = c_{1/2} \left( \frac{\ell}{a} \right)^{\ell/2} \quad \Rightarrow \quad \mathcal{E} = \frac{c}{2} \ln \frac{\ell}{a} + 2 \ln c_{1/2}, \] (22)

which again is the result that for pure bipartite states the logarithmic negativity equals the Rényi entropy of order 1/2.

3. A naive finite temperature result for the negativity of a single interval in infinite space and why it goes wrong

In a general one-dimensional QFT, finite temperature expectation values are simply obtained by evaluating the path integral on a cylinder of circumference \( \beta = 1/T \) in the imaginary time direction. This correspondence is particularly useful in a CFT, because a cylindrical geometry can be obtained from the complex plane by the conformal transformation

\[ z \rightarrow w = (\beta/2\pi) \ln z, \] (23)

where \( z \) is the complex coordinate on the plane and \( w = \sigma + i\tau \) lives on the cylinder. Under the conformal mapping \( z \rightarrow w = w(z) \), the correlation functions of primary operators transform like [53]

\[ \langle \Phi_1(z_1, z_2) \Phi_2(z_3, z_4) \cdots \rangle = \prod_j w'(z_j) \delta_j \langle \Phi_1(w_1, w_2) \Phi_2(w_3, w_4) \cdots \rangle. \] (24)

Then the obvious ‘temptation’ is to apply the above formula to the correlation function of twist fields determining the negativity of an interval of length \( \ell \) in an infinite system at temperature \( 1/\beta \), i.e. assuming

\[ \text{Tr} \left( \rho_B^{T_n} \right) = \left\langle T_n^2(\nu) \bar{T}_n^2(\nu) \right\rangle_{\beta}, \] (25)

where \( \langle \cdot \rangle_{\beta} \) stands for expectation values on the cylinder. We anticipate that this apparently innocuous formula is wrong. Notice that, since from now on we will consider only bipartite systems, we denoted the finite interval with \( A \) and the remainder of the system with \( B \), but compared to the previous sections we change notations as \( (A_1, A_2, B) \rightarrow (A, B, \emptyset) \). In this specialization to the bipartite system, the density matrix \( \rho \) corresponds to the entire system and it is not reduced.

The rhs of equation (25) can be derived using equation (24), providing for even \( n \)

\[ \left\langle T_n^2(0) \bar{T}_n^2(\ell) \right\rangle_{\beta} = c_{n/2}^2 \left( \frac{\beta}{\pi a} \sinh \frac{\beta \ell}{\beta} \right)^{-\ell/2}, \] (26)

that analytically continued to \( n_\ell = 1 \) gives

\[ \| \rho_B^{T_n} \| = c_{1/2}^2 \left( \frac{\beta}{\pi a} \sinh \frac{\beta \ell}{\beta} \right)^{\ell/2}, \quad \Rightarrow \quad \mathcal{E}_{\text{naive}} = \frac{c}{2} \ln \left( \frac{\beta}{\pi a} \sinh \frac{\beta \ell}{\beta} \right) + 2 \ln c_{1/2}. \] (27)

This result resembles the one for the entanglement entropy at finite temperature [3], and indeed it is nothing but the finite temperature Rényi entropy of order 1/2. But this naive result makes no sense at all for several reasons. First, for the finite temperature mixed state, the Rényi entropy is not an entanglement measure while the negativity is. However, one could pretend that for CFTs the two could coincide, but this is not the case. Indeed, let us look at this result for fixed \( \ell \) and increasing the temperature from 0 to some finite value \( T = 1/\beta \). Equation (27) is a monotonous increasing function of \( T \), which goes against the common sense suggesting the entanglement to be a decreasing function of the temperature. Even more
dramatically for very high temperature, when the system becomes classical equation (27) predicts an infinite entanglement, which is absurd for a classical system.

Let us now try to understand what is going wrong in the apparently simple and straightforward calculation above. In order to do so we should first go back to the definition of density matrix in a finite temperature QFT. This is given by a cylinder of circumference $\beta$ with an open cut on the axis $\tau = 0$. The upper and lower edges of the cut are the rows and the columns of the density matrix. Then matrix multiplication corresponds to sew together an upper and lower edge of two cylinders. To give a practical example, $\rho^{T_n}$ is nothing but the partition function of $n$ of those cylinder joined cyclically in such a way to have a ‘fatter’ cylinder of circumference $n\beta$. As explained in more details in [3], in the reduced density matrix of a segment $A$ one should sew the cut along $B$ inside the single cylinder, in such a way that when constructing $\rho^{T_n}_A$, we end up in a $n$-sheeted Riemann surface in which the cylinders are connected cyclically only along the interval $A$.

The construction of the partial transposition has been derived in [17, 18] to which we refer for more details. The partial transposition with respect to an interval $A$ amounts to exchange rows and columns corresponding to that interval, which is exchanging the lower and upper edges of the cylinder along $A$ in the QFT construction. Thus, when we consider $\rho^{T_n}_A$, the resulting surface is such that the axis at $\tau = 0$ on the $j$th cylinder is connected to the upper cylinder along $B$ but to the lower one along $A$. In the top picture of figure 1, this is shown with arrows of different verses, pointing up and down to respectively indicate the connections to

Figure 1. Partial transposition and $\text{Tr } (\rho^{T_n})^\gamma$ of one interval $A$ at finite temperature. Top: simple arrows indicate that in $\text{Tr } (\rho^{T_n})^\gamma$ one passes from the $j$th copy to the $(j + 1)$th one by following them through the cut (depending on the verse of the arrow). Middle: deforming the dashed green line as indicated, part of it becomes a cut extending along the whole cylinder and parallel to its axis, while the remaining part merges with the red segment. Bottom: the double arrow denotes a double jump, from the $j$th copy to the $(j + 2)$th one, following it through the cut. The $j$th copy is sewed to the $(j + 1)$th one through the dashed line. Because of this connection, the $n_n$-sheeted Riemann surface occurring in $\text{Tr } (\rho^{T_n})^\gamma$ does not factorize into the product of two identical $(n_n/2)$-sheeted Riemann surfaces.
the \((j + 1)\)th cylinder when moving following the arrow. We can now deform the cut associated to \(B\) as shown in the middle picture of figure 1 and this deformation does not change the topology of the surface. Proceeding with the deformation, the \(j\)th sheet becomes the cylinder depicted in the bottom picture: it is connected to the \((j + 1)\)th cylinder through the dashed green line and to the \((j + 2)\)th one through the interval \(A\) (represented pictorially as a double arrow). There is no way to remove this dashed green line which connects consecutive sheets and therefore for \(n = n_e\) the corresponding Riemann surface does not decouple into two identical \((n_e/2)\)-sheeted Riemann surfaces. Always because of such connection through the dashed green line, the Riemann surface occurring in \(\text{Tr} (\rho^{T_A})^n\) factorizes into the product of two identical \((n_e/2)\)-sheeted Riemann surfaces.

At this point it is natural to wonder why a similar problem does not arise at \(T = 0\) in which case the cylinder degenerates to the whole complex plane which is topologically equivalent to a sphere. In figure 2 we proceed in the same way as in figure 1, but substituting the cylinder with a sphere. In the first three panels everything proceeds in complete analogy to the cylinder case resulting finally in a dashed green line parallel to the equator. However, in this case, the dashed green line can be shrunk to a point and therefore it vanishes. Thus, since the \(j\)th sheet is connected only to the \((j + 2)\)th one along the segment \(A\), we are allowed to use the construction in [18] to relate, at zero temperature, \(\text{Tr} (\rho^{T_A})^n\) to \(\text{Tr} \rho_A^n\).

A final comment is necessary at this point. The above reasoning shows that the negativity cannot be calculated by a simple mapping from the cylinder to the sphere if the partial
transposition involves an infinite part of an infinite system at finite temperature. This is not the case if one, for example, is interested in the negativity between two (adjacent or disjoint) finite intervals at finite temperature. For this reason, to quote a concrete example, the finite temperature calculation of the negativity between two adjacent intervals in [25], which is based on the calculation of a three-point function on the plane, is indeed free from these troubles and therefore correct.

4. The correct finite temperature negativity for one interval in the infinite line

After having understood what goes wrong in equation (25), we should find a way to take into account the branch cut (i.e. the dashed-green line in figure 1) in the partial transposed reduced density matrix. Denoting by \( w = \sigma + i\tau \) (\( \sigma \in \mathbb{R} \) and \( \tau \in [0, \beta) \)) the complex coordinate on the cylinder, the easiest way to tackle the problem is to let the branch cut starting and ending not at \( \text{Re} \{w\} = \pm \infty \), but at some large and finite values that we denote as \( \pm L \). Proceeding according to this idea, we should then calculate the following four-point function on the infinite cylinder of circumference \( \beta \)

\[
\left \{ T_n(-L) T_n^2(-\ell) T_n^2(0) T_n(L) \right \}_\beta ,
\]

where \( L > \ell > 0 \). The locations of the twist operators are aligned along the line \( \tau = 0 \) parallel to the axis of the cylinder. In order to compute the negativity, we should first calculate the four-point function above for finite \( L \), then take the replica limit \( \to \infty \) and only after the limit \( \to \infty \). As we will see explicitly below, the two limits do not commute explaining why we get a different result compared to the naive one (27). For simplicity in the formulas, we will omit the dependence on the inverse UV cutoff \( a \) during the course of the calculation and we will restore it only at the end. Notice that the above prescription provides automatically that the negativity of part \( B \) of the system \( \mathcal{E}_B \) equals \( \mathcal{E}_A \), because in equation (28) the exchange \( A \) and \( B \) is obtained by interchanging \( T_n \leftrightarrow T_n^2 \)

By employing the conformal map \( z = e^{2\pi i \beta / \ell} \) and using equation (24), we can write equation (28) in terms of the corresponding four-point function on the complex plane, namely

\[
\left \{ T_n(-L) T_n^2(-\ell) T_n^2(0) T_n(L) \right \}_\beta \equiv \left \{ T_n(e^{-2\pi i \beta / \ell}) T_n^2(e^{-2\pi i \beta / \ell}) T_n^2(1) T_n(e^{2\pi i \beta / \ell}) \right \}_{\ell, \beta} \epsilon .
\]

On the complex plane, a general four-point function of primary fields \( V_j(z_j, \bar{z}_j) \) with different scaling dimensions \( \Delta_{(j)} \) can be written, for instance, as follows

\[
\prod_{j=1}^4 V_j(z_j, \bar{z}_j) = \frac{\prod_{i<j} \frac{\prod_{i,j} \frac{\Delta_{13} + \Delta_{14} - \Delta_{24} - \Delta_{34}}{\Delta_{13} + \Delta_{14} - \Delta_{24} - \Delta_{34}}}{\Delta_{13} + \Delta_{14} - \Delta_{24} - \Delta_{34}}} G(x), \quad x = \frac{z_{12} z_{34}}{z_{13} z_{24}},
\]

being \( z_{ij} = |z_i - z_j| \) and \( x \) the cross ratio of the four points. Specifying equation (30) to our case, the four-point function occurring in the rhs of equation (29) can be written as
\[
\left\{ T_n(z_1) \overline{T}_n^2(z_2) T_n^2(z_3) T_n(z_4) \right\} = \frac{G_n(x)}{x^{\frac{2\lambda}{14} + \frac{2\lambda}{23} + \frac{2\lambda}{14} + \frac{2\lambda}{23}}},
\]

where the points \(z_i\) are still arbitrary complex numbers. It is clear that there is a degree of arbitrariness in the way of writing the above four-point function since any power of the harmonic ratio \(x\) can be absorbed in the scaling function \(G_n(x)\). We will use this arbitrariness to our advantage in such a way to have reasonable limits for \(x \to 0\) and \(x \to 1\). To fix these limits we must consider the OPEs

\[
T_n(u) \overline{T}_n(v) = \frac{c_n}{|u - v|^{2\lambda}} + \ldots, \quad T_n^2(u) \overline{T}_n^2(v) = \frac{c_n^{(2)}}{|u - v|^{2\lambda}} + \ldots, \quad u \to v,
\]

and

\[
T_n(u) \overline{T}_n^2(v) = \frac{C_{r_n} \tau_n \tilde{\tau}_n}{|u - v|^{2\lambda}} \overline{T}_n(v) + \ldots, \quad u \to v,
\]

with the corresponding OPE for \(\overline{T}_n(u) T_n^2(v)\) with \(C_{r_n} \tau_n \tilde{\tau}_n = C \tau_n \tilde{\tau}_n\).

From equation (32), we have the following cluster property for \(z_3 \to z_2\) and \(z_4 \to z_1\):

\[
\left\{ T_n(z_1) \overline{T}_n^2(z_2) T_n^2(z_3) T_n(z_4) \right\} = \left\{ T_n(z_1) \overline{T}_n(z_4) \right\} \left\{ \overline{T}_n^2(z_2) T_n(z_3) \right\} + \ldots,
\]

while from equation (33) we have

\[
\left\{ T_n(z_1) \overline{T}_n^2(z_2) T_n^2(z_3) T_n(z_4) \right\} = \frac{C_r^2 \tau_n \tilde{\tau}_n c_n}{(z_{12} z_{34})^{A_n^2} x^{A_n^2}} + \ldots, \quad z_2 \to z_1, \quad z_4 \to z_3,
\]

where the dots denote less divergent terms. The expansions (34) and (35) correspond respectively to \(x \to 1\) and \(x \to 0\). These expressions suggest us to write the four-point function of twist fields in the following form

\[
\left\{ T_n(z_1) \overline{T}_n^2(z_2) T_n^2(z_3) T_n(z_4) \right\} = \frac{c_n c_n^{(2)}}{x^{\frac{2\lambda}{14} + \frac{2\lambda}{23} + \frac{2\lambda}{14} + \frac{2\lambda}{23}}} \overline{T}_n(z_4) T_n(z_3),
\]

where (34) and (35) impose respectively that

\[
F_2(1) = 1, \quad F_2(0) = \frac{C_r^2 \tau_n \tilde{\tau}_n}{c_n^{(2)}}.
\]

This choice of the universal function \(F_n(x)\) is such that it has finite limits both for \(x \to 0\) and \(x \to 1\).

Specialising to the four points in the rhs of equation (29) we have

\[
\left\{ T_n \left( e^{-2\pi L/\beta} \right) \overline{T}_n^2 \left( e^{-2\pi \ell/\beta} \right) T_n^2 \left( 1 \right) \overline{T}_n \left( e^{2\pi L/\beta} \right) \right\}_C
= \frac{c_n c_n^{(2)}}{2 \sinh(2\pi L/\beta)^{14}} \left( 1 - e^{-2\pi \ell/\beta} \right)^{\frac{2\lambda}{14} x^{\frac{2\lambda}{14}}},
\]

10
and the harmonic ratio becomes
\[ x = \frac{e^{-2\pi \ell / \beta} - e^{-2\pi \ell / \beta}}{1 - e^{-2\pi \ell / \beta}} \left( e^{2\pi \ell / \beta} - e^{-2\pi \ell / \beta} \right), \]
(39)
whose large \( L \) limit is
\[ \lim_{L \to \infty} x = e^{-2\pi \ell / \beta}. \]
(40)
Plugging equation (38) in equation (29), the desired cylinder four-point function is
\[ \langle T_n(-L) \bar{T}_n^2(-\ell) T_n^2(0) \bar{T}_n(L) \rangle = c_n c_n^{(2)} \left[ \frac{\beta}{\pi} \sinh \left( \frac{\pi \ell}{\beta} \right) \right]^{2\Delta_n} \left[ \frac{\beta}{\pi} \sinh \left( \frac{2\pi L}{\beta} \right) \right]^{2\Delta_n} \frac{T_n(x)}{x^{4\Delta_n^2}}. \]
(41)
Notice that, taking \( L \to \infty \) for finite integer \( n \), the above expression vanishes, signaling that we should first take the replica limit and only after the large \( L \) one, as anticipated above.

Thus, taking the replica limit at finite \( L \), we find
\[ \lim_{n \to 1} \left[ \langle T_n(-L) \bar{T}_n^2(-\ell) T_n^2(0) \bar{T}_n(L) \rangle \right] = \mathcal{E}_{\text{naive}} + \frac{c}{4} \ln(x) + f(x), \]
(42)
where \( \mathcal{E}_{\text{naive}} \) is given by equation (27) and we defined
\[ f(x) = \lim_{n \to 1} \ln \left[ T_n(x) \right]. \]
(43)
In the above expression, the \( L \) dependence is fully encoded in the harmonic ratio \( x \), thus we can take the limit \( L \to +\infty \), obtaining the logarithmic negativity (restoring the \( a \) dependence)
\[ \mathcal{E} = \mathcal{E}_{\text{naive}} - \frac{\pi \ell}{2\beta} + f \left( e^{-2\pi \ell / \beta} \right) = \frac{c}{2} \ln \left[ \frac{\beta}{\pi a} \sinh \left( \frac{\pi \ell}{\beta} \right) \right] - \frac{\pi \ell}{2\beta} + f \left( e^{-2\pi \ell / \beta} \right) + 2 \ln c_{1/2}. \]
(44)
This formula represents the main result of our paper and now we are going to discuss all its implications, which are numerous. The most remarkable and important feature of equation (44) is that the linear term in \( \ell / \beta \) exactly cancels the large temperature divergence of \( \mathcal{E}_{\text{naive}} \) which was the main motivation of this calculation. For large temperature and at fixed \( \ell \) equation (44) is valid only as long as \( \beta \gg a \) and so it never becomes negative, as it could seem at a first superficial look. Another fundamental feature is that the logarithmic negativity depends on the full operator content of the model through the function \( f(x) \). This is a relevant difference compared to \( \mathcal{E}_{\text{naive}} \), which instead depends only on the central charge like the entanglement entropy. In the limit of very large \( T \), we would expect the negativity to vanish since a quantum system should crossover to a classical one. However, in the above expression it is clear that this limit is dominated by some non-universal constants like the UV cutoff \( a \) signalling that probably the vanishing at high-\( T \) is not a direct feature of CFT, but it is connected to non-universal physics.

Although equation (44) depends on the UV physics via the cut-off \( a \), there is a straightforward way to construct a universal scaling quantity by subtracting to the negativity its value at \( T = 0 \), finding \( (T = 1/\beta) \)
\[ \mathcal{E}_r(T) \equiv \mathcal{E}(T) - \mathcal{E}(0) = \frac{\zeta}{2} \ln \left[ \frac{1}{\pi T} \sinh(\pi T) \right] - \frac{\pi \ell T}{2} + f \left( e^{-2 \pi T} \right), \quad (45) \]

which depends only on the ratio \( \ell/\beta = \ell T \) and it can be written as

\[ \mathcal{E}_r(T) = \frac{\zeta}{2} \left[ \ln \left( 1 - e^{-2 \lambda} \right) - \ln (2 \lambda) \right] + f \left( e^{-2 \lambda} \right), \quad \lambda \equiv \pi T. \quad (46) \]

The explicit calculation of the negativity requires the evaluation of the four-point function (38) on the complex plane for some specific models, but this is a very cumbersome calculation. Indeed this four-point function can be obtained from the known six-point functions of twist fields \( T_\phi \) [52] and fusing two pairs of them to to \( T_{\phi,\phi} \), closely following [18]. However, this procedure is very cumbersome even for the easiest CFTs. Furthermore, even if we would manage to calculate this four-point function, the replica limit is an even more difficult task. In fact, none of the explicitly calculated four-point functions has been continued to arbitrary complex \( n \) in order to obtain a closed form of the negativity (see [18] for a discussion of this point). Anyhow, equation (44) contains most of the physics of the negativity, even if we do not know the explicit form of \( f(x) \). Indeed, the most interesting limits \( \ell \gg \beta \) and \( \beta \gg \ell \) can be analytically derived using the OPE of the twist fields (or better the short-interval expansion) developed in [46].

### 4.1. High temperature regime

The high temperature regime is given by \( \beta \ll \ell < L \) or, equivalently, \( x \to 0 \). We wrote equations (41) and (44) in such a way that this limit is straightforward. Indeed according to equation (37), the scaling functions \( F_n(x) \) tends to a constant value independent of \( x \) and so will do its replica limit \( f(x) \). Consequently for \( \ell \gg \beta \), the negativity (44) attains a constant non-universal value because, as already stressed above, the leading linear terms in \( \ell \) cancel. The study of the approach to this constant value requires the knowledge of the subleading terms in the OPE (33), which is a more cumbersome and involved calculation. We limit ourselves to mention that since the replica limit goes outside the realm of unitary CFT (as signalled by the fact that the scaling dimension \( \Delta_n(2) \) tends to the negative value \(-c/4\)), logarithmic subleading corrections to this asymptotic behaviour could also arise (as indeed happens in the case of other short-distance expansions [18]).

### 4.2. Low temperature regime

The low temperature regime is attained for \( \beta \gg \ell \), i.e. when the length of the interval \( A \) is much smaller than the inverse temperature. It is however important to stress that a reasonable result is obtained only for \( L \gg \beta \), and so, in order to recover the zero temperature limit, we should first take the limit \( L \to \infty \) and only after send \( \beta \to \infty \). In this limit we have \( x = e^{-2 \pi T} \to 1 \), so equation (44) gives the correct zero temperature result (22), because the normalization \( F_n(1) = 1 \) implies \( f(1) = 0 \).

The correction to the zero temperature behaviour are more involved but they can be obtained as an application of the short-length expansion developed in [46], which requires to take into account the next order in the OPE (32). The short-length expansion can be thought as the following OPE (for a more precise treatment we refer to [46])

\[ T_n(u) T_n(v) = \sum_{\{ k_j \}} \frac{c_n}{|u - v|^{2\Delta_n + \sum \Delta_j}} \phi_{k_j}(u_j) \prod_{j=1}^n \phi_{k_j}(u_j), \quad u \to v, \quad (47) \]
where \( \{ \phi_k \} \) denotes a complete set of local fields for a single copy of the CFT, \( u_j \) is the point \( u \) on the \( j \)th sheet, and \( d_{k} \) are dimensionless universal numbers, which for primary operators can be explicitly calculated as [46]

\[
d_{k}^{(n)} = n^{-2} \sum (\Delta_j + \Delta_i) \prod_{j=1}^{n} \phi_k (e^{2\pi i / n})_c .
\] (48)

The leading term as \( u \to v \) is given by taking all the \( \Delta_j = 0 \), that is \( \phi_k = 1 \), the identity operator, recovering equation (32). The next term comes from taking all the \( k_j = 0 \) except one. However in this case \( \phi_k \) cannot be primary, since the one-point function \( \langle \phi_k \rangle_c \) in equation (48) would vanish. The most interesting case is when \( \phi_k \) is a component of the stress tensor on the sheet \( j \), \( T_j \) or \( T_j \) which has been studied in [46] leading to

\[
d_{k}^{(n)} = d_{k}^{(n)} = 1/6(1 - 1/n^2) .
\]

The next contribution comes from taking two of the \( k_j \) to be non-zero. Since the product must couple to the identity block this requires the two operators to be in the same block, and if they are real and primary they must be the same operator. Thus, taking \( k_j = k_j = k \) and \( j_1 \neq j_2 \), we have

\[
d_{k}^{(n)} = \left[ e^{2\pi i j_1 / n} - e^{2\pi i j_2 / n} \right] \left[ e^{-2\pi i j_2 / n} - e^{-2\pi i j_1 / n} \right] .
\] (49)

For the low temperature expansion of the negativity we need to consider the OPE of \( T_n^2 \), which can be easily written in terms of the ones of \( T_n^2 \) since, for \( u \to v \), we have

\[
T_n^2 (u) T_n^2 (v) = \begin{cases} T_n (u) T_n (v) & \text{odd } n, \\ \left( T_{n/2} (u) T_{n/2} (v) \right)^2 & \text{even } n. \end{cases}
\] (50)

Let us now focus on the even case, when for \( \ell \to 0 \) we have

\[
T_n^2 (0) T_n^2 (\ell) = \frac{c_{n/2}}{\ell^2 \Delta n} \sum_{k_i} \sum (\Delta_j + \Delta_i) d_{k_i}^{(n/2)} \prod_{j=1}^{n} \phi_k (\ell_j) \\

\times \sum_{k_i} \sum_{k_j} \sum (\Delta_j + \Delta_i) d_{k_i}^{(n/2)} \prod_{j=1}^{n} \phi_k (\ell_j) .
\] (51)

The leading term in this expression is again obtained by taking all the \( \Delta_j = \Delta_i = 0 \), that is \( \phi_i = \phi_k = 1 \). A first non-trivial contribution is obtained by choosing the identity in one of the two sums and one \( k_i \neq 0 \) in the other. This contribution comes with a factor 2, one for each sum. Let us consider explicitly the contribution of the stress-energy tensor \( T_j \) of the sheet \( j \) for which we have

\[
T_n^2 (0) T_n^2 (\ell) = \frac{c_{n/2}}{\ell^2 \Delta n} \left( 1 + \ldots + 2\ell^2 d_{T_j}^{(n/2)} T_j (\ell) + \ldots \right) .
\] (52)

Let us recall that the stress energy tensor can be inserted in \( n_v/2 \) possible sheets and that one should take also into account the antiholomorphic component \( T_i \), meaning that the above contribution should be multiplied by \( n_v \). Thus inserting this expression directly in equation (28) we obtain
\[
\left\langle T_{n}(-L)\bar{T}_{n}^{2}(-\ell)T_{n}(0)\bar{T}_{n}(L)\right\rangle _{\beta} = \frac{c_{n}^{2}\ell_{2}}{\ell^{2\Delta_{k}^{(2)}}} \left\langle T_{n}(-L)\left(1 + 2\ell^{2}d_{\ell j_{2}}^{(1/2)}T\ell + \ldots\right)\bar{T}_{n}(L)\right\rangle _{\beta} .
\]

We are interested in the replica limit \( n_{e} \to 1 \) of this expression. In this case, since the operator is inserted on a single sheet, we have \( \lim_{n_{e} \to 1} (T_{n}(-L)O_{j}(x)\bar{T}_{n}(L))_{\beta} = \left\langle O(x) \right\rangle _{\beta} \), so that

\[
\lim_{n_{e} \to 1} \left\{ T_{n}(-L)\bar{T}_{n}^{2}(-\ell)T_{n}(0)\bar{T}_{n}(L)\right\} _{\beta} = \frac{c_{1/2}^{2}}{\ell^{2\Delta_{k}^{(2)}}} \left\langle \left(1 + 2\ell^{2}d_{\ell j_{2}}^{(1/2)}T\ell + \ldots\right)\right\rangle _{\beta} = \epsilon c_{1/2}\epsilon^{2/2}\left(1 + 2\ell^{2}12\beta^{2} + \ldots\right) .
\]

where in the second line we used \( \left\langle T \right\rangle _{\beta} = -\pi^{2}c/(6\beta^{2}) \), \( d_{\ell j_{2}}^{(1/2)} = -1/2 \) and \( \Delta_{k}^{(2)} = -c/4 \).

Taking the logarithm we have the negativity

\[
E = \frac{c}{2} \ln \ell + 2\ln c_{1/2} + \ldots + c\frac{\pi^{2}\ell^{2}}{12\beta^{2}} + \ldots
\]

where in the second line we used \( \left\langle T \right\rangle _{\beta} = -\pi^{2}c/(6\beta^{2}) \), \( d_{\ell j_{2}}^{(1/2)} = -1/2 \) and \( \Delta_{k}^{(2)} = -c/4 \).

Taking the logarithm we have the negativity

\[
E = \frac{c}{2} \ln \ell + 2\ln c_{1/2} + \ldots + c\frac{\pi^{2}\ell^{2}}{12\beta^{2}} + \ldots
\]

Notice that this expression coincides with low temperature expansion of \( \Delta_{\text{naive}} \), which indeed should be fully understood in terms of insertions of the stress energy tensor.

Primary operators contribute, for example, by choosing the identity in one sum in equation (51) and taking two of the \( k_{j} = k_{j_{2}} = k \) to be non-zero in the other, since the insertion of a single primary has zero prefactor as in equation (48). Thus, we have (assuming also for simplicity \( \Delta_{k} = \Delta_{k_{1}} \))

\[
\left\langle T_{n}(-L)\bar{T}_{n}^{2}(-\ell)T_{n}(0)\bar{T}_{n}(L)\right\rangle _{\beta} = \frac{c^{2}_{n}2^{\ell^{2}d_{\ell j_{2}}^{(1/2)}}}{\ell^{2\Delta_{k}^{(2)}}} \left\langle \left(1 + 2\ell^{2}d_{\ell j_{2}}^{(1/2)}T\ell + \ldots\right)\right\rangle _{\beta} = \epsilon \ell^{2}\epsilon^{2/2}\left(1 + 2\ell^{2}12\beta^{2} + \ldots\right) .
\]

In this case, the calculation of the constant in front of \( \ell^{2\Delta_{k}} \) is more cumbersome (because we cannot take averages on different sheets separately) and also the replica limit is not as straightforward as in the previous case. However, from the above expression, we immediately conclude that the contribution to the negativity is of the form

\[
E = \frac{c}{2} \ln \ell + 2\ln c_{1/2} + \ldots + C_{k}\left(\ell^{\Delta_{k}}\right) + \ldots
\]

where the constant \( C_{k} \) is still undetermined, but it is reasonable that, since it comes from the limit \( n_{e} \to 1 \), for some operators will be negative (in the same way \( d_{\ell j_{2}}^{(1/2)} \) is negative for \( n = 1/2 \).

If we consider the small temperature expansion of \( E_{s}(T) \) in equation (45) we have

\[
E_{s}(T) = E(T) - E(T = 0) = c\frac{\pi T^{2}}{12} + C_{k}(\ell T)^{\Delta_{k}} + \ldots
\]

In this expression there are two different contributions: one analytic from the stress energy tensor (which coincide with the expansion of \( E_{\text{naive}} \)) and a non-analytic and non-trivial \( 4\Delta_{k} \), where \( \Delta_{k} \) is the scaling dimension of the most relevant operator coupling with \( \bar{T}_{n}^{2} \). Which contribution is more relevant depends on the precise operator content of the theory and indeed
it will be interesting to provide specific examples which will be considered in following publications. At higher-order the computation of negativity is very complicated because it gets contributions from many sources (the cross terms from the sums in equation (51), the descendent fields, etc).

4.3. Semi infinite systems

A simple and important generalization of the previous calculation is the negativity of a semi-infinite CFT on the half-line $\sigma < 0$. In this case we have to compute the two-point function

$$\langle T_n(-L)T_n^2(-\ell) \rangle_{\beta},$$

in the geometry where $\sigma \leq 0$ and the Euclidean time $\tau$ is periodic with period $\beta$. The conformal map $z = e^{2\pi \nu/\beta}$ ($w = \sigma + i\tau$) maps the half-cylinder into the unit disk. Using equation (24) we have

$$\langle T_n(-L)T_n^2(-\ell) \rangle_{\beta} = \left( \frac{2\pi}{\beta} \right)^{\Delta_{(1)} + \Delta_{(2)}} \frac{\langle T_n(e^{-2\pi L/\beta})T_n(e^{-2\pi \ell/\beta}) \rangle_{\text{disk}}}{e^{2\pi \Delta_{(1)} L/\beta} e^{2\pi \Delta_{(2)} \ell/\beta}}.$$ (60)

On the unit disk, the two-point function of two primary operators with dimensions $\Delta_{(1)}$ and $\Delta_{(2)}$ can be written as

$$\langle V_1(z_1)V_2(z_2) \rangle_{\text{disk}} = \frac{B(y)}{(1-|z_1|^2)^{\Delta_{(1)}}(1-|z_2|^2)^{\Delta_{(2)}}}, \quad y = \left| \frac{z_1 - z_2}{1 - z_1 \bar{z}_2} \right|^2,$$ (61)

where $y$ is the harmonic ratio of the half-line and $B(y)$ the universal scaling function with a boundary. In analogy to equation (38) for the plane, we can choose the scaling function of twist fields $B_n(y)$ in such a way that

$$\langle T_n(e^{-2\pi L/\beta})T_n^2(e^{-2\pi \ell/\beta}) \rangle_{\text{disk}} = \frac{\tilde{c}_n \tilde{c}_n^{(2)}}{(1-e^{-4\pi L/(\beta \beta)})^{\Delta_{(1)}}(1-e^{-4\pi \ell/(\beta \beta)})^{\Delta_{(2)}}} y^{\Delta_{(2)}/2},$$ (62)

where, on the half cylinder, the harmonic ratio is

$$y = \left( \frac{e^{-2\pi L/\beta} - e^{-2\pi \ell/\beta}}{1 - e^{-2\pi (L+\ell)/\beta}} \right)^2.$$ (63)

In the limit $L \to +\infty$, we have $y \to e^{-4\pi \ell/\beta}$. The non-universal constants $\tilde{c}_n$ and $\tilde{c}_n^{(2)}$ are the boundary analogous of $c_n$ and $c_n^{(2)}$ to which are related through the Affleck–Ludwig boundary entropy [3, 66, 67]. Plugging equation (62) into equation (60), we get

$$\langle T_n(-L)T_n^2(-\ell) \rangle_{\beta} = \frac{\tilde{c}_n \tilde{c}_n^{(2)} B_n(y)y^{-\Delta_{(2)}/2}}{[(\beta/\pi) \sinh(2\pi L/\beta)]^{\Delta_{(1)}} [(\beta/\pi) \sinh(2\pi \ell/\beta)]^{\Delta_{(2)}}}.$$ (64)
Taking the replica limit (i.e. the limit $n \to 1$), we get

$$\lim_{n \to 1} \left\langle T_n(-L) \overline{T}_n^2(-\ell) \right\rangle = \frac{c}{4} \ln \left\{ \frac{\beta}{\pi a} \sinh \left( \frac{2\pi \ell}{\beta} \right) \right\} + \frac{c}{2} \ln y + \lim_{n \to 1} \ln B_n(y) + 2 \ln \tilde{c}/2,$$  

(65)

where in particular one should notice the dependence on $\sinh 2\pi \ell/\beta$ instead of $\sinh \pi \ell/\beta$ obtained on the infinite line (analogously to the entanglement entropy [3, 5]). We recall that the universal function $B_n(y)$ generically depends also on the boundary state of the BCFT and it cannot be simply obtained from $T_n$ in the bulk. In the limit $L \to +\infty$ equation (65) gives

$$\mathcal{E} = \frac{c}{4} \ln \left\{ \frac{\beta}{\pi a} \sinh \left( \frac{2\pi \ell}{\beta} \right) \right\} - \frac{\pi \ell}{2\beta} + f_{\text{bdy}} \left( e^{-4\pi \ell/\beta} \right) + 2 \ln \tilde{c}/2,$$  

(66)

where we defined $f_{\text{bdy}}(y) = \lim_{n \to 1} \ln B_n(y)$. As for negativity at finite temperature in the infinite line, the linear term in $\ell$ exactly cancels the linear divergence of the first naive term at high temperature.

The low and high temperature limits of this expression are obtained in analogy with the infinite line case and we do not repeat the calculations here.

4.4. Finite system

We want to conclude this section by stressing that the calculation for finite systems, either with periodic boundary conditions or in a BCFT are immensely more complicated than the calculations reported in this paper because we should consider either a toroidal or annulus geometry. In these cases, the calculation of multi-point twist-field correlations is still beyond our reach.

5. Numerical results for the harmonic chain

In this section we check that the scaling forms previously obtained are indeed recovered in numerical calculations of a lattice model. We consider the harmonic chain with Hamiltonian

$$H = \sum_{i=1}^{L} \left\{ \frac{p_i^2}{2M} + \frac{M\omega^2}{2} q_i^2 + \frac{K}{2} (q_{i+1} - q_i)^2 \right\},$$  

(67)

where $L$ is the number of lattice sites of the chain, $M$ a mass scale, $\omega$ the one-particle oscillation frequency, and $K$ a nearest neighbour coupling. The variables $p_i$ and $q_i$ satisfy standard commutation relations $[q_i, q_j] = [p_i, p_j] = 0$ and $[q_i, p_j] = i\delta_{ij}$. We consider the harmonic chain because it is the only lattice model in which the partial transpose and the negativity can be obtained by means of correlation matrix techniques [28, 29, 68, 69]. The model is critical for $\omega = 0$ and its continuum limit is conformal with central charge $c = 1$. Unfortunately, in a system with periodic boundary conditions, the mass term $\omega$ cannot be set equal to zero because the $\langle q_i q_j \rangle$ correlation function would diverge at zero momentum. The presence of this zero-mode strongly affects the results also at zero temperature [18, 29] and at finite $T$ gives rise to effects which obscure the universal conformal physics (indeed finite $T$ negativity of the harmonic chain has already been considered in [7–9]). Thus, in order to avoid this problem and to have clean results in the conformal regime, we impose Dirichlet boundary conditions $q_0 = q_{L+1} = 0$ and $p_0 = p_{L+1} = 0$. 

The Hamiltonian (67) can be diagonalized with standard techniques (see e.g. [18, 70]). In order to calculate the negativity we need the dispersion relation

$$\omega_k = \sqrt{\omega + \frac{4K}{M} \sin^2 \left( \frac{\pi k}{2(L+1)} \right)} > \omega, \quad k = 1, \ldots, L, \quad (68)$$

and the finite temperature correlators

$$\langle q_a q_b \rangle_\beta = \frac{1}{L+1} \sum_{k=1}^L \frac{1}{M \omega_k} \coth \left( \frac{\omega_k}{2T} \right) \sin \left( \frac{\pi k a}{L+1} \right) \sin \left( \frac{\pi k b}{L+1} \right) \equiv Q_{ab}, \quad (69)$$

$$\langle p_a p_b \rangle_\beta = \frac{1}{L+1} \sum_{k=1}^L M \omega_k \cosh \left( \frac{\omega_k}{2T} \right) \sin \left( \frac{\pi k a}{L+1} \right) \sin \left( \frac{\pi k b}{L+1} \right) \equiv P_{ab}. \quad (70)$$

As anticipated, in these correlators we can set $\omega = 0$, while in the case of periodic boundary conditions the correlator $\langle q_a q_b \rangle$ diverges when $\omega \to 0$.

From the correlators (69) and (70), the logarithmic negativity for any subsystem $A$ of the harmonic chains can be computed following well established methods [8, 28, 29]. Indeed the partial transposition changes the sign of all the momenta corresponding to the subsystem $A$. Thus we consider the matrix $\Gamma \equiv \mathbf{R}_A \cdot \mathbf{P} \cdot \mathbf{R}_A$, being $\mathbf{P}$ the matrix for the momenta (70) and $\mathbf{R}_A$ the $L \times L$ diagonal matrix having $-1$ in correspondence of the sites defining $A$ and $+1$ for the remaining ones. Then, denoting by $\lambda_j^2$ the eigenvalues of $Q \cdot \mathbf{P}^\dagger$, the trace norm of the partial transpose and the negativity are given by

$$\| \rho^T_A \| = \prod_{j=1}^L \left| \lambda_j + \frac{1}{2} \right| - \left| \lambda_j - \frac{1}{2} \right|^{-1}$$

$$= \prod_{j=1}^L \max \left[ 1, \frac{1}{2\lambda_j} \right], \quad \Rightarrow \quad \mathcal{E}_A = \ln \left( \| \rho^T_A \| \right). \quad (71)$$

Thus the computation of $\mathcal{E}_A$ requires the diagonalization of a $L \times L$ matrix preventing us from taking the thermodynamic limit $L \to \infty$, as it is instead straightforwardly done for the entanglement entropy.

In the left panel of figure 3 we report the logarithmic negativity $\mathcal{E}$ at temperature $T$ for a subsystem composed by the first $\ell$ sites embedded in a finite chain of length $L$. The parameters in the Hamiltonian (67) have been fixed to $M = K = 1$ and we only consider the critical chain with $\omega = 0$. A first peculiar feature evident from this figure is that the logarithmic negativity becomes zero for $T > T_{sd}$. This is a well known phenomenon called sudden death entanglement (which has been first found in a different context [71]). As already discussed for the zero temperature large distance negativity [18], the sudden death of entanglement is due to the lattice nature of the system and it is absent in a QFT. Indeed, if one restores the lattice spacing $a$ in the above equations, it can be shown that $T_{sd} \propto a^{-1}$ [8].

Thus, in order to cleanly see the CFT scaling regime, we should limit to consider a regime of temperature in which the lattice effects did not take place yet, i.e. $T \ll a^{-1}$. A zoom for these value of temperatures is shown in the right panel of figure 3. In this figure we also subtracted to the negativity its zero temperature value, i.e. we consider the quantity $\mathcal{E}_\ell(T)$ in equation (45), which, from CFT, we expect to be a function of the scaling variable $\pi T$. Thus all data at different $\ell$ and $T$ should collapse on the same curve given by equation (66), i.e.
This is however not the case for the data in the right panel of figure 3. The origin of this discrepancy is easily understood and can be traced back to the fact that we are studying finite chains of length $L$. Although, we always consider the regime $\ell \ll L$, the temperature is slowly increased starting from 0. Therefore, there is an interval of temperatures in which $\beta$ is greater than $L$ and so the system behaves such as it was effectively at zero temperature since the finiteness of the imaginary time direction is less important than the finiteness in real space. And in fact, it is rather evident from the right panel of figure 3 that the negativity is practically constant for very small temperatures. At a closer look, it should be also clear that $\mathcal{E}_s$ starts decreasing when $T > 1/L$. In order to exactly take into account this finite size effect within CFT, we should consider the theory on an annulus, which, as stressed in section 4.4, is still beyond our possibilities. However, we can quantitatively describe this phenomenon as follows. We can introduce a threshold temperature $T_{\text{th}}$ which coincides with the point where the negativity moves from its zero temperature value. We can then consider

$$\mathcal{E}_s(T) = \frac{c}{4} \ln \left( \frac{2\pi T}{\ell} \right) - \frac{c\pi T}{2} + f_{\text{bdy}} \left( e^{-\pi T} \right).$$

(72)

This is however not the case for the data in the right panel of figure 3.

Figure 3. Logarithmic negativity $\mathcal{E}$ for a subsystem composed of $\ell$ contiguous sites embedded in a critical harmonic chain of length $L$ with Dirichlet boundary condition. Left: $\mathcal{E}$ for a large range of $\ell T$. For all finite $\ell$, $\mathcal{E}$ vanishes for $T \geq T_{\text{th}}(\ell, L)$ (sudden death). Right: subtracted negativity $\mathcal{E}_s \equiv \mathcal{E}(T) - \mathcal{E}(0)$ for small values of $\ell T$, i.e. for $T \ll T_{\text{th}}$.

Figure 4. Subtracted logarithmic negativity $\mathcal{E}_s(T) \equiv \mathcal{E}(T) - \mathcal{E}(0)$ as in figure 3. After shifting the temperature by $1/(2L)$, the data collapse on a master curve for temperatures smaller than those when finite size effects become important. Notice that the shift $1/(2L)$ vanishes in the thermodynamic limit.
the negativity as function of $T-T_L$. It is evident from the figure that $T_L \propto L^{-1}$, but we can also exactly guess the pre-factor from the following heuristic reasoning. On the annulus, we expect the negativity to be a function of $\pi \ell T^2$ (as in equation (66) for infinite system) and of $\pi \ell L$ (as in finite size at $T=0$). Thus $T_L$ should be $T_L = 1/(2L)$. The results for the subtracted negativity plotted as function of $\pi \ell (T - T_L) = \pi \ell (T - 1/(2L))$ are reported in figure 4. In this final plot we see that all the curves collapse on a single universal function for $\pi \ell T < 2$ (when we expect to be in the CFT scaling regime). It is important to stress that the shift $T_L = 1/(2L) \to 0$ as $L \to \infty$.

6. Conclusions

In this paper we have studied the QFT approach to the logarithmic negativity of a finite interval embedded in an infinite one dimensional system at finite temperature. We have focused on conformal invariant field theories. We have first shown that the replica limit of the twist field correlation function $\langle T^2_n(0) T^2_n(\ell) \rangle_\beta$ in a cylindrical geometry provides a wrong result. The reason for the failure of this naive approach has been identified in the lack of decoupling of the sheets composing the appropriate Riemann surface, as pictorially depicted in figure 1.

The correct result for the negativity can be obtained by considering the four-point function of twist fields

$$\langle T_a(-L)T^2_a(-\ell)L T^2_n(0)T_a(L) \rangle_\beta,$$

(73)

where two auxiliary fields are inserted at $w = \pm L$. From this correlation function, the negativity is obtained by first taking the replica limit and only after taking $L \to \infty$. In this way, we find that the logarithmic negativity of a finite interval of length $\ell$ in an infinite CFT is given by

$$\mathcal{E} = \frac{c}{2} \ln \left( \frac{\beta}{\pi \alpha} \sinh \left( \frac{\pi \ell}{\beta} \right) \right) - \frac{\pi c \ell}{2 \beta} + f \left( e^{-2\pi \ell/\beta} \right) + 2 \ln c_{1/2},$$

(74)

where $f(x)$ is a universal scaling function, depending on the full operator content of the theory, such that $f(0) = 0$ and $f(1) = \text{const}$. The main feature of this results are:

- The naive approach based on the calculation of $\langle T^2_n(0) T^2_n(\ell) \rangle_\beta$ provides only the first term in equation (74). For large temperature and at fixed $\ell$, this first term diverges linearly in $T = \beta^{-1}$ which is clearly an unphysical result. This divergence is canceled by the second term in equation (74).
- The finite temperature negativity depends on the full operator content of the theory and not only on the central charge, as opposite to the finite temperature entanglement entropy.
- The above formula suggests that the vanishing of the negativity at very high temperature is governed by some non-universal physics since it happens for $\beta \gg a$.
- The quantity $\mathcal{E}(T) = \mathcal{E}(T) - \mathcal{E}(0)$ is a universal function of $\ell T$ and does not depend on the UV physics encoded in the inverse cutoff $a$.
- In the limit of low temperature a universal expansion can be constructed by means of the short length expansion developed in [46]. In this expansion, the stress-energy tensor contributes to first naive piece (quite naturally since it only depends on the central charge), while the other operators are responsible of the non trivial function $f(x)$. 
In the case of a CFT on the semi-infinite line, we found that the negativity of an interval starting from the boundary also has the universal scaling form

$$\mathcal{E} = \frac{c}{4} \ln \left( \frac{\beta}{\pi a} \sinh \left( \frac{2\pi \ell}{\beta} \right) \right) - \frac{\pi c \ell}{2\beta} + f_{\text{bdy}} \left( e^{-4\pi \ell/\beta} \right) + 2 \ln \tilde{c}_{1/2}, \quad (75)$$

in which the interpretation of the various terms is analogous to the case of an infinite system. We have checked this last universal scaling against exact numerical computations for the critical harmonic chain.

There are a large number of open questions which surely deserve further investigation. The main open problem concerns the determination of the scaling function $f(e^{-2\pi \ell/\beta})$ at least for the simplest CFTs, but this is a very difficult task because it requires the calculation of a six-point function of twist fields, fusing two pairs of them, and taking the replica limit. At the moment this looks like an impossible mission, unless one finds a way to shortcut the procedure sketched above. A more affordable problem is to systematically build the low temperature expansion of equation (73) for a specific CFTs such as for the free compactified boson. This expansion could shed some light on the general structure of the universal function $F_{\beta}(x)$ in which we are interested. However, some non-perturbative terms (in $T$) are expected to play a crucial role (as it happens at $T = 0$ [17, 18]) in order to obtain the full scaling of equation (73) reported equation (41), in which the term $x^{-\Delta_{(2)}}$ is clearly non perturbative in $T$ for $x \to e^{-2\pi T}$.

Acknowledgments

We are grateful to Benjamin Doyon for very useful discussions and for informing us about his work [26] before publication. This work was supported by the ERC under Starting Grant 279391 EDEQS (PC).

Note added in proof. After the completion of this work, we became aware that some of the results derived here have been independently found in a different way by B Doyon and M Hoogeveen [26].
