Equal column sum and equal row sum dimension group realizations

Abstract Motivated by connections between minimal actions, especially Tplitz, on Cantor sets, and dimension groups, we find realizations of classes of dimension groups as limits of primitive matrices all of which have equal column sums, or equal row sums.

David Handelman

All groups are abelian, free means free as an abelian group, all partially ordered groups are unperforated and torsion-free. Equivalence classes representing elements of the direct limit, \( \lim A_n : F_n \to F_{n+1} \) are expressed as \([v,n]\), where \(v\) belongs to the \(n\)th free abelian group.

Suppose \(U\) is a noncyclic subgroup of the rationals, and let \(\tau : G \to U \subset \mathbb{R}\) be an onto group homomorphism from a torsion-free group \(G\) to \(U\). We may impose an ordered group structure on \(G\) simply by declaring \(g \in G^+ \setminus \{0\}\) iff \(\tau(g) > 0\). This makes \(G\) into a simple dimension group with unique trace, and the trace is rational-valued; all such simple dimension groups are constructed in this manner. That is, \(G\) is an extension (in the category of abelian groups) of a torsion-free abelian group \(\ker \tau\) by the subgroup \(U\) of the rationals.

As \(G\) is a countable dimension group, by [EHS], it has a representation as ordered groups, \(G \cong \lim A_n : \mathbb{Z}^{f(n)} \to \mathbb{Z}^{f(n+1)}\) where \(f : \mathbb{N} \to \mathbb{N}\) is a function, we take the usual coordinatewise ordering on each \(\mathbb{Z}^{f(n)}\) and impose the usual direct limit ordering. The \(A_n\) have only nonnegative entries (and, by telescoping, can be made strictly positive when \(G\) is simple). However, [EHS] does not give specific representations, that is, the matrices \(A_n\) cannot be constructed from the argument, except by extremely complicated machinations. Here we consider the case that \(G\) be of rank \(k+1\) (so \(\ker \tau\) is rank \(k\)), and provide explicit realizations for \(G\) with the ECS property (equal column sums: each of the nonnegative (or strictly positive) matrices \(A_n\) has all of its column sums equal).

With an ECS realization, there is a canonical choice of trace, namely (up to scalar multiple), the sequence of normalized multiples of constant rows; in this case, we say the trace has an ECS realization. We show that for general dimension groups with order unit, a trace admits an ECS realization iff it is faithful, rational-valued, and good (in the sense of Akin, after translation to dimension groups as in [BeH]). In this case, there is no control on the matrix sizes, but we do not require simplicity.

When we take the transposes of the matrices used for ECS realizations, and thus obtain ERS—equal row sum—realizations, the resulting dimension groups run over all possible simple dimension groups of finite rank with unique trace (not generally rational-valued) which could admit an ERS realization. These are very closely related to Tplitz systems (pairs \((X,T)\) consisting of a Cantor set and a minimal self-homeomorphism, which is an almost everywhere one-to-one extension of an odometer), as explained to me by Chris Skau, whose question about ERS realizations motivated this paper.

An ERS realization of a simple dimension group \(G\) with respect to a (noncyclic rank one subgroup) \(H\) such that \(\tau(H) \neq 0\) and \(G/H\) is torsion-free is an ordered group isomorphism \(\phi : G \to \lim A_n : \mathbb{Z}^{f(n)} \to \mathbb{Z}^{f(n+1)}\) where \(f : \mathbb{N} \to \mathbb{N}\) is some function, \(A_n\) are nonnegative integer matrices each having equal row sums, the direct limit ordering is imposed, such that \(\phi(H) = \cup_n [1_{f(n)}, n] \mathbb{Z}\), with \(1_{f(n)}\) the column consisting of ones. If \(f(n) = s\) for all \(n\), the realization is of size \(s\).

If \(G\) and \(H\) are as in the previous paragraph, and there exists an ERS realization of \(G\) with respect to \(H\) that is also ECS, then we refer to this as an ECRS realization of \(G\) with respect to \(H\).

1 Supported in part by an NSERC Discovery Grant.
We establish following results on ECS, ERS, and ECRS realizations.

Let \( G \) be a dimension group.

(i) If \( G \) is simple, of rank \( k + 1 \) with unique trace \( \tau \), and \( \tau(G) \) is a subgroup of the rationals, then there exists an ECS realization of \( G \) of size \( k + 2 \). (Theorem 4.1)

(ii) Let \( \tau \) be a trace on \( G \) with \( \tau(G) \subseteq \mathbb{Q} \). Then there exists an ECS realization of \( G \) representing \( \tau \) if and only if \( \tau \) is good (in the sense of Akin, as translated to the dimension group setting [BeH]) and faithful (that is, \( \ker \tau \cap G^+ = \{0\} \)). (Theorem 6.1(b))

(iii) Suppose \( G \) is simple and has unique trace \( \tau \), and \( H \) is a noncyclic rank one subgroup of \( G \) such that \( \tau(H) \neq 0 \) and \( G/H \) is torsion-free.

(a) If \( \text{rank } G = k + 1 \), then there exists a size \( k + 2 \) ERS realization of \( G \) with respect to \( H \). (Theorem 7.1(a))

(b) There exists an ERS realization of \( G \) with respect to \( H \). (Theorem 7.1(b))

(iv) Suppose \( G \) is as in (iii), and in addition, \( \tau(G) \subseteq \mathbb{Q} \).

(a) If \( \tau(G) \) has no primes of infinite multiplicity (that is, \( \tau(G) \) is not \( p \)-divisible for any prime \( p \)), then \( G \) admits an ECRS realization with respect to \( H \) if and only if \( \lambda := |\tau(G)/\tau(H)| \geq \text{rank } G \); when \( \lambda < \infty \), there is an ECRS realization of size \( \lambda \) but none of other sizes. (Theorem 11.9)

(b) If \( \tau(G) \) has a prime of infinite multiplicity (that is, \( \tau(G) \) is \( p \)-divisible for some prime \( p \)), then \( G \) admits an ECRS realization with respect to \( H \); this can be constructed to be bounded if \( |\tau(G)/\tau(H)| < \infty \). (Theorem 11.13)

Part (ii) above applies to all dimension groups (with an order unit), but the other parts require simplicity and unique trace.

Much of the time, we work in the category of abelian groups with group homomorphism to the reals: a torsion-free abelian group \( G \) together with a group homomorphism \( t : G \rightarrow \mathbb{R} \) such that \( t(G) \) is dense in \( \mathbb{R} \); we denote this \((G,t)\). Isomorphism in this category is the obvious one, \((G,t) \simeq (G',t')\) if there exists a group isomorphism \( \phi : G \rightarrow G' \) such that \( t'\phi \) is a nonzero scalar multiple of \( t \). Automatically, this induces an isomorphism \( \ker t \simeq \ker t' \).

Suppose that \( G \) and \( G' \) are noncyclic simple dimension groups with unique trace, \( \tau \) and \( \tau' \) respectively. Then \( G \simeq G' \) as ordered groups if and only if \((G,\tau) \simeq (G',\tau')\) as abelian groups with real-valued group homomorphism. One way is trivial. Conversely, suppose \( \phi : G \rightarrow G' \) is a group isomorphism such that \( \tau'\phi = \lambda \tau \) for some nonzero real \( \lambda \). By replacing \( \phi \) by \(-\phi\) if necessary, we may assume \( \lambda > 0 \). Then \( \phi \) is an isomorphism of ordered groups.

To see this, we note that \( g \in G^+ \setminus \{0\} \) if \( \tau(g) > 0 \); this is equivalent to \( \tau'(\phi(g)) > 0 \), which is equivalent to \( \phi(g) \in (G')^+ \setminus \{0\} \). As \( \phi \) is a group isomorphism, this says both \( \phi \) and \( \phi^{-1} \) are order preserving, hence \( \phi \) is an order isomorphism.

Hence to decide if two simple dimension groups with unique trace are order isomorphic, it is sufficient to find a group isomorphism between them that scales the trace(s). This makes life simple, at least when the dimension group has unique trace.

The dimension groups we will be considering for ECS realizations have an additional property, that the range of their trace is (up to nonzero scalar multiple) a subgroup of the rationals. So we consider them as groups with real-valued group homomorphism, \((G,t)\) such that \( t(G) \) is rank one and dense in \( \mathbb{R} \) (so up to scalar multiple, \( t(G) = U \subseteq \mathbb{Q} \)).

Although we will often be talking about extensions of abelian groups, \( 0 \to C \to G \to U \to 0 \), it is too restrictive to deal with the classification as extensions (that is, within \( \text{Ext}^1(C,U) \)); instead, we are dealing with the coarser classification, isomorphism for maps \( G \to U \), where we are allowed
to multiply by $\pm 1$ (and if $U$ is $p$-divisible, by powers of $p$). There are still generically uncountably many isomorphism classes of these, since $\text{Aut}(C)$ and $\text{Aut}(U)$ are usually countable.

As usual, if a group or ordered group is given as a direct limit, $\lim M_n : F_n \to F_{n+1}$ (typically, $F_n$ will be free abelian groups, and if the ordered direct limit is required, the entries of $M_n$ will be nonnegative), then elements of the direct limit can be written as equivalence classes, $[a, n]$ where $a \in F_n$, and the equivalence relation is generated by $[a, n] = [M_n a, n + 1]$.

1 Via subsemigroups

For this section, $G$ need only be a partially ordered group with positive cone $G^+$. Let $P$ denote the set of nonnegative integers. If $\{a_i\} \subseteq G^+$, we denote by $\sum a_i P$, the set of sums $\{\sum a_i n(i) \mid n(i) \in P\}$, the semigroup (or subsemigroup) generated by $\{a_i\}$.

Let $\{S_n\}_{n \in \mathbb{N}}$ be a collection of subsemigroups of $G^+$ with $S_1 \subseteq S_2 \subseteq S_3 \subseteq \ldots$ such that $G^+ = \cup S_n$. Suppose $S_n$ is generated by $\{a_i^{(n)}\}_{i=1}^{f(n)}$. Since $S_n \subseteq S_{n+1}$, we can find an $f(n+1) \times f(n)$ matrix $A_n$ (called a transition matrix) with entries from $P$ such that for all $i$,\n
\begin{equation}
(*) \quad a_i^{(n+1)} = \sum_{j=1}^{f(n+1)} (A_n)_{ij} a_j^{(n+1)};
\end{equation}

there is usually a great deal of choice available for the matrix entries, since there is no assumption of any sort of unique decomposition. Note the subscript $ji$, not $ij$.

Let $F_n = \mathbb{Z}^{f(n)}$, the free abelian group on $f(n)$ generators (denoted $e_i^{(n)}$, but when superscripted $(n)$ is understood, it is removed), equipped with the usual coordinatewise ordering. Now form the direct limit dimension group from the $A_n$s, $H = \lim A_n : F_n \to F_{n+1}$. Define $\psi_n : F_n \to G$ via $\psi_n(e_i) = a_i^{(n)}$. This is a well-defined positive group homomorphism from $F_n$ to $G$. The condition in $(*)$ is precisely what we need in order that $\psi_{n+1} \circ A_n = \psi_n$. Hence the family $\{\psi_n\}$ induces a positive group homomorphism $\Psi : H \to G$ (explicitly, $\Psi[v, n] = \psi_n(v)$ where $v \in F_n$).

Since $G^+ = \cup S_n$, $\Psi(H^+) = G^+$; if we assume $G$ is directed (as we may as well), that is, $G = G^+ - G^+$, then $\Psi$ is onto. If $\Psi$ is one to one, then it is an isomorphism of ordered groups (in particular, $G$ is a dimension group), and we have a realization for it using the matrices $A_n$. If rank $H \leq \text{rank } G < \infty$, then $\Psi$ is automatically an isomorphism (since an onto homomorphism from a torsion-free abelian group of finite rank to a torsion-free group of the same or more rank is automatically one to one), then $\Psi$ is an isomorphism.

The construction of $\Psi$ depends on the choice(s) of the generators for the semigroups $S_n$, and then on the matrices $A_n$; different choices for the matrices (even fixing the generators of all the $S_n$) can result in different $\Psi$ functions, some of which may be one to one while others need not be.

We summarize this in one gigantic statement.

**Lemma 1.1** Suppose that $G$ is a partially ordered abelian group with an increasing set of subsemigroups, $S_1 \subseteq S_2 \subseteq \ldots$ such that $G^+ = \cup S_n$, and suppose that $A_n$ is the transition matrix associated to a choice of generators for $S_n \subseteq S_{n+1}$, with each $S_n$ generated by $\{a_i^{(n)}\}$. Form the dimension group $H = \lim A_n : F_n \to F_{n+1}$.

(a) There is a unique positive group homomorphism $\Psi : H \to G$ such that $[e_i^{(n)}, n] \mapsto a_i^{(n)}$; moreover, $\Psi(H^+) = G^+$.

(b) If $\Psi$ is one to one, then it is an isomorphism of ordered abelian groups, and thus $G$ is a dimension group.
(c) If $G$ is torsion-free such that $\text{rank } H \leq \text{rank } G$ and $\text{rank } H < \infty$, then $\Psi$ is an ordered group isomorphism.

2 Realizing $G$ as ECS (free kernel that splits)

Over this and the next few sections, we deal with the simple dimension group $G$ of rank $k + 1$ having unique trace $\tau$, and in addition, $\tau(G) = U$ is a rank one (necessarily noncyclic) subgroup of the reals. For expository reasons, we proceed in three steps.

This section deals with a rather special case, that $\ker \tau$ be free of rank $k$ and the extension splits. In the next section, we drop the splitting property (but maintain freeness of the kernel); finally, we deal with the general case, wherein $\ker \tau$ is an arbitrary rank $k$ torsion-free abelian group, and the extension by $U$ is arbitrary. We could go straight to the general case, but this would have resulted in a very complicated argument. Instead, as we proceed through the cases, we find the extra complications can be dealt with in a relatively smooth manner.

Here we deal with the easiest case, $G = U \oplus \mathbb{Z}^k$ where $G^+ \setminus \{0\} = \{(u, w) \mid u > 0\}$. Although we know that $G = U \oplus \mathbb{Z}^k$ is a dimension group, and $G^+ \setminus \{0\} = \{(u, w) \mid u \in \mathbb{Q}^+ \text{ and } w \in \mathbb{Z}\}$, and thus is a limit of free abelian groups with their coordinatewise limit by [EHS], the latter does not give an explicit form. Here we obtain from a natural (but not the most natural) subsemigroups of $G^+$, an explicit realization with all the matrices being size $k + 2$ and column stochastic (all column sums equal for each matrix; this is abbreviated ECS). The following is the result of this section.

PROPOSITION 2.1 Let $G = U \oplus \mathbb{Z}^k$ where $U$ is a noncyclic subgroup of the rationals, and $G$ is the simple dimension group obtained from the map $G \to U$. Then $G$ can be realized as a direct limit (in the category of ordered abelian groups) $\lim A_n : \mathbb{Z}^{k+2} \to \mathbb{Z}^{k+2}$ where $A_n$ are primitive and ECS.

First, we find a suitable representation of $\mathbb{Z}^k$ as a union of $k + 1$ subsemigroups. For $1 \leq i \leq k$, let $\epsilon_i$ denote the standard basis vector of $\mathbb{Z}^k$, and set $\epsilon_{k+1} = -\sum \epsilon_i$. Obviously $\sum_{i=1}^{k+1} \epsilon_i = 0$ and it is easy to verify that $\sum_{j=1}^{k+1} \epsilon_i P = \mathbb{Z}^k$.

Now set the supernatural number of $U$ be given. We may block (telescope) all the primes and their powers that appear, so that we have a sequence of positive integers $p_1, p_2, \ldots$, with $p_n > (k + 1)^2$ for all $n$ and $U \simeq \lim \times p_i : \mathbb{Z} \to \mathbb{Z}$. Let $q_n = \prod_{i=1}^n p_i$. Now define the elements, for $i = 0, 1, 2, \ldots, k + 1$,

$$a_i^{(n)} = \begin{cases} \left( \frac{1}{q_n}, 0 \right) & \text{if } i = 0 \\ \left( \frac{1}{q_n}, \epsilon_i \right) & \text{if } 1 \leq i \leq k + 1 \end{cases}$$

Set $S_n = \sum_{i=0}^{k+1} a_i^{(n)} P$, so that $f(n)$ is constant in $n$ with value $k + 2$. Now we can write (in lots of different ways) $a_i^{(n)}$ as a nonnegative linear combination of the $a_i^{(n+1)}$, for example, $a_0^{(n)} = p_{n+1} a_0^{(n+1)}$ and $a_i^{(n)} = \sum_{j \neq 0,2} a_j^{(n+1)} + 2a_i^{(n+1)} + (p_{n+1} - k - 1)a_0^{(n+1)}$ (this exploits the facts that $\sum_{i=1}^{k+1} \epsilon_i = 0$ and $p_{n+1} > k + 1$; in fact, we assumed $p_{n+1} > (k + 1)^2$ which we will need later). This yields that $S_n \subseteq S_{n+1}$; the matrices resulting from these representations are not suitable for our purposes, as the resulting map $\Psi$ is not one to one.

It is elementary that $G^+ = \cup S_n$; an arbitrary element of $G^+$ is of the form $x = (b/q_n, v)$ where $b$ is a positive integer and $v \in \mathbb{Z}^k$. Let $d$ be the maximum absolute value of the coordinates of $v$ (as an element of $\mathbb{Z}^k$, i.e., the usual coordinates), and find $l$ so that $p_{n+1} p_{n+2} \cdots p_{n+l} > (k+1)d(b+1)$. We can find positive integers $r(1), r(2), \ldots, r(k+1)$ with $\sum_{i=1}^{k+1} r(i) \epsilon_i = v$ such that $\sum r(i) < d(k+1)$. Then

$$\left( \frac{b}{q_n}, v \right) = \sum_{i=1}^{k+1} r(i) \left( \frac{1}{q_{n+l}}, \epsilon_i \right) + \left( b(p_{n+1} \cdot p_{n+2} \cdots p_{n+l}) - \sum_{i=1}^{k} r(i) \right) \left( \frac{1}{q_{n+l}}, 0 \right)$$
expresses \( x \) as an element of \( S_{n+1} \).

Now we make a very particular choice of the transition matrices, \( A_n \); not only do they have to satisfy (*), but they have to be rank \( k + 1 \) (or less, but strictly less is not possible, except for finitely many \( n \)). Since the matrices are all square of size \( k + 2 \), the rank condition turns out to be not so onerous, especially since imposing the obvious constraint on the trace will force the rank condition to apply.

Temporarily drop the subscript \( n \) on some of the variables, so we will obtain a matrix \( A \) whose large eigenvalue is \( p \) (corresponding to \( p_n \)); we insist that \( p > (k + 1)^2 \). We write,

\[
\begin{align*}
a_0^{(n)} &= (p - k - 1)a_0^{(n+1)} + \sum_{i=1}^{k+1} a_i^{(n+1)} \\
a_i^{(n)} &= (p - 1)a_0^{(n+1)} + a_i^{(n+1)} \text{ for } 1 \leq i \leq k \\
a_{k+1}^{(n)} &= (p - k^2 - k - 1)a_0^{(n+1)} + \sum_{i=1}^{k} ka_i^{(n+1)} + (k + 1)a_{k+1}^{(n+1)}.
\end{align*}
\]

These relations are trivially verified by using \( \sum_{i=1}^{k+1} \epsilon_i = 0 \). The corresponding matrix (we act from the left, so each equation gives rise to a column), is rather simple to describe (but really tedious to \( \text{TeX} \)). There is a \( k \times k \) identity matrix occupying most of the space.

\[
A = \begin{bmatrix}
p - k - 1 & p - 1 & p - 1 & p - 1 & \cdots & p - 1 & p - 1 & p - k^2 - k - 1 \\
1 & 1 & 1 & \cdots & I_k & \cdots \\
1 & 1 & \cdots & I_k \\
1 & \cdots & I_k \\
1 & 0 & 0 & 0 & \cdots & 0 & 0 & k + 1
\end{bmatrix}.
\]

A consequence of the equations is that the column sums are all \( p \). If we sum all but the first column, the result is \( k + 1 \) times the first column (as follows from \( p - k^2 - k - 1 + k(p - 1) = (k + 1)(p - k - 1) \)). Hence rank \( A < k + 2 \), that is, rank \( A \leq k + 1 \).

Now restore the subscript \( n \); we obtain square matrices \( A_n \) of size \( k + 2 \) with nonnegative entries, such that rank \( A_n \leq k + 1 \), each with large eigenvalue \( p_n \) (this latter is not needed now). Then the rank of \( H = \lim A_n : \mathbb{Z}^{k+2} \to \mathbb{Z}^{k+2} \) is at most \( \inf \text{rank } A_n \leq k + 1 \), and so the positive map \( \Psi : H \to G \) obtained from this sequence of relations is an isomorphism of ordered groups. This yields an ECS realization of \( G \).

\[ \star \]

# 3 Arbitrary extensions by free abelian groups

Now we try to find explicit realizations of dimension groups \( G \) that are given as arbitrary extensions of \( \mathbb{Z}^k \) by \( U \) a subgroup of the rationals. Explicitly, we have a short exact sequence of abelian groups \( 0 \to \mathbb{Z}^k \to G \to U \to 0 \); regarding \( U \) as a subgroup of the reals, the quotient map \( \tau : G \to U \) yields the ordering; for nonzero \( g \) in \( G \), \( g \in G^+ \) iff \( \tau(g) > 0 \). This describes all dimension groups with unique trace, whose values lie in the rationals, and whose kernel is free abelian of finite rank. The previous constructions of course dealt with the case wherein \( \tau \) is split.

**PROPOSITION 3.1** Let \( G \) be a noncyclic simple dimension group with unique trace \( t \) such that \( t(G) := U \) is a subgroup of the rationals, and such that \( \ker t \) is free of rank \( k \). Then \( G \) admits an ECS realization by primitive matrices of size \( k + 2 \).
Given the data \((G, \tau, U, \ker \tau)\) we can construct semigroups \(S_n \subseteq S_{n+1} \subseteq \ldots \) of \(G^+\) with the property that \(G^+ = \cup S_n\). To begin with, write \(U = \lim_p \times p_n : \mathbb{Z} \to \mathbb{Z}\); form \(q_n = \prod_{i=1}^n p_i\), and make an initial selection, one for each \(n\), of \(g_n \in \tau^{-1}(1/q_n)\). Then \(g_n - p_{n+1}g_{n+1} \in \ker \tau\), so we can write \(g_n = p_{n+1}g_{n+1} + v^n\) for unique \(v^n \in \ker \tau = \mathbb{Z}^k\) (obviously, \(v^n\) depends on the selection of the sequence \((g_n)\). The sequence \((v_n, p_{n+1})\) determines the isomorphism class of \(G\), but by itself, this is not that useful.

The obvious candidate for the subsemigroup \(S_n\) is the semigroup generated by
\[
\{g_n, g_n + \epsilon_1, \ldots, g_n + \epsilon_k; g_n + \epsilon_{k+1}\},
\]
where \(\epsilon_i\) have their usual meaning: standard basis elements if \(i < k + 1\) and \(\epsilon_{k+1} = -\sum_{j=1}^k \epsilon_j\); it is convenient to define \(\epsilon_0 = 0\), so we can write \(S_n = \sum_{i=0}^{k+1} (g_n + \epsilon_i)P\). Unfortunately, there is no guarantee that \(S_n \subseteq S_{n+1}\) (in other words, that the matrix entries be nonnegative), largely because at this stage, we have no control over \(v^n\).

The idea is to make a better choice of \(g_n\), and then a telescoping (amounting to telescoping the \(p_n\)), and if we are careful, we will obtain \(S_n \subseteq S_{n+1}\) for all \(n\), and the corresponding transition matrices can be written down; in fact, we will write down the transition matrices, verify the entries are all nonnegative, from which it follows that the \(S_n\) are increasing.

Let us see what we need to obtain this; we will write down the relations between the generators, and hope for the best. Fix \(n\) and order \((g_n + \epsilon_i)\) according to the subscript of the \(\epsilon_i\), with \(0 \leq i \leq k + 1\). The relations are given by \(g_n + \epsilon_i = \sum_j A_{ji}(g_{n+1} + \epsilon_j)\), where \(A_{ji}\) are integers, hopefully nonnegative, and this forces various equations.

Since \(\tau(g_n + \epsilon_i)\) are all equal to \(1/q_n = p_{n+1}/q_{n+1}\) and \(\tau(g_{n+1} + \epsilon_i) = 1/q_{n+1}\), we deduce that for all \(j\), \(\sum_i A_{ji} = p_{n+1}\), that is, the row sums of \(A^T\) are all \(p_{n+1}\), so that the column sums of \(A\) are all \(p_{n+1}\). (This is a useful way of calibrating the matrix—I am always confused as to whether it should be \(A\) or \(A^T\), and keeping in mind that the column sums must be equal determines which it is.)

Now fix \(i\); we have the equation, \(g_n + \epsilon_i = p_{n+1}g_{n+1} + \sum_j A_{ji}\epsilon_j\). Using \(g_n = p_{n+1}g_{n+1} + v^n\), we have, for all \(i = 0, 1, \ldots, k + 1\) (suppressing the subscript \(n\) on \(A_n\), as otherwise it gets too crowded),
\[
v^n + \epsilon_i = \sum_{j=0}^{k+1} A_{ji}\epsilon_j.
\]
When \(i = 0\) (so \(\epsilon_i = 0\)), we obtain
\[
A_{j,0} - A_{k+1,0} = (v^n)_j \quad \text{if } j > 0
\]
\[
A_{00} = p_{n+1} - \sum_{i>0} A_{i,0} = p_n - (k+1)A_{k+1,0} - \sum_{i=1}^k (v^n)_i.
\]
Already we see a problem; the coefficients are suppose to be nonnegative, and so we require \(p_n \geq (k+1)A_{k+1,0} + \sum_{i} (v^n)_i\) with \(A_{k+1,0} \geq 0\) (we have no control then the sum of the coefficients of \(v^n\)). Anyway, we continue; for \(1 \leq i \leq k\),
\[
A_{i,i} = A_{k+1,i} + (v^n)_i + 1
\]
\[
A_{j,i} = A_{k+1,i} + (v^n)_j \quad \text{if } j \neq i \text{ and } 1 \leq j \leq k
\]
\[
A_{0,i} = p_{n+1} = \sum_{j=1}^{k+1} A_{j,i} = p_{n+1} - (k+1)A_{k+1,i} - \sum_{i=1}^k (v^n)_i - 1.
\]
Finally, with \( i = k + 1 \),

\[
A_{j,k+1} = A_{k+1,k+1} + (v^n)_j - 1 \quad \text{if } k + 1 > j > 0
\]

\[
A_{0,k+1} = p_{n+1} - \sum_{i>0} A_{i,k+1} = p_n - (k+1)A_{k+1,k+1} - \sum_{i=1}^k (v^n)_i - k.
\]

Now set \( a_i = A_{k+1,i} \) (obviously this depends on \( n \), but for now we suppress the sub superscript); then all the entries are linear in the choice of \( a_i \). If the entries do happen to be nonnegative, then the resulting matrix \( A_n = (A_{ij}) \) (order of the subscripts reversed) will implement the embedding \( S_n \subseteq S_{n+1} \). The resulting matrix is similar to the preceding ones, in that the interior \( k \times k \) matrix is \( v \cdot 1^T + 1 \cdot (a_1, \ldots, a_k) + 1_k \) where \( 1 \) is the column of size \( k \) consisting of ones, we regard \( v \) as a column, and \( \cdot \) represents the usual product of matrices. Notice that \( v \cdot 1^T \) is \( k \times k \) but \( v^T 1 \) is just the sum of the coefficients of \( v \), \( \sum_{i=1}^k (v^n)_i \). We sometimes suppress the sub superscripts \( n \) or \( n + 1 \) in \( v^n \) and \( p_{n+1} \), and the implicit superscripts in \( a_i^{(n)} \).

\[
(1)
A_n = \begin{pmatrix}
p_{n+1} - (v^n)^T 1 - (k + 1) a_0 & (p_n - (v^n)^T 1)(a_1, a_2, \ldots, a_k) & v^n & v^n + (a_{k+1} - 1) 1 \\
v^n + a_0 1 & a_0 & v^n T 1 & a_1, a_2, \ldots, a_k \\
a_0 & v^n T 1 & a_1, a_2, \ldots, a_k & a_{k+1}
\end{pmatrix}
\]

where the \((0,k+1)\) entry (the upper right; left blank, because of overflow) is \( p_{n+1} - v^T 1 - (k+1)a_0 + k \). The column sums are all \( p_{n+1} \), as follows from the choice of generators of the subsemigroups. Without yet worrying about positivity or rank, we can calculate the eigenvalues and their geometric multiplicities, by explicitly computing the left eigenvectors.

First, \( 1^T_{k+2} \) is the left eigenvector for \( p \). Next, define \( v := \{ w \in \mathbb{Z}^{1 \times k} \mid wv = 0 \} \) (we use \( \mathbb{Z}^n \) to mean \( \mathbb{Z}^{\times 1} \), that is, the default is columns). For each \( u \in v \), the row of size \( k + 2 \), \((0, u, -u^T 1)\), is a left eigenvector for the eigenvalue 1. If \( u \neq 0 \) (as we are assuming implicitly anyway), then \( v \) is rank \( k - 1 \), and thus even the geometric multiplicity of 1 is at least \( k - 1 \).

This leaves two eigenvalues. We may find \( u_0 \in \mathbb{Q}^{1 \times k} \) such that \( u_0v = 1 - p + v^T 1_k \); then \((1, u_0, k + 1 - u_0 1_k) \) is another left eigenvector for the eigenvalue 1 (we may multiply by an integer and so obtain an integer eigenvector if desired), and since its first coordinate is not zero, it is not in the \( \mathbb{R} \)-span of the previous eigenvectors for 1; hence the multiplicity of 1 is at least \( k \).

There is one remaining eigenvalue, in addition to \( p, 1^k \), and it is easily determined from the trace; the trace of the matrix is \( p + k + \sum_{i=1}^{k+1} a_i - (k+1)a_0 \), hence the last remaining eigenvalue is \( \sum_{i=1}^{k+1} a_i - (k+1)a_0 \). Since we want the rank of the matrix to be \( k + 1 \), we are free to choose any selection of integers \( a_i \) such that \( \sum_{i=1}^{k+1} a_i = (k+1)a_0 \) (that is, \( a_0 \) is the average of all the others). When this is imposed, we see quickly that the corresponding relation holds for the columns, that is, the sum of all but the first column is \( k + 1 \) times the first. In other words, if we set \( z = (k + 1, -1, -1, \ldots, -1)^T \in \mathbb{Z}^{k+2} \), then \( Az = 0 \). Moreover, \( z \) is independent of the choice of \( n \) (that is, \( A_n z = 0 \) for all \( n \)).

A particular consequence is that \( W := \perp_z = \{ w \in \mathbb{Z}^{1 \times (k+2)} \mid wz = 0 \} \) is a common \( A_n \)-invariant subgroup (on the left, of course, meaning \( WA_n \subseteq W \) for all \( n \)); moreover, the eigenvalues of \( A_n \) restricted to this subgroup are exactly \( p, 1^k \) (the zero eigenvector has conveniently been eliminated, since \( z \) spans, as a real vector space, the right zero-eigenspace of all the \( A_n \)).

Now we modify the sequence \( (a_n) \) and corresponding \( (v^n) \) to permit a selection of integers \( a_i, n \) (and with \( \sum_{i=1}^{k+1} a_i = (k+1)a_0 \) so that the matrix \( A_n \) has only nonnegative entries.

Let \( G \) be given by the sequence \( (p_{n+1}, v^n) \). Let \( E \in \text{GL}(k, \mathbb{Z}) \) and \( W \in \mathbb{Z}^k \); then the group extension given by the sequence \( (p_{n+1}, Ev^n + (p_{n+1} - 1)W) \) is equivalent. To see this, form the
square matrices of size \( k + 1 \), \( A_n = \begin{pmatrix} p_{n+1} & 0 \\ v^n & 1_k \end{pmatrix} \) and \( F = \begin{pmatrix} 1 & 0 \\ W & E \end{pmatrix} \). Then \( F^{-1} = \begin{pmatrix} 1 & 0 \\ -E^{-1}W & E^{-1} \end{pmatrix} \), and

\[
D_n := FA_nF^{-1} = \begin{pmatrix} Ev^n + (p_{n+1} - 1)W & 0 \\ \vdots & \vdots \end{pmatrix}.
\]

Now \( G \simeq \lim A_n : \mathbb{Z}^{k+1} \to \mathbb{Z}^{k+1} \) as abelian groups, and the map on each copy of \( \mathbb{Z}^{k+1} \) given by \( F \) induces a group isomorphism from \( G \) to \( G' := \lim D_n : \mathbb{Z}^{k+1} \to \mathbb{Z}^{k+1} \). The corresponding data for the sequence of \( D_n \)'s is

\[
(p_{n+1}, Ev^n + (p_{n+1} - 1)W)
\]

and these maps preserve the map to \( U \). Of course the drawback with this equivalence relation is that it applies to all the \( v^n \)'s at once.

**LEMMA 3.2** Suppose \( V \in (\mathbb{R}^+)^k \). There exist \( E \in \text{GL}(k, \mathbb{Z}) \) and \( W \in \mathbb{Z}^k \) such that the coefficients of \( EV - W \) are all nonnegative, and sum to less than one.

**Proof.** Define \( W^0 \in \mathbb{Z}^k \) via \( (W^0)_i = \lceil V_i \rceil \) (the floor function). Then \( V_0 := V - W^0 \) has all its coefficients nonnegative and strictly less than one. If either all or all but one of the entries of \( V_0 \) is zero, we are done.

Otherwise, let \( s = \max \{ V_i \} \) and \( t = \max \{ V_i \setminus \{ s \} \} \) (the notation is not very clear, but if there is a tie for maximum, then \( t = s \)). We apply the division algorithm to \( s \) and \( t \); there exists an integer \( m > 1 \) such that \( s = mt + s' \) where \( 0 \leq s' < t \); this is implemented by an elementary transformation, hence by an element of \( \text{GL}(k, \mathbb{Z}) \), and the new vector (replacing \( s \) in one its positions by the smaller \( s' \)) either has strictly smaller maximal entry, or the multiplicity of its maximal entry has been reduced. If in the resulting vector, there are still more than one entry, we can continue the process.

It is easy to see that it either terminates in a single nonzero entry (which occurs precisely when all the nonzero entries of \( V \) are rational multiples of each other), or we can make the maximal entry as small as we like, say less than \( 1/k \). Either way, we have constructed \( E \) as a product of elementary transformations (hence in \( \text{GL}(k, \mathbb{Z}) \)) such that \( E(V - W^0) \) has only nonnegative entries and whose entries sum to less than 1. Now set \( W = EW^0 \in \mathbb{Z}^k \).

**LEMMA 3.3** Suppose that the extension \( G \) of \( \mathbb{Z}^k \) by \( U \) is implementable by \( (p_{n+1}, v^n) \) such that \( v^n/p_{n+1} \) converges (in \( \mathbb{R}^k \)) and \( p_{n+1} \to \infty \). Then the corresponding dimension group \( G \) with unique trace being the map to \( U \) is realizable as a limit \( A_n : \mathbb{Z}^{k+2} \to \mathbb{Z}^{k+2} \) with \( A_n \) of the form (1) primitive.

**Proof.** Set \( V = \lim v^n/p_{n+1} \). By the preceding, there exists \( E \in \text{GL}(k, \mathbb{Z}) \) and \( W \in \mathbb{Z}^k \) such that \( EV - W \) has only nonnegative entries adding to \( \lambda \leq 1 \). Now the extension corresponding to \( (p_{n+1}, v^n) \) is equivalent to \( (p_{n+1}, (v^n)') := Ev^n - (p_{n+1} - 1)W \), so it suffices to show that \( (p_{n+1}, (v^n)') \) can be realized by a sequence of primitive matrices of the form (1).

We observe that \( (v^n)'/p_{n+1} = Ev^n/p_{n+1} - W(p_{n+1} - 1)/p_{n+1} \), and this sequence converges to \( EV - W \). Thus, given \( \epsilon < \min \{ (1 - \lambda)/3(k+1), \lambda/3k \} \), for all sufficiently large \( n \), we have

\[
-\epsilon 1 \leq (v^n)'/p_{n+1} \text{ and the sum of the entries is less than } \lambda + \epsilon.
\]

Set \( a_0 = a_1 = \cdots = a_{k+1} \) to be 1 if \( \min(v^n)'_i \geq 0 \) and equal to \( 1 - \min(v^n)'_i \) otherwise.

If \( \min(v^n)'_i \geq 0 \), then we note that from \( \sum(v^n)'_i \leq (\lambda + \epsilon)p_{n+1} \), we obtain an upper bound on the sum, \( p_{n+1} \mu \), where \( \mu = 1 - (1 - \lambda)(1 - 1/3k) \) (what is important is that the coefficient is bounded above away from one, uniformly in sufficiently large \( n \)). Then \( p_{n+1} - \sum(v^n)'_i - (k+1) - 1 \geq p_{n+1}(1 - \mu) - (k+2) \). Since \( p_{n+1} \to \infty \), for all further sufficiently large \( n \), this expression is positive; thus the matrix \( A_n \) in (1) has only nonnegative entries.
If \( \min(v^n)_i' < 0 \), then for any \( j \),

\[
p_{n+1} - \sum (v^n)_i' - (k+1)a_j - 1 \geq p_{n+1} - p_{n+1}(\lambda + \epsilon) - (k+1) - (k+1)p_{n+1}\epsilon - 1
\]

\[
\geq p_{n+1}(1 - \lambda - (k+2)\epsilon) - (k+1).
\]

Now \( 1 - \lambda - (k+1)\epsilon > 1 - \lambda - (1 - \lambda)/3 = 2(1 - \lambda/3) > 0 \). Hence by further increasing \( n \), we have that for all sufficiently large \( n \), the matrix entries of \( A_n \) are nonnegative. We can always delete a finite number of the matrices at the outset. Because \( (k+1)a_0 = \sum_{i=1}^{k+1} a_i \), the rank of each \( A_n \) is \( k+1 \), so that Lemma 1.1 applies.

**LEMMA 3.4** Let \( G \) be a group extension of \( \mathbb{Z}^k \) by noncyclic \( U \subseteq \mathbb{Q} \) with data \((p_{n+1}, v^n)\). Then there is an equivalent representation, \((q_{n+1}, (v^n)'\)), such that \( q_{n+1} \) is increasing, \( q_{n+1} \to \infty \), and \((v^n)'/q_{n+1}\) converges.

**Proof.** First, we may make an initial telescoping, and thus may assume that \( p_{n+1} \) are increasing to infinity at the outset. Now we perform the following substitution transform, to ensure that the \((v^n)\) result at \( \infty \) at the outset. Because \( (k+1)a_0 = \sum_{i=1}^{k+1} a_i \), the rank of each \( A_n \) is \( k+1 \), so that Lemma 1.1 applies.

Now \( \lambda + \epsilon \), suppose we have defined this up to \( n = m - 1 \); that is, \( g_i = p_{i+1}a_{i+1} + v^i \) for \( 1 \leq i \leq m - 1 \). Now set \( g_{m+1}' = g_m + u^m \), the \( u^m \) to be determined. Then we have \( g_m = p_{m+1}a_{m+1} + v^m - p_{m+1}u^m \) (and the subsequent relations, for larger \( m \), are also affected, but we come to them by the induction argument). We can obviously choose \( u^m \in \mathbb{Z}^k \) so that all the entries of \( v^m - p_{m+1}u^m \) lie in the set \( \{0,1,2,\ldots, p_{m+1} - 1\} \). This completes the induction, and allows us to assume that the newly relabelled \( v^n \) satisfy \( 0 \leq v^n \leq (p_{n+1} - 1)1 \).

In particular, with the current notation, \( \{v^n/p_{n+1}\} \) is a bounded sequence in \([0,1]^k\). Hence there exists a subsequence indexed by \( n(i) \in \mathbb{N} \) such that \( \{v^{n(i)}/p_{n(i)+1}\} \) converges, say to \( V \in [0,1]^k \). The integers \( n(1) < n(2) < n(3) < \cdots \to \infty \) suggest a telescoping; set \( M_j = \left( \begin{array}{c} p_{j+1} \\ v^j \\ I_k \end{array} \right) \), discard the \( M_j \) for \( j < n(1) \), and define

\[ M^{n(i)} = M_{n(i)+1}^{-1} \cdots M_{n(i)+1} \cdots M_{n(i)}; \]

the upper left entry is \( g_i = \prod_{j=1}^{n(i)-n(i)} p_{n(i)+j} \), and of course the lower right \( k \times k \) is the identity matrix. The column of size \( k \) to the left of the identity is obtained by an easy induction argument. This yields (and probably better is to prove this by induction):

\[
\frac{v^{n(i)}}{q} - \frac{v^{n(i)}}{p_{n(i)+1}} \leq \sup \left\| \frac{v^j}{p_{n(i)+1}} \right\| \leq \frac{1}{p_{n(i)+2}} \left( 1 + \frac{1}{p_{n(i)+2}} + \left( \frac{1}{p_{n(i)+2}} \right)^2 + \left( \frac{1}{p_{n(i)+2}} \right)^3 + \ldots \right)
\]

\[
= \frac{1}{p_{n(i)+2}} - 1.
\]

The \( \delta \) was obtained from \( \{v^n/p_{n+1}\} \) being a bounded sequence. We have used \( p_{n+2} \geq p_{n+1} \) to convert the estimate into a geometric series. Finally, since \( p_{n+1} \to \infty \), the sequence \( \left\{ \frac{v^{n(i)}}{q} \right\} \) converges.

The previous two results yield Theorem 3.1.
4 Arbitrary extensions

In this section, we deal with arbitrary extensions of $U$ by arbitrary finite rank torsion-free abelian groups, instead of $\mathbb{Z}^k$; that is, let $C$ be a rank $k$ torsion-free abelian group, $U$ a noncyclic subgroup of the rationals, and consider extensions $0 \to C \to G \to U$. We realize the dimension group $G$ with strict ordering induced by $G \to U \subset \mathbb{R}$ as a limit of ECS matrices of size $k+2$. The arguments are rather similar to those of the previous section, but involve a couple of extra features.

Let $C = \ker t$; this has rank $k$, so we can write $C$ as a limit (as abelian groups) $B_n : \mathbb{Z}^k \to \mathbb{Z}^k$ for some choice of $B_n$ with $\det B_n \neq 0$. We can incorporate the identity as many times as we wish, say $B_1, I_{k_1}, \ldots, I_{k_k}, B_2, I_{k_1}, \ldots, I_{k_k}, B_3, \ldots$, and this gives the same abelian group (the idea is that we will be telescoping the $k+1$ size matrices, and we want to ensure that the absolute column sums of the $B_n$ are $O(p_{n+1})$). Re-indexing, we can obtain $G$ (the extension) as the abelian group direct limit arising from the square matrices of size $k+1, \begin{pmatrix} p_{n+1} & 0 \\ v_n & B_n \end{pmatrix}$, and we can assume that $\| B_n \|_{\infty, \infty} = O(\sqrt{p_{n+1}})$ (or anything reasonable).

When we realize the corresponding semigroup coming from the relations, we obtain rather similar matrices to those previously encountered. Let $\epsilon_i^n$ be the standard basis elements for $\mathbb{Z}^k$ at the $n$th level, and define $\epsilon_0^n = 0$ and $\epsilon_{k+1}^n = -\sum_{i=1}^k \epsilon_i^n$.

We can express $G$ (as an abelian group with real-valued homomorphism) as the limit, $G = \lim M_n := \left( \begin{pmatrix} p_{n+1} & 0 \\ v_n & B_n \end{pmatrix} : \mathbb{Z}^{k+1} \to \mathbb{Z}^{k+1} \right)$, where the common left eigenvector $x = (1, 0, 0, \ldots, 0)$ induces the map to $U$. Call the $n$th copy of $\mathbb{Z}^{k+1}$, $F_n$, so the elements of $G$ are the equivalence classes $[a, n] = [M_n a, n + 1]$ where $a \in F_n$, and the map to $U$ is given by $t : [a, n] \mapsto xa/p_1 \cdots p_n$. In particular, the corresponding positive cone (of the dimension group, once we put the strict ordering arising from $t$) will be $\cup t^{-1}(1/p_1 \cdots p_n)P$.

Set $g_n = [x^T := (1, 0, 0, \ldots, 0)^T, n]$; so $t(g_n) = 1/p_1 \cdots p_n$. Then $g_n - p_{n+1}g_{n+1} = [M_n x^T - x^T, n + 1]$, and this is simply the column whose top entry is 0 and the rest of which is $v^n$, which we write as $\sum_{i=1}^k v^n_i \epsilon_i^n + 1$.

Take as our generators for the positive cone at the $n$th level, $g_n + \epsilon_i^n$ (now $i = 0, 1, \ldots, k+1$ to incorporate the two extra elements required); we rewrite this as $g_n + \sum_{j=1}^k (B_n)_{ji} \epsilon_j^{n+1}$ (arising from the effect of $B_n$; note that the coefficients are transposed). From the equation $g_n = p_{n+1}g_{n+1} + \sum_{i=1}^k v^n_i \epsilon_i^{n+1}$, we want to find a $(k+2) \times (k+2)$ matrix $A^n := (A^n)_{ij}$ (for $0 \leq i, j \leq k+1$; this is not supposed to represent the $n$th power of some matrix $A$, but is merely superscripting the index the previous notation was $A_n$; we frequently drop the super/subscript $n$ for simplicity) such that for all $i$,

$$g_n + \sum_{j=1}^k (B_n)_{ji} \epsilon_j^{n+1} = \sum_{j=0}^{k+1} (A^n)_{ji}(g_{n+1} + \epsilon_j^{n+1}).$$

We are free to choose the entries of $A^n$ (subject of course to positivity constraints) so long as this set of equations holds. First, from $t(g_n + \epsilon_j^n) = 1/p_1 \cdots p_n$, the column sums of $A^n$ must all be $p_{n+1}$.

Hence we require $\sum_{j=0}^{k+1} A^n_{ji} = p_{n+1}$ for all $i$. Using the relation $g_n - p_{n+1}g_{n+1} = \sum_{i=1}^k v^n_i \epsilon_i^{n+1}$, the previous equations become

$$\sum_{j=0}^{k+1} A^n_{ji} \epsilon_j^{n+1} = \sum_{i=1}^k v^n_i \epsilon_i^{n+1} + \begin{cases} 0 & \text{if } i = 0 \\ \sum_{j=1}^k (B_n)_{ji} \epsilon_j^{n+1} & \text{if } 1 \leq i \leq k \\ -\sum_{i=1}^k \sum_{j=1}^k (B_n)_{ji} \epsilon_j^{n+1} & \text{if } i = k+1. \end{cases}$$

Restrict to the case $j > 0$ (each entry in the top row is determined by the remaining ones in its column, as the column sums are all $p_{n+1}$); taking coordinates, we obtain the following equations,
successively obtained by setting $i = 0, 1 \leq i \leq k$, and $i = k + 1$,

$$A_j = v_j + A_{k+1,0}$$
$$A_{ji} = v_j + (B_n)_{ji} + A_{k+1,j} \quad \text{for } 1 \leq i \leq k$$
$$A_{j,k+1} = v_j - \sum_{l=1}^{k} (B_n)_{jl} + A_{k+1,k+1}.$$

Set $a_i = A_{k+1,0}$ (of course, we should really write this as $a_{(i,n)} = A^k_{n+1,0}$ to indicate dependence on $n$), so we obtain these as free parameters, which determine all the rest of the entries (and $A_{0,i} = p_{n+1} - \sum_{j=1}^{k+1} A_{ji}$). The matrix $A^n$ has the following form (recalling that $1$ is the column of $1$s of size $k$). The following display is labelled (**), but because of the width, the label is not obvious.

$$A^n = \begin{pmatrix}
  p_{n+1} - v^n T - (k+1) a_0 & (p_{n+1} - v^n T) 1^T - (k+1) a_1, a_2, \ldots, a_k \\
  v^n + a_0 1 & B_n + v^n 1^T + 1 a_1, \ldots, a_k \\
  a_0 & v^n - B_n 1 + a_{k+1} 1
\end{pmatrix},$$

where the $(0, k+1)$ entry (the upper right; left blank, because of horizontal overflow) is $p_{n+1} - v^n T - (k+1) a_0 + 1^T B_n 1$. The matrix $B_n + v^n 1^T + 1 a_1, \ldots, a_k$ appearing in the middle is a $k \times k$ block. If we sum all of the columns except the leftmost, we obtain $(k+1)v^n + \left(\sum_{i=1}^{k+1} a_i\right) 1$; thus if we impose the condition $\sum_{i=1}^{k+1} a_i = (k+1) a_0$, the rank of the matrix $A^n$ is at most $k + 1$.

The only restriction to deal with is positivity. We find a telescoping of $A^n$, so we obtain these as free parameters, which determine all the rest of the entries (and $A_{0,i} = p_{n+1} - \sum_{j=1}^{k+1} A_{ji}$). The following display is labelled (**), but because of the width, the label is not obvious.

$$A^n = \begin{pmatrix}
  p_{n+1} - v^n T - (k+1) a_0 & (p_{n+1} - v^n T) 1^T - (k+1) a_1, a_2, \ldots, a_k \\
  v^n + a_0 1 & B_n + v^n 1^T + 1 a_1, \ldots, a_k \\
  a_0 & v^n - B_n 1 + a_{k+1} 1
\end{pmatrix},$$

where the $(0, k+1)$ entry (the upper right; left blank, because of horizontal overflow) is $p_{n+1} - v^n T - (k+1) a_0 + 1^T B_n 1$. The matrix $B_n + v^n 1^T + 1 a_1, \ldots, a_k$ appearing in the middle is a $k \times k$ block. If we sum all of the columns except the leftmost, we obtain $(k+1)v^n + \left(\sum_{i=1}^{k+1} a_i\right) 1$; thus if we impose the condition $\sum_{i=1}^{k+1} a_i = (k+1) a_0$, the rank of the matrix $A^n$ is at most $k + 1$.

We begin, as in the preceding case, with the original relations, $g_n = p_{n+1} g_{n+1} - v^n$. Replace $g_{n+1}$ by $g_{n+1}' = g_{n+1} + u^n$ (where $u_n$ is to be determined), so that the new relation is $g_n = p_{n+1} g_{n+1}' + v^n - p_{n+1} u^n$. We may choose $u^n$ so that $v'_n = v^n - p_{n+1} u^n$ has all its entries in $\{0, 1, 2, \ldots, p_{n+1} - 1\}$. Now the relation for $g_{n+1}'$ in terms of $g_{n+1} + u^n$ can be adjusted, and we continue by induction. Relabelling everything in sight (including the matrices $M_n$), we are now in the situation that $v^n \geq 0$ and $\|v^n\| < p_{n+1}$.

Since $\{v^n/p_{n+1}\}$ is a bounded set of $\mathbb{R}^k$, it contains a convergent subsequence, say $v^{n(i)}/p_{n(i)+1} \rightarrow V \in [0, 1]^k$. This yields an obvious telescoping; set $M^{(i)} = M_{n(i)+1} \cdot M_{n(i)+1} - \ldots - M_{n(i)+1}$ and $q_{i+1} = \prod_{j=n(i)+1}^{n(i)+1} p_j$, and $B^{(i)} = B_{n(i)+1} \cdot B_{n(i)+1} - \ldots - B_{n(i)+1}$; then $M^{(i)} = \left(\begin{smallmatrix}
  q_{i+1} & 0 \\
  v^{n(i)} & B^{(i)}
\end{smallmatrix}\right)$.

The column $v^{(i)}$ has a relatively simple expression,

$$v^{(i)} = q_{i+1} \left(\frac{v^{n(i)+1}}{p_{n(i)+1}+1} + \frac{B_{n(i)+1}-1}{p_{n(i)+1}+1} + \frac{B_{n(i)+1}-2 v^{n(i)+1}-1}{p_{n(i)+1}+1} + \ldots \right).$$

Hence

$$\frac{v^{(i)}}{q_{i+1}} - \frac{v^{n(i)+1}}{p_{n(i)+1}+1} \leq \sum \frac{v^{n(i)+1}-j}{p_{n(i)+1}-j+1} \cdot \frac{B_{n(i)+1}-j+1}{p_{n(i)+1}-j+2} \cdot \ldots \cdot \frac{B_{n(i)+1}}{p_{n(i)+1}}$$

(The norm on the matrices is the maximum absolute column sum, which is either $\infty - \infty$ or $1 - 1$.) Since we have made the norms of $B_{n}$ be $\mathbf{0}(p_{n+1})$, this goes to zero. Hence $v^{(i)}/q_{i+1} \rightarrow V$. As before, we find $W \in \mathbb{Z}^k$ and $E \in \text{GL}(k, \mathbb{Z})$ such that the absolute sum of the entries of $EW - W$ is less than one. Now conjugate the matrices simultaneously with $D = \left(\begin{smallmatrix}
  1 & 0 \\
  W & E
\end{smallmatrix}\right)$ as before, and the
new matrices are of the form \((q_i + 1 \begin{pmatrix} 0 & 0 \\ v_i & B_i \end{pmatrix})\) where we can make the substitution for \(a_i^{(n)}\) as we did in the previous case with a slight modification; as before, we make \(a_i^{(n)} = a^{(n)}\) equal to each other for \(1 \leq i \leq k\), and we require that that
\[
\min_{k+1} \left\{ p_{n+1} - (v^n)^T 1, p_{n+1} - (v^n)^T 1 + 1^TB_n 1 \right\} \geq a^{(n)} \geq \max \left\{ 0, 1^TB_n 1 - v^n, -(B_n)_{ij} - v^n 1^T \right\}_{1 \leq i, j \leq k}
\]
in order that the resulting matrices be nonnegative, and of rank \(k+1\). But \(\|B_n\|_{\infty, \infty} = o\left(\sqrt{p_{n+1}}\right)\) (which obviously persists after the telescoping), so the entries of \(B_n/p_{n+1}\) go to zero; dividing the expressions by \(p_{n+1}\), the \(B_n\) entries contribute negligibly to the obstruction. Now Lemma 1.1 applies, and we have a realization of \(G\) by ECS matrices of size \(k+2\). This yields:

**Theorem 4.1** Let \(t : G \to U \subseteq \mathbb{Q}\) be a simple dimension group with unique trace \(t\), such that \(t\) is rational-valued. If rank \(G = k+1\), then \(G\) admits an ECS realization by matrices of size \(k+2\), and they are of the form \((**)\).

5 Nearly ultrasimplicial dimension groups

Effros called a dimension group **ultrasimplicial** if it has a realization as ordered direct limit (with nonnegative matrices) \(G \simeq \lim A_n : \mathbb{Z}^{f(n)} \to \mathbb{Z}^{f(n+1)}\) where ker \(A_n = \{0\}\) for all \(n\) (so the obvious map \(\mathbb{Z}^{f(n)} \to G\) is one to one). Elliott [E] showed that the simple dimension group with unique trace \(Z\) has the projection onto \(\mathbb{Z}^{f(n)}\); this is the split case, covered by Proposition 2.1 with \(p_n = 2\) for all \(n\) and \(k = 1\) is not ultrasimplicial, whereas any totally ordered group is ultrasimplicial, and Riedel [R1] showed that if \(G\) is free of finite rank and with unique trace, then it is ultrasimplicial. It follows easily from Riedel’s result that if \(G\) is a simple dimension group with unique trace \(\tau\) and rank \(\tau(G) > 1\), then \(G\) is ultrasimplicial ([H1]). This is practically the complementary class to the dimension groups considered here (which are characterized by rank \(\tau(G) = 1\) and rank \(G < \infty\)) among simple dimension groups with unique trace.

Motivated by the results here, we say a dimension group is **co-rank one ultrasimplicial** if there exists a realization as partially ordered groups \(G \simeq \lim A_n : \mathbb{Z}^{f(n)} \to \mathbb{Z}^{f(n+1)}\) (as usual, \(A_n\) have only nonnegative entries, and the free groups are equipped with the coordinatewise ordering) such that the kernel of any telescoping (with \(m > n\) ) \(A_m A_{m-1} \ldots A_{n+1} A_n\) has rank at most one (alternatively, the map \(\mathbb{Z}^{f(n)} \to G\) given by \(x \mapsto [x, n]\) has kernel of rank at most one). Then among other things, combining the ultramatricial results ([H1], Corollary 4) with Theorem 4.1, we obtain that any finite rank simple dimension group with unique trace is co-rank one ultrasimplicial. A simple direct limit argument extends this to

**Theorem 5.1** Every simple dimension group with unique trace is co-rank one ultrasimplicial.

Riedel [R2] also showed that some free rank three simple dimension groups with two pure traces are not ultrasimplicial. It is possible that every simple dimension group is co-rank one ultrasimplicial, although I really doubt it.

6 Good and not-so-good traces

The previous results showed that if \(G\) is a simple dimension group with unique trace, the trace is rational-valued, and \(G\) is of rank \(k+1\), then it admits an ECS representation of size \(k+1\). For this section, we drop the requirement that \(G\) have unique trace. We show that if \((G, \tau)\) is a dimension group (having order units) and \(\tau\) is a rational-valued trace, then \(G\) admits an ECS realization with \(\tau\) obtained from the sequence of rows consisting of multiples of \(1^T\) if and only if \(\tau\) is good (as defined in [BeH] and below; when the trace is unique, it is automatically good). However, even in the finite rank case, the argument does not yield **bounded** ECS realizations.
Suppose \( G = \lim M_i : \mathbb{Z}^n(i) \to \mathbb{Z}^{n(i+1)} \) is an ECS representation of the dimension group \( G \), with the \( i \)th matrix having row sum sum \( c_i \). Then ECS merely says that \( 1^n_{n(i+1)}M_i = c_i1^n_{n(i)} \). This allows us to define a trace \( \tau \) on \( G \), via \( \tau([w,j]) = 1^n_{n(j)}w/\prod_{i=1}^{j-1} c_i \). We call this trace the trace associated to the representation of \( G \) via \( M_i \). Obviously \( \tau \) is faithful (that is, ker \( \tau \cap G^+ = \{0\} \)).

Different ECS realizations of the same group \( G \) can yield inequivalent traces, moreover, some of the traces so obtained can be pure, while others need not, and their value groups may differ. For example, consider the situation with \( M_j = \left( \begin{array}{cc} 1 & 2' \\ 2 & 1 \end{array} \right) \), a well-known construction with two pure traces; the trace obtained from this ECS representation is not pure.

For a particular ECS realization, the value group of the trace is \( \tau(G) = \bigcup_{i=1}^{k} \mathbb{Z}^{\frac{1}{e_i}} \). Thus \( \tau(G) \subseteq \mathbb{Q} \). In particular, if each \( c_j \) is a power of the same integer \( k \), then \( \tau(G) = \mathbb{Z}[1/k] \).

The set of order units of \( G \) will be denoted \( G^{++} \). Following \[BeH\], a trace \( \tau : G \to \mathbb{R} \) is good if for all \( b \in G^+ \), \( \tau([0,b]) = \tau(G) \cap [0,\tau(b)] \); it is order unit good when this property holds for all \( b \) in \( G^+ \). Notation that is not explained here will probably be found in \[BeH\].

**THEOREM 6.1** Suppose that \( G \) is a dimension group with order unit and let \( \tau \) be a trace of \( G \).

(a) Suppose there is ECS realization of \( G \) implementing \( \tau \). Then \( \tau \) is a faithful good trace with rational values.

(b) Let \((G, u, t)\) be a countable dimension group with order unit and trace such that \( t(G) \) is a subgroup of the rationals. If \( t \) is faithful and good (as a trace), then there exists a realization of \( G \) as a direct limit of simplicial groups whose realizing matrices have the equal column sum property such that \( t \) is the corresponding trace.

It is possible that the hypothesis in (b) that \( t \) be good can be weakened to refinability ([BeH]) of \( t \).

Towards (a), we have already observed that \( \tau \) is a faithful rational-valued trace. To show that \( \tau \) is good, we have an elementary lemma.

**LEMMA 6.2** Let \( n \) be a positive integer, and \( \mathbb{Z}^n \) the simplicial group of rank \( n \). Define a trace \( t \) on \( \mathbb{Z}^n \) by \( t(v) = 1^n_{n}v \) (so the vector \( v \) is sent to the sum of its coordinates). Then \( t \) is good.

**Proof.** Select nonnegative vectors \( a = (a_i)^T \), \( b = (b_i)^T \) in \( \mathbb{Z}^n \) such that \( \sum a_i < \sum b_i \). We fix \( b \) and systematically alter \( a \). Let \( S_-(a) = \{i \mid a_i > b_i\} \), \( S_+(a) = \{j \mid a_j < b_j\} \), and \( S_0(a) = \{i \mid a_i = b_i\} \). Obviously \( S_+(a) \) is not empty. If \( S_-(a) \) is empty, we are finished; otherwise, we proceed by induction on \( \sum S_-(a)(a_i - b_i) \). Select \( j \in S_+(a) \), and \( k \in S_-(a) \), and define \( a' \) by subtracting 1 from \( a_j \) and adding 1 to \( a_k \), and leaving the rest of the entries unchanged. Then \( 1^n_{n}a' = 1^n_{n}a \), \( S_+(a) \subset S_+(a') \cup S_0(a') \), and \( S_-(a') \subseteq S_-(a) \), and moreover, \( \sum S_-(a')(a'_i - b_i) \leq \sum S_-(a)(a_i - b_i) - 1 \).

The transformation \( a \mapsto a' \) is repeated until the \( S_- \)-set is empty, and we are done. 

Now \( \tau \) is the inverse limit of traces obtained as in this lemma, so is the limit of good traces, hence is good. This concludes the proof of (a).

**Proof of (b).** Start with an arbitrary \( \mathbb{Z}^n \) with basis \( \{e_j\} \) and map \( e_j \mapsto g_j \neq 0 \) in \( G^+ \). Let \( t(G) = \bigcup_k \prod_{i \leq k} m(i)^{-1} \mathbb{Z} \) (i.e., the \( m(i) \)'s are the successive factors realizing the supernatural number of \( t(G) \)); set \( \mathcal{M}_k = \prod_{i \leq k} m(i) \). There exists \( k \) such that each \( t(g_j) = a_j/\mathcal{M}_k \) for some positive integer \( a_j \).

By goodness, there exists \( h \in G^+ \) such that \( t(h) = 1/\mathcal{M}_k \), so again by goodness, there exists \( h_{jil} \) in \( G^+ \) such that \( g_j = \sum_{l=1}^{a_j} h_{jil} \). This allows us to create a simplicial map \( \mathbb{Z}^n \to \mathbb{Z}^{\sum a_j} \) by
sending \( e_j \mapsto \sum_{i=1}^{n_j} E_{jl} \), and we also have the obvious map from \( \mathbb{Z} \sum a_j \) to \( G \) via \( E_{jl} \mapsto h_{jl} \); then the maps to \( G \) are compatible.

The upshot of this preliminary construction is that all the basis elements of the new simplicial group are sent to the same value under \( t \). Now we apply the usual construction (as in [EHS]), that is, adjoin the next pre-selected generator of the positive cone, make it the image of a map, and fix up the kernel, so we arrive at the following (all maps are positive):

\[
\begin{array}{ccc}
  \mathbb{Z}^{n(1)} & \xrightarrow{\text{Z}} & \mathbb{Z}^{\prime} \\
  G & \xrightarrow{=} & G \\
  \mathbb{Z}^{n(1)} & \xrightarrow{\text{Z}} & \mathbb{Z}^{\prime} \\
  G & \xrightarrow{=} & G
\end{array}
\]

such that the kernel of the left vertical map is contained in the kernel of horizontal map, and \( \mathbb{Z}^{n(1)} \) is the \( \mathbb{Z} \sum a_j \) of two paragraphs above. We extend the horizontal map to a better simplicial group.

The standard basis elements \( E_i \) of the left simplicial group map to elements \( h_i \) with the property that \( t(h_i) = 1/M_k \) for some \( k \). Let \( F_j \) be the standard basis elements of the right, say with images \( g_j \) (we have re-indexed the bases). Then \( h_i = \sum b(i,j)g_j \) for some integers \( b(i,j) \), so that \( 1/M_k = \sum b(i,j)t(g_j) \). Then applying the method of the preliminary construction, we obtain a map \( \mathbb{Z}^{n'} \to \mathbb{Z}^{n''} \) (together with a map to \( G \)) such that the images of the new basis elements all have value at \( t \) equalling \( 1/M_{k'} \) for some \( k' \geq k \) (we can make sure that \( k' > k \) for infinitely many iterations of this process).

So we are in the following situation:

\[
\begin{array}{ccc}
  \mathbb{Z}^{n(1)} & \xrightarrow{\text{Z}} & \mathbb{Z}^{\prime} \\
  G & \xrightarrow{=} & G \\
  \mathbb{Z}^{n(1)} & \xrightarrow{\text{Z}} & \mathbb{Z}^{\prime} \\
  G & \xrightarrow{=} & G
\end{array}
\]

with the generators of the left group mapping to \( 1/M_k \) under \( t \) and the generators of the right group mapping to \( 1/M_{k'} \) under \( t \); and of course, the kernel of the vertical map from the preceding \( \mathbb{Z}^n \) is contained in the kernel of \( \mathbb{Z}^n \to \mathbb{Z}^{n(i)} \), etc. The image of \( E_i \) in the right group is the \( i \)th column of the transition matrix; if the image of \( E_i \) is \( \sum c_j F_j \), applying \( t \), we obtain \( 1/M_k = \sum c_j/M_{k'} \). Hence \( \sum c_j \), the column sum, is independent of the choice of column. So the transition matrix has equal column sums.

Now we repeat this process with the new \( \mathbb{Z}^{n''} \) (adjoin the next element of the positive cone etc). Since this sequence of transition matrices just obtained intertwines the sequence built up via the [EHS] method, both give the same dimension group as limit.

An example given in [BeH] is a simple rank two dimension group with two pure traces, such that the value groups are both \( \mathbb{Z}[1/2] \) and their kernels are discrete. In fact, in that example, there are no additive functions (let alone traces, pure or impure) \( t : G \to \mathbb{Q} \) such that the kernel is not cyclic; in particular, none of the countably many traces with rational value groups is good (by [BeH, 1.8], the kernel of a good trace \( \tau \) has dense range in \( \tau^+ \)).

To prove this, we note that \( G \) is strongly indecomposable and an extension of a cyclic group by \( \mathbb{Z}[1/2] \); now if \( \ker t \) were not cyclic, there would be (up to isomorphism) a noncyclic subgroup...
of \( \mathbb{Q} \) sitting inside \( G \). Applying one of traces to this subgroup, we see that it must be disjoint from the kernel, so that its image in \( \mathbb{Z}[1/2] \) is an isomorphic copy. But this forces the supernatural number of the subgroup to be \( 2^\infty \), hence the subgroup is 2-divisible, hence the restriction of the trace is of finite index, and therefore we have a splitting from a finite index subgroup of \( G \), which is impossible, as \( G \) is strongly indecomposable.

Hence the kernel of any trace of \( G \) with rational values is either zero or cyclic. Since \( G \) is simple, this means that no trace with rational values can be good, and thus \( G \) cannot be represented by an ECS limit.

It is amusing to ask when other positive maps \( \mathbb{Z}^n \rightarrow \mathbb{Z} \) are good or (better, for our purposes, order unit good, since a limit of order unit good traces is still order unit good, and if the limit group happens to be simple, the limit trace is then good). In fact, no others are good, but some others are order unit good.

**LEMMA 6.3** Let \( w = (c(i)) \in \mathbb{Z}^{1 \times n} \) be a nonnegative row, for which \( \gcd \{ c(i) \} = 1 \). Then the trace \( \mathbb{Z}^n \rightarrow \mathbb{Z} \) given by \( v \mapsto vw \) is good iff all the nonzero \( c(i) \) are 1.

**Proof.** We may discard the zero entries, and so reduce to the case wherein all the \( c(i) > 0 \). If they are not all equal, by permuting the entries, we may assume \( c(1) < c(2) \). Set \( b = (0, 1, 0, \ldots, 0)^T \) and \( a = (1, 0, \ldots, 0)^T \), so that \( wa = c(1) < c(2) = wb \). However, \( b \) is an atom, so the value of any nonnegative less than \( b \) at the trace is zero.

There is a characterization of order unit good traces in \( \mathbb{Z}^n \), but it is far more complicated.

**7 Introductory section on ERS**

As usual, \( 1_s \) denote the column of size \( s \) all of whose entries are 1. When \( s \) is understood, it may be deleted.

Let \( G \) be a dimension group (with order unit) that is not simplicial, and \( H \) be a rank one subgroup such that \( G^{++} \cap H \neq 0 \). Suppose we have an order isomorphism of \( G \) with a limit of maps,

\[
G \simeq \lim A_n : F_n \rightarrow F_{n+1},
\]

where \( F_n = \mathbb{Z}^{f(n)} \) is the usual simplicially ordered free abelian group of columns of size \( f(n) \), and \( A_n \) are \( f(n+1) \times f(n) \) matrices with nonnegative integer entries, and suppose in addition, we have the following properties:

(a) for all \( n \), there exists a (positive) integer \( p_{n+1} \) such that \( A_n 1_{f(n)} = p_{n+1} 1_{f(n+1)} \);

(b) the isomorphism from \( G \) to the direct limit sends the subgroup \( H \) to \( \bigcup_n [1_{f(n)}, n] \mathbb{Z} \).

We make a couple of observations. Condition (a) says that each \( A_n \) has all of its row sums equal (to \( p_{n+1} \)); we say the matrix \( A_n \) **satisfies ERS** when this occurs. Condition (a) also implies \( [1_{f(n)}, n] \mathbb{Z} \subseteq [1_{f(n+1)}, 1] \mathbb{Z} \), so the union of rank one groups is an ascending union of rank one groups (and thus is always a group, and rank one). We also note that \( 1_{f(n)} \) is an order unit in \( F_n \) and its image under \( A_n \) is an order unit in \( F_{n+1} \) (by (a)). Hence \( [1_{f(n)}, n] \) is an order unit in the direct limit. Moreover, if \( G_0 \) denotes the direct limit, and \( H_0 \) denotes \( \bigcup_n [1_{f(n)}, n] \mathbb{Z} \), then \( G_0 / H_0 \) is torsion-free (just observe that if \( kg_0 \in H_0 \), then \( g_0 \) must be represented by an element of the form \( t[1_{f(n)}, n] \)). We call the sequence (or \( G_0 \)) an **ERS realization of G with respect to H** when (a) and (b) hold. This of course forces \( G/H \) to be torsion-free and \( H \cap G^{++} \neq \{0\} \). Moreover, \( p_{n+1} > 1 \) for infinitely many \( n \), or else the limit is simplicial, which we forbid; hence \( H \) is not cyclic.

Sometimes, if \( H \) is understood, or we are talking about whether there exists an \( H \) for which an ERS realization exists with respect to \( H \), we say an **ERS realization for G exists**. If the matrix sizes, \( \{ f(n) \} \) are bounded, then there is a telescoping so that they are all equal, say of size \( s \), and then the matrices have \( 1_s \) as a common right eigenvector. In that case, we say that \( G \) has a **bounded (or size s) ERS realization** (with respect to \( H \)).
For example, if as an abelian group, \( G \simeq U \oplus \mathbb{Z}^k \) where \( U \subseteq \mathbb{Q} \), then there is only one choice for \( H \), namely \( U \), and an ERS realization also requires that none of the traces kill \( U \). If instead the underlying group of \( G \) is \( \mathbb{Z}[1/3] \oplus \mathbb{Z}[1/2] \) and the only trace is given by summing (that is, \((a, b) \mapsto a + b\)), so \( G \) is a simple dimension group with unique trace, and the trace has kernel \( \{(m, -m)\}_{m \in \mathbb{Z}} \simeq \mathbb{Z} \), then there are exactly two choices for \( H , (\mathbb{Z}[1/2], 0) \) and \((0, \mathbb{Z}[1/3]) \). On the other hand, if \( G \) has the same underlying group, but as pure traces the projections on each coordinate, then \( G \) is a simple dimension group with two pure traces, but there are no candidates for \( H \) (so no ERS realizations exist for \( G \)).

If \( G \) is simple with unique trace in \( \tau \), the conditions on \( H \) are equivalent to \( \tau(H) \neq 0 \) (equivalently, since \( H \) is rank one, \( \ker \tau \cap H = \{0\} \) and \( G/H \) is torsion-free. The last is a pink herring* because for every rank one subgroup \( H_0 \) of a torsion free group \( J \), there is a unique rank one subgroup \( H \) of \( J \) such that \( H_0 \subseteq H \) and \( J/H \) is torsion-free.

Our results on ERS realizations show that for simple dimension groups with unique trace, the obvious necessary conditions are sufficient, and we obtain a bound on the size in terms of the rank. All our dimension groups are countable.

**THEOREM 7.1** Let \( G \) be a simple dimension group with unique trace \( \tau \), together with a noncyclic rank one subgroup \( H \) such that \( \tau(H) \neq 0 \) and \( G/H \) is torsion-free.

(a) If rank \( G = k + 1 \), then there exists an ERS realization of \( G \) with respect to \( H \) of size \( k + 2 \).

(b) There exists an ERS realization of \( G \) with respect to \( H \).

Part (a) (proved in the next section as part of 8.5) includes an explicit bound in terms of the rank (which is sharp: some of these dimension groups cannot be realized even without the ERS property at the same size as their rank). Part (b) (established in section 9) is a routine consequence of (a), and of course permits infinite rank (which means that the \( f(n) \) have to be unbounded).

We have a huge class of ERS representations available: begin with an ECS realization of a dimension group by square matrices, for example as obtained in 4.1, and take the sequence of transposes. The resulting dimension groups are not that closely related to the original ones from which they emanated. For example, although the dimension group defined by the transposes obtained from the previous construction will have unique trace; generically, this is not rational-valued. (This will become clear later.)

We have to enter the looking-glass world of torsion-free abelian groups, and as a result, intuition goes out the window. For example, the group \( G = \mathbb{Z}[1/2] \oplus \mathbb{Z}[1/3] \) is a simple-minded direct sum of two rank one groups; however, the addition map \( \mathbb{Z}[1/2] \oplus \mathbb{Z}[1/3] \to \mathbb{Z}[1/6] \) \((a, b) \mapsto a + b\) is onto and has kernel isomorphic to \( \mathbb{Z} \) (explicitly, \((1, -1)\mathbb{Z}) \); hence we have a nonsplit extension of \( G , \mathbb{Z} \to G \to \mathbb{Z}[1/6] \), by rank one groups, completely different from the direct summands. More generally, if \( \{m(i)\}_{i=1}^k \) are pairwise relatively prime integers each exceeding one with \( m = \prod m(i) \), then \( G = \oplus \mathbb{Z}[1/m(i)] \) is an extension of \( \mathbb{Z}^k \) by \( \mathbb{Z}[1/m] \).

**8 Transposes**

Suppose \( J \) is an abelian group, and is given as an extension \( 0 \to L \to J \to M \to 0 \), with \( \tau : J \to M \)

---

* not as misdirecting as a red herring.

2 It is not true in general that if \( G \) is a limit of square strictly positive matrices (so is a simple dimension group) and \( G \) has unique trace, then the limit dimension group of their transposes need have unique trace (although it is simple). This is left as an exercise to the reader, but with a hint: first do it for upper triangular \( 2 \times 2 \) matrices where the number of traces—corresponding to certain eigenvectors—can easily be made to change by transposition, then perform a perturbation so the matrices are strictly positive.
denoting the quotient map. We say the extension is nearly split* if there exists a subgroup \( J_0 \) of \( J \) such that \( L \subseteq J_0, J_0 = L \oplus H_0 \) for some subgroup \( H_0 \) of \( J \) missing \( \ker \tau \) and \(|J/J_0| < \infty \). Equivalently, there exists a subgroup \( H_0 \) of \( J \) such that \( H_0 \cap L = \{0\} \) and \( \tau(H_0) \) is of finite index in \( M \).

In the following, the norms on rows are the maximum of the absolute values, and the norms on matrices are the maximum absolute column sums.

**LEMMA 8.1** Let \( t : G \to V \) be an onto group homomorphism from a torsion-free group \( G \) of rank \( s \) to a dense subgroup \( V \) of the reals. Let \( H \) be a noncyclic rank one subgroup of \( G \) such that \( \ker t \cap H = \{0\} \) and \( G/H \) is torsion-free. Then there exists a realization of \( G \) as an abelian group, as the direct limit of matrices of the form

\[
\lim M_n := \begin{pmatrix} p_{n+1} & u^n \\ 0 & B_n \end{pmatrix} : \mathbb{Z}^s \to \mathbb{Z}^s
\]

with \( p_{n+1} > 1, B_n \in \mathbb{Z}^{(s-1) \times (s-1)}, \det B_n \neq 0, \text{ and } u^n \in \mathbb{Z}^{1 \times (s-1)} \) such that

1. \( H \cong \lim \times p_{n+1} : \mathbb{Z} \to \mathbb{Z} \)
2. \( G/H \) is given up to rational multiple by a sequence of rows of the form \( r^i = (1/p_2 \ldots p_i, \rho_i) \) satisfying \( r^{i+1} M_i = r^i \), with \( t[a, i] = r^i a \).
3. The isomorphism of \( G \) with the direct limit identifies \( H \) with \( \cup_{k \in \mathbb{N}}[(1,0,0,\ldots,0)^T, k]\mathbb{Z} \).
4. \( \|B_n\| \leq p_{n+1}^{1/8} / (s!)^{2/s} \) and \( \|u^n\| \leq p_{n+1}^{1/4} \).

Moreover, if \( G/H \) is free, then \( \ker t \) is free; if additionally, \( t(G) \) is rank one, then the image of \( \ker t \) in \( G/H \) is of finite index, the extension \( \ker t \to G \to t(G) \) is nearly split, and we can take \( B_n = I_{s-1} \).

**Remark.** When we change the matrices \( B_n \) to the identity, the corresponding \( u^n \) will also change.

**Proof.** We can write \( V \) first as countably generated, say by \( \{l_n\} \subset \mathbb{R} \), and \( t(H) = \cup(1/q_{n+1})\mathbb{Z} \) where \( q_n > 1 \) divides \( q_{n+1} \), and form the subgroups \( V_n = (1/q_{n+1})\mathbb{Z} + \sum_{i=1}^n l_i \mathbb{Z} \), so that \( V_n \subseteq V_{n+1} \). Next, consider \( \ker t \); we can write this as an increasing union of free abelian groups, \( J_n \subset J_{n+1} \), all having the same rank as \( \text{rank} \ker t = s - \text{rank} V \) (this is true of any finite rank torsion-free abelian group). Select \( h_n \in H \) and \( g_n \in G \) such that \( t(h_n) = 1/q_{n+1} \) and \( t(g_n) = l_n \), and form the group \( G_n \) generated by \( \{J_n, h_n, g_1, g_2, \ldots, g_n\} \); this is finitely generated, hence being a subgroup of a torsion-free group, is free; moreover, its rank must rank \( J_n + \text{rank} V = \text{rank} \ker t + \text{rank} V = s \).

Then \( G_n \subseteq G_{n+1} \), and since \( \ker t = \cup J_n \subset \cup G_n \), and \( \cup G_n \to V \) is onto, it follows that \( G = \cup G_n \). Now define \( H_n = H \cap G_n \); this is cyclic and its image under \( t \) contains (possibly strictly) \( h'_n \mathbb{Z} \). We may choose its generator, \( h_n \), so that \( t(h_n) > 0 \) (which of course uniquely

* Nearly split is almost the same as quasi-split used in abelian group theory (that there exist a map \( \sigma : M \to J \) such that \( \tau \sigma = n \) times the identity for some nonnegative integer \( n \), and when \( J \subseteq \mathbb{Q} \), the definitions coincide. However, quasi-split is also used in other contexts, and I thought it would be confusing here. Different is the notion of almost split, used in representation theory of finite-dimensional algebras.

In [R], nearly split is defined for extensions of nonabelian groups; it agrees with the definition here when restricted to torsion-free abelian groups. The equivalence classes of nearly split extensions are closed under Baer sums and differences, hence form a subgroup of \( \text{Ext} \), although a very small one. We never use the additive structure of the group of extensions.
determines it). Since $G/H$ is torsion-free, so is $G_n/H_n = G_n/(h_nZ)$. Hence for each $n$, there is an ordered $Z$-basis whose first entry is $h_n$.

The matrix implementing $G_n \subseteq G_{n+1}$ with respect to the two bases is precisely of the form displayed (but without the estimates in (iv) being satisfied), where $p_{n+1}$ is uniquely determined by $h_n = h_{n+1}p_{n+1}$. Condition (i) is straightforward to verify. We have seen that $G = \cup G_n$, so we obtain a sequence of matrices whose limit abelian group is $G$. The matrices $B_n$ are the maps $G_n/h_nZ \to G_{n+1}/h_{n+1}Z$, and the limit of these is $G/H$. From the rank conditions, rank $B_n = s-1$ for almost all $n$, so det $B_n \neq 0$ for almost all $n$ (and so by deleting an initial segment of the direct limit, we can ensure that det $B_n \neq 0$ for all $n$). The second part of (ii) just follows from the definitions. Condition (iii) comes from the construction.

Now we want to adjust the sequence in order to arrange that (iv) holds.

Having the original construction of $B_n$ as the quotient maps on $G_n/h_nZ \cong Z^s/h_nZ$, let $f : N \to N$ be any strictly increasing function. Define $G^n = G_n + h_f(n)Z$. Then $G^n \subseteq G^{n+1}$, and $t(h_f(n))/t(h_f(n+1)) = p_f(n+1)+1p_f(n+1) \cdot \cdots \cdot p_f(n+2)$. In particular, we can take the basis for $G_n$ given by $(h_n, y_{n,1}, \ldots, y_{n,k})$, and observe that $(h_f(n), y_{n,1}, \ldots, y_{n,k})$ is a $Z$-basis for $G^n$. The map $M^n : G^n \to G^{n+1}$ with respect to this basis then has its first column simply $(p_f(n+1)+1p_f(n+1) \cdot \cdots \cdot p_f(n+2), 0, 0, \ldots, 0)^T$. Moreover, the induced map $G^n/h_f(n)Z \to G^{n+1}/h_f(n+1)Z$ is naturally the same as the induced map $G^n/h_nZ \to G^{n+1}/h_{n+1}Z$, that is $B_n$. Hence the form of the transition matrices $M^n$ is

$$
\begin{pmatrix}
p_f(n+1)+1p_f(n+1) \cdot \cdots \cdot p_f(n+2) & u^n \\
0 & B_n
\end{pmatrix}
$$

for some (different, but relabelled) $u^n \in Z^{s \times s}$. Thus the new $p_{n+1}$ is the product $p_f(n+1)+1p_f(n+1) \cdot \cdots \cdot p_f(n+2)$, which we can make as large as we like (by choosing $f$ to grow fast), while fixing $B_n$. Relabel the upper left corner $p_{n+1}$. Thus we can ensure that $\|B_n\| < \sqrt[p_{n+1}]{1}/(s!)^2$ (or smaller if we like) and $p_n$ increasing.

Having this, we can now ensure that $\|u^n\| < p_{n+1}^{1/4}$. Set $U_n = \begin{pmatrix} 1 & y_n \\ 0 & 1_{s-1} \end{pmatrix}$ where $y_n \in Z^{1 \times (s-1)}$ is to be determined. Each $U_n$ is in $GL(s, Z)$ and $U_n^{-1} = \begin{pmatrix} 1 & -y_n \\ 0 & 1_{s-1} \end{pmatrix}$. Then $\lim M^n : Z^s \to Z^s$ is isomorphic to $\lim U_{n+1}M^nU_n^{-1} : Z^s \to Z^s$ (via $[a, m] \mapsto [U_n a, m]$). We calculate

$$
U_{n+1}M^nU_n^{-1} = \begin{pmatrix} p_{n+1} & u^n - p_{n+1}y_n + y_{n+1}B_n \\ 0 & B_n
\end{pmatrix}.
$$

Set $y_1 = 0$. Obviously, $0 \neq |\det B_n| \leq \|B_n\|^{s-1} \cdot (s-1)! < p_{n+1}^{1/4}$. Now $B_n^{-1}$ exists as a matrix with rational entries, and det $B_n \cdot (B_n)^{-1}$ is simply the adjoint matrix of $B$, so has integer entries. Let $d_n = |\det B_n|$. Then we have $Z^{1 \times (s-1)}d_nB_n^{-1} \subseteq Z^{1 \times (s-1)}$. Applying $B_n$, we have $d_nZ^{1 \times (s-1)} \subseteq Z^{1 \times (s-1)B_n}$.

This means that for any vector $z \in Z^{1 \times (s-1)}$, we can find $y \in Z^{1 \times (s-1)}$ such that $\|z - yB_n\| < d_n$. Of course, we can arrange this. Given $y_1, \ldots, y_{n+1}$ inductively so that $\|(u^n - p_{n+1}y_n) - y_{n+1}B_n\| < d_n$. After relabelling $U_{n+1}M^nU_n^{-1}$ to $M_n$, the resulting upper right corner entry (again called $u^n$) thus satisfies $\|u^n\| < d_n < p_{n+1}^{1/4}$.

Each (newly relabelled) $h_n$ appears as $[(1,0,\ldots,0)^T, n]$ from the $Z$-basis construction, and since $H = \cup h_nZ$, the identification with $H$ follows again.

Now we deal with the Moreover statement. The map ker $t \to G/H$ is one to one; so if $G/H$ is free, then ker $t$, being a subgroup, is free as well. Since $G$ has finite rank, $G/H$ is free of rank $s - 1$. If additionally, $t(G)$ has rank one, then ker $t$ has rank $s - 1$, the same as that of $G/H$, and since both are free, the image ker $t$ is of finite index in $G/H$. 

Since $G/H \simeq \lim B_n : \mathbb{Z}^{s-1} \to \mathbb{Z}^{s-1}$ (\(\mathbb{Z}^{s-1}\) is an abbreviation for \(\mathbb{Z}^s/h_n\mathbb{Z}\), and $G/H$ is free of maximal rank, it must happen that $|\det B_n| = 1$ for all but finitely many $n$ (from finite generation of the direct limit). If $G/H$ is free, then $\ker t \oplus H$ is of finite index in $G$: to see this, note that $G \to G/H$ splits, so there exists a subgroup $J$ of $G$ such that $H \oplus J = G$ and $J$ maps isomorphically to $G/H$. There is no guarantee that $\ker t \subseteq J$; however, the exact sequence $H \to H \oplus \ker t \to L$ (where $L$ is the image of $\ker t$ in $G/H$) yields $G/(H \oplus \ker t)$ is finite, since it embeds in $(G/H)/L$, which is finite.

Still in the case that $G/H$ is free, we may discard an initial segment of non-elements of $GL(s-1, \mathbb{Z})$, so assume each $B_n$ is in $GL(s-1, \mathbb{Z})$. Then we can systematically pre- and post-multiply the $M_n$ by matrices of the form diag $(1, E_n)$ where $E_n \in GL(s-1, \mathbb{Z})$ to arrange that the lower right blocks are all the identity.

For the general case, the matrices $B_n$ can be put in Hermite normal form (the normal forms arising from the action of $GL(s-1, \mathbb{Z})$ on $\mathbb{Z}^{(s-1) \times (s-1)}$ from the left). It is not clear whether this would be useful.

An immediate observation is that $e := (1, 0, \ldots, 0)^T$ is a common right eigenvector for all the matrices $M_n$ appearing there, with eigenvalue $p_{n+1}$, and if we identify $G$ with the direct limit, then $H = \cup [e, k] \mathbb{Z}$. We can also recalculate $t$ in terms of the direct limit.

**Lemma 8.2** Let $B_i : \mathbb{Z}^d \to \mathbb{Z}^d$ be a bunch of matrices, and let $J$ be their limit as an abelian group. Suppose that for all $i$, the left kernel of $B_i$, that is, \( \{ w \in \mathbb{Z}^{1 \times l} \mid wB_i = 0 \} \), is the same, $\mathbb{Z}z$, for some $z \in \mathbb{Z}^{1 \times l}$; we may assume that $z$ is unimodular. Set $W = z^\perp = \{ v \in \mathbb{Z}^l \mid vz = 0 \}$; then $B_i W \subseteq W$ and form the direct limit, $lim J_0 := C_i : W \to W$, where $C_i = B_i W$. Then the natural map $J_0 \to J$ given by $[v,s] W \to [v,s]$ is an isomorphism (of abelian groups).

**Proof.** Since $z(B_i W) = 0$, not only is $B_i W \subseteq W$, but in fact $B_i(W) \subseteq W$. If $B_{n+t}B_{n+t-1} \cdots B_{n+1}v = 0$ for $v$ as an element of $W$, then it is obviously true as an element of $\mathbb{Z}^l$, and it follows that the map $J_0 \to J$ is well defined and one to one. Next, if $y \in \mathbb{Z}^l$, then $B_n y \in W$, so that $[y,s] = [B_n y, s+1]$ which is in the image of the map $J_0 \to J$. Hence the map is onto.

In the ECS cases discussed in the previous section, the sequence of vectors $(v^n)$ is compatible with the addition operation on the Ext group, that is, with the Baer sum $(p_{n+1},v^n + (v^n')$) represents the Baer sum of the extensions arising from $(p_{n+1},v^n)$ and $(p_{n+1},(v^n')$); however, many different sequences can represent the same equivalence class, and it is very difficult to decide when they do. The same applies here, although if $G/H$ is free, then as abelian groups (but not as extensions), $G \simeq \mathbb{Z}^{s-1} \times H$.

Here $\rho$ denotes the spectral radius. The following is well known in a more general setting, dealing with projective convergence and weak ergodicity. But we do not need this generality in our situation.

**Lemma 8.3** Let $G = \lim C_i : \mathbb{Z}^s \to \mathbb{Z}^s$ be a sequence of primitive matrices for which there exists positive real numbers $f(m,n)$ with $m > n$ such that $\lim_{m \to \infty} f(m,k+1)/f(m,k) \to 1/\rho(C_k)$ for all $k$, and for all $n$

$$\lim_{m \to \infty \& m > n} \frac{C_mC_{m-1} \cdots C_n}{f(m,n)} = V_n$$

exists and is nonzero. Then the candidate map $V : G \to \mathbb{R}^s$ via $V[a,k] = V_k/\prod_{i=1}^{k-1} \rho(C_i)$ is well-defined, and every pure trace of $G$ factors through it. In particular, $G$ has unique trace iff rank $V_n = 1$ for almost all $n$.  

19
Remark. The simplest situation in which the hypotheses hold occur when \( \rho(C_mC_{n-1} \cdots C_m) = \prod_{i=1}^{m} \rho(C_i) \) for all \( m > n \), that is, when the spectral radius is multiplicative on the matrices. For example, this occurs when the \( C_n \) have a common right Perron eigenvector, or a common left Perron eigenvector.

Proof. \([a,k] = [C_k a, k + 1] \), and the latter is sent to \( V_{k+1} C_k a / \prod_{i=1}^{k} \rho(C_i) \). Now \( C_m \cdots C_{k+1} c_k / f(m,k) = (C_m \cdots C_{k+1} / f(m,k+1)) C_k (f(m,k+1)/f(m,k)) \). The left side converges to \( V_k \); the right side converges to \( V_{k+1} C_k a / \rho(C_k) \). Hence \( V_{k+1} C_k a = \rho(C_k) V_k a \), so \( V \) is well-defined.

Next, suppose that \([a,k] \) is an order unit in \( G \); then there exists \( m > k \) such that \( C_{m-1} C_{m-2} \cdots C_k a \) is strictly positive; as \( V_m \) has only nonzero entries, this means \( V_m C_{m-1} C_{m-2} \cdots C_k a \) is nonnegative and not all entries are zero, and thus \( V[a,k] \) is nonnegative and nonzero (as an element of \( R^* \)), and thus \( V \) is a positive group homomorphism. Each row of \( V_n \) is either zero, or induces a trace on \( G \) (via \( R^* \to R \)). Discard any zero rows from \( V_n \) (for all sufficiently large \( n \)) obtaining a newly-labelled \( V_n \), which is now a map from \( G \) to \( R^{s'} \) with \( s \leq s' \) such that every row of \( V_n \) is not zero. Then the map \( V \) sends order units if \( G \) to order units of \( R^{s'} \).

Conversely, if \([a,k] \) is an arbitrary element of \( G \) such that \( V[a,k] > 0 \), then there exists \( m > k \) such that \( C_{m-1} C_{m-2} \cdots C_k a - V_k a \) is smaller than the infimum of the entries of \( V_k a \), and thus \( C_{m-1} C_{m-2} \cdots C_k a \) is strictly positive, hence \( C_{m-1} C_{m-2} \cdots C_k a \) is strictly positive, and thus \([a,k] \) is an order unit of \( G \). Now consider all the traces on \( G \) obtained by composing \( V \) with any positive vector space map \( R^* \to R \). What we just obtained is that these are enough to determine the order units of \( G \), and this implies that these traces include all the extreme points in the trace space of \( G \), hence the factorization for pure traces.

If \( \text{rank} V_n = 1 \), then the trace space is 0-dimensional (after normalization, a single point); conversely, if \( G \) has unique trace, then all the composed traces are equal up to normalization, and it follows immediately that \( \text{rank} V_n = 1 \) for almost all \( n \).

Suppose \( A_i \) are primitive matrices of the same size with common right Perron eigenvector. Then the spectral radius is multiplicative on products of the \( A_i \), and moreover, \( A_i / \rho(A_i) \) are uniformly bounded (by row sum) by 1, as are their products. Hence there exists a subsequence, \( 1 = n(1) < n(2) < n(3) \ldots \), such that for the sequence \((C_i := A_{n(i+1)-1} \cdots A_{n(1)+1} A_{n(1)})\), we have for all \( k \),

\[
\frac{C_m \cdot C_{m-1} \cdots C_k}{\prod_{k=1}^{m} \rho(C_i)}
\]

converges to a matrix, necessarily nonzero, as the row sums are all one. Hence by suitably telescoping, we use 8.3 to derive the pure traces from rows of the limit matrices, and if \( G \) has unique trace, the limit matrices eventually have rank one, so we can pick any fixed row.

There is a more general uniqueness criterion in terms of projective convergence that is very well known, applies to all unique trace dimension groups and corresponding Bratteli diagrams, but is not easy to use.

Denote by \( B(p,B,v,a) \) for \( p \) and \( a \) positive integers, \( v \in Z^k \) and \( B \in Z^{k \times k} \), the matrix

\[
B(p,B,v,a) = \begin{pmatrix}
* & v + a1 & B + vT1 + a11T & v + (a-1)1 \\
\ast & \ast & \ast & \ast \\
v + a1 & B + vT1 + a11T & v + (a-1)1 & a \\
1 & 1 & 1 & 1 \\
\end{pmatrix}
\]

where \( 1 \) is the column of size \( k \) consisting of ones, and the column sums are all \( p \) (hence the entries marked with an asterisk are uniquely determined). Then it is easy to check that \( B(p,B,v,a) B(p',B',v',a') = B(pp',BB',p'v + Bv,pa) \). Setting \( A_n = B(p_{n+1},B_{n},v^n,A_n) \), then inductively

\[
A_n A_{n+1} \cdots A_{n+j} = B(p_{n+i+1},B_n \cdots B_{n+j},v^{(n,j)},A_n) \prod_{i=1}^{j} p_{n+i+1},
\]
where
\[
v^{(n,j)} = p_{n+1} \cdots p_{n+j+1} \left( \frac{v^n}{p_{n+1}} + \frac{B_n v^{n+1}}{p_{n+1}p_{n+2}} + \frac{B_n B_{n+1} v^{n+2}}{p_{n+1}p_{n+2}p_{n+3}} + \cdots + \frac{B_n \cdots B_{n+j}}{p_{n+1} \cdots p_{n+j+1}} \right).
\]

We assume as we may that \(\|B_n\| = O \left( \frac{1}{p_{n+1}} \right)\), and that \(\{v^n/p_{n+1}\}\) is bounded. Then
\[
\lim_{n \to \infty} v^{(n,j)}/p_{n+1} \cdots p_{n+j+1}
\]
exists (provided \(p_n \to \infty\)); call it \(V^{\infty,n}\); this forces \(A^T_{n+j} A^T_{n+j-1} \cdots A/p_{n+1} \cdots p_{n+j}\) to converge to the rank one matrix
\[
1_{k+2} \left( 1 - (V^{\infty,n})^T 1 \right) = \frac{(k+1)a^n}{p_{n+1}}, V^{\infty,n} + \frac{a^n}{p_{n+1}} 1^T, a^n \right).
\]

Call the row appearing in this factorization, \(W^{\infty,n}\); if the \(A_n\) are primitive, then it is strictly positive. The family \(\{W^{\infty,n}\}\) satisfies \(W^{\infty,n} A^T_n = W^{\infty,n-1}\), hence induces a trace on the dimension group \(G = \lim A^T_n: Z^{k+2} \to Z^{k+2}\) via \(\tau[n,m] = W^{\infty,m} x\). As \(G\) has unique trace, this is it, up to scalar multiple.

Now we consider \(G\) as an abelian group with trace; then we obtain a group isomorphism from the restriction to \((z^T)^+\) (where \(z = (-k+1,1,1,\ldots,1)^T\)); using as ordered \(Z\)-basis for the latter, the columns \((1, \ldots, 1)^T, (0,1,0,\ldots,0,1)^T, (0,0,\ldots,0,1,1,\ldots,1)^T\) (it is easy to check that this is a \(Z\)-basis), the group isomorphism from 8.2 is with the group given as
\[
J := \lim M_n = (p_{n+1} (v^n)^T 0\ B_n^T) : Z^{k+1} \to Z^{k+1}.
\]
Moreover, the effect of \(W^{\infty,1}\) on the basis yields the group homomorphism obtained from the rows \(R_n := (1, V^{\infty,1})\); that is, the corresponding homomorphism from \(J\) to \(R\) is given by \(t[x,k] = R_k x\). Since each \(M_n\) is one to one, a group homomorphism from \(J\) is uniquely determined by its affect on the first level, that is, on elements of the form \([x,1]\).

In the following, the norms on rows are the maximum of the absolute values, and the norms on matrices are the maximum absolute column sums.

**LEMMA 8.4** Let \(p_{n+1} \uparrow \infty\), let \(B_i\) be \(k \times k\) integer matrices such that \(\det B_i \neq 0\) and \(\|B_i\| = O \left( \frac{1}{p_i} \right)\), and let \(z_i \in \mathbb{Z}^{1 \times k}\) with \(\|z_i\| < p_{i+1}\); let \(r^1 = (1,\rho^1)\) where \(\rho^1 \in \mathbb{R}^{1 \times k}\). Then there exist a sequence \(\{w^i\}\), with \(w^i \in \mathbb{Z}^{k}\) and \(\|w^i\| < \|z_i\| + (p_{i+1} + \|B_i\|)/2\) for all \(i > 1\) together with group isomorphisms \(F_i: \mathbb{Z}^{k+1} \to \mathbb{Z}^{k+1}\) such that the following diagram

\[
\begin{array}{cccccccc}
\mathbb{Z}^{k+1} & \xrightarrow{F_1} & \mathbb{Z}^{k+1} & \xrightarrow{F_2} & \mathbb{Z}^{k+1} & \xrightarrow{F_3} & \cdots & \mathbb{Z}^{k+1} \\
\mathbb{R} & \xrightarrow{F_1} & \mathbb{R} & \xrightarrow{F_2} & \mathbb{R} & \xrightarrow{F_3} & \cdots & \mathbb{R} \\
\mathbb{Z}^{k+1} & \xrightarrow{F_1} & \mathbb{Z}^{k+1} & \xrightarrow{F_2} & \mathbb{Z}^{k+1} & \xrightarrow{F_3} & \cdots & \mathbb{Z}^{k+1}
\end{array}
\]

The diagram commutes and \(\kappa: \mathbb{Z}^{k+1} \to \mathbb{R}\) is a homomorphism with \(\kappa(r^1) = 1\).
commutes, and such that
\[ \rho^1 = \frac{w^1}{p_2} + \frac{w^2 B_1}{p_3 p_2} + \frac{w^3 B_2 B_1}{p_4 p_3 p_2} + \frac{w^4 B_3 B_2 B_1}{p_5 p_4 p_3 p_2} + \ldots. \]

Proof. We will define \( F_i = \begin{pmatrix} 1 & y_i \\ 0 & 1 \end{pmatrix} \) (where \( y_i \in \mathbb{Z}^{1 \times k} \)), and then define \( w_i \in \mathbb{Z}^{1 \times k} \) so that all the properties hold. First set \( y_1 = 0 \). Now define
\[
\begin{align*}
z^\infty &= \frac{z_1}{p_2} + \frac{z_2 B_1}{p_3 p_2} + \frac{z_3 B_2 B_1}{p_4 p_3 p_2} + \ldots \\
&= \frac{z_1}{p_2} + \sum_{i=2}^{\infty} \frac{z_i B_{i-1} B_{i-2} \ldots B_1}{p_{i+1} p_i \ldots p_2}.
\end{align*}
\]
That the sum exists is a consequence of \( \|z_i\|/p_{i+1} \) being bounded, \( \|B_i\| = o \left( \sqrt{p_{i+1}} \right) \), and summability of \( 1/\sqrt{p_{i+1} \ldots p_2} \).

Now define
\[
y_{n+1} = \left[ p_{n+1} p_n \cdot \ldots \cdot p_2 (\rho^1 - z^\infty) (B_n \cdot B_{n-1} \cdot \ldots \cdot B_1)^{-1} \right];
\]
of course, the inverses of \( B_i \) exist as matrices with rational entries. Here the integer function \( \lfloor \cdot \rfloor \) means to take the nearest integer in each entry. Let \( Y_{n+1} \) denote the thing on the right before we take the integer function; it is an element of \( \mathbb{R}^{1 \times k} \). Then obviously we have \( y_{n+1} \in \mathbb{Z}^{1 \times k} \) and \( \|y_{n+1} - Y_{n+1}\| \leq 1/2 \).

Finally, set \( w^n = z_n + y_{n+1} B_n - p_{n+1} y_n \). It is easy to check that the squares in the diagram all commute. We show that \( \rho^1 \) is the infinite sum in (2).

Let \( S_n \) be the sum of the first \( n \) terms on the right side of (2). When we substitute \( w^i = z_i + y_{i+1} B_n - p_{n+1} y_i \), we find that the series partially telescopes:
\[
S_n = \left( \frac{z_1}{p_2} + \sum_{i=2}^{n} \frac{z_i B_{i-1} B_{i-2} \ldots B_1}{p_{i+1} p_i \ldots p_2} \right) + \frac{y_{n+1} B_n B_{n-1} \ldots B_1}{p_{n+1} \ldots p_1},
\]
as follows immediately by induction. Now \( Y_{n+1} B_n \cdot \ldots \cdot B_1 (p_{n+1} \ldots p_2)^{-1} = \rho^1 - z^\infty \), hence \( \|y_{n+1} B_n \cdot \ldots \cdot B_1 (p_{n+1} \ldots p_2)^{-1} - (\rho^1 - z^\infty)\| < 1/\sqrt{p_{n+1} \ldots p_1} \). Thus \( \lim S_n \) exists and
\[
\lim S_n = z^\infty + (\rho^1 - z^\infty) = \rho^1.
\]

Next, we estimate \( \|w^n/p_{i+1}\| \). We have
\[
\begin{align*}
\|w^n - z_n\|_{p_{n+1}} &= \left\| \frac{y_{n+1} B_n - p_{n+1} y_n}{p_{n+1}} \right\| \\
&\leq \left\| \frac{Y_{n+1} B_n - p_{n+1} Y_n}{p_{n+1}} \right\| + \left\| (Y_{n+1} - y_{n+1}) B_n + p_{n+1} (Y_n - y_n) \right\| \\
&\leq 0 + \left\| \frac{B_n}{2p_{n+1}} \right\| + \frac{1}{2}.
\end{align*}
\]
Thus \( \|w^n/p_{n+1}\| \leq \|z_n/p_{n+1}\| + (1/2) (\|B_n\|/p_{n+1} + 1). \)

\[ \bullet \]
We are permitted to telescope the bottom row, and then apply the same transformation to the resulting upper right corner entries as we did in the ECS case (for the lower left corners), conjugating by a block upper triangular element of\(GL(k+2, \mathbb{Z})\), to ensure we could choose the \(a^n\) so that the resulting matrices are positive. This yields the following.

**THEOREM 8.5** Let \(G\) be a simple dimension group of rank \(k+1\) with unique trace \(\tau\), and let \(H\) be a noncyclic rank one subgroup of \(G\) such that \(G/H\) is torsion-free and \(\tau(H) \neq 0\). Then there exists an ERS realization of \(G\) of size \(k+2\) such that the image of \(H\) in the direct limit is \(\cup_{j \in \mathbb{Z}} [(1,1,\ldots,1)^T,j] \mathbb{Z}\). If \(G/H\) is free, then the extension \(0 \to \ker \tau \to G \to \tau(G) \to 0\) is nearly split.

This does not require the trace to be rational-valued; since there is no restriction on \(\tau(G)\) except \(\tau(H) \neq 0\), the value group, \(\tau(G)\) can be an arbitrary subgroup of \(\mathbb{R}\) containing \(\tau(H)\) and of rank at most \(k+1\) (when equality occurs, \(G\) is totally ordered).

**9 Infinite rank ERS**

The following is a routine argument involving direct limits, but it allows us to prove 7.1(b) via 7.1(a), as well as results on simultaneous ERS and ECS realizations (ECRS).

**LEMMA 9.1** Let \(G_n\) be a family of dimension groups and let \(\phi^n : G_n \to G_{n+1}\) be ordered group homomorphisms that send order unit to order units to order units. Let \(G\) be the ordered group \(\lim \phi^n : G_n \to G_{n+1}\).

(a) Suppose \(H_n\) are noncyclic rank one subgroups of \(G_n\) such that \(H_n \cap G^{++} \neq 0\) for all \(n\), \(\phi^n(H_n) \subseteq H_{n+1}\), and each \(G_n\) admits an ERS realization with respect to \(H_n\). Define \(H = \lim \ker A_n\). Then \(G\) admits an ERS realization with respect to \(H\) obtained from telescoping.

(b) Suppose that \((G,u)\) is given as the direct limit of \(\psi^j : G^j \to G^{j+1}\) where each \(G^j\) is a simple dimension group with unique trace, and each admits an ECS realization. Then \(G\) admits an ECS realization with respect to its unique trace.

(c) If each of the \(G_n\) admit an ERS realization with respect to \(H_n\) that is simultaneously ECS, then \(G\) admits an ERS realization with respect to \(H\) that is also ECS.

**Proof.** (a) For each \(n\), let \(G_n \simeq \lim \phi^n_i : F_{i,n} \to F_{i,n+1}\) (where \(F_i = \mathbb{Z}[i(i,n)]\) with the simplicial ordering) be an ERS realization of \(G_n\) with respect to \(H_n\). Let \(\{e^n_{ji}\}\) be the basis standard of \(F_{i,n}\). We may of course replace \(\phi^e\) is positive, given \(i\), there exists \(m = m(i,n)\) such that for all \(j \leq f(i,n)\), \(\phi^n[e^n_{ji}] = [w^{j,i,m}, m]\) where \(w^{j,i,m}\) has all of its entries nonnegative.

Since \(\phi^n(H_n) \subseteq H_{n+1}\), we have \(\phi^n[1_f(i,n), i] = p[1_f(i,n), i] = p\) for some integers \(l > n\) and \(p \geq 1\). Thus \(\sum f(i,n) [e^n_{ji}, i] = p[1_f(i,n), l]\). Hence there exists \(m' = m'(i,n)\) such that for all \(j \leq f(i,n)\), \(\phi^n[e^n_{ji}] = [w^{j,n+1,i,m}, m']\) where \(w^{j,n+1,i,m} \geq 0\) and \(\sum_j f(m',n+1) w^{j,n+1} = 1\). This means we can define a positive matrix \(C^n_i : F^n_i \to F^{n+1}_{m'(i,n)}\) which sends \(1_f(i,n)\) to a multiple of \(1_f(m',n+1)\); in particular, \(C^n_i\) has equal row sums.

Beginning with \(i = 1\), we obtain a telescoping of the sequence for \(G_2\) by composing and then relabelling \(F^2_{m'(1,1)}\) as \(F^2_{1}\) (and telescoping and relabelling the mappings), \(F^2_{\max(m'(1,1),m'(2,1))}\) as \(F^2_{2}\), etc., so that now the matrices \(C^1_i\) go straight down, that is map \(F^1_i \to F^2_i\) (in the new notation). We may iterate this construction inductively. It is now straightforward that \(G \simeq \lim C^{m,n}_i \circ \phi^m_i : F^n_i \to F^{n+1}_{m'(i,n)}\), the order-isomorphism sending \(H\) to the obvious limit of \(H_n\), that is we have an ERS realization of \(G\) with respect to \(H\).

(b) That \(G\) has unique trace is trivial. As in the preceding argument, we may telescope the various rows, and assume that each \(\phi^j\) is implemented by nonnegative matrices \(A^j_i : F^j_i \to F^j_{i+1}\), and we
may assume that no \( A^j \) has any zero rows (in fact, since each \( G^j \) is simple, it is easy to arrange that the matrices be strictly positive).

The element \( u \) comes from some \( G^j \), so we may normalize the unique trace \( \tau_j \) of \( G^j \) at its pre-image. Then \( \tau_{j+1} \circ \phi_j = \tau_j \) (from uniqueness); hence, \( \tau^j[f, n] = \tau^{j+1}[A^j_n, n] \) (where \( f \in F^j_n \)). Since we have assumed each realization is ECS, this says \( \tau^j[e_i, n] = \tau^{j}[e_{i'}, n] \) for all standard \( \mathbb{Z} \)-basis elements \( e_i, e_{i'} \) of \( F^j_n \), for all \( j \), and in particular, \( \tau^j[f, n] = \lambda_{j,n} \sum f_i \), where \( f = \sum f_i e_i \) for some positive rational number \( \lambda_{j,n} \).

Thus for each basis element \( e_i \), we have (where \( 1^T \) represents the row of the appropriate size consisting of ones)
\[
\lambda_{j+1,n} 1^T A^j_n e_i = \tau^{j+1}[A^j_n e_i, n] = \tau^j[e_i, n] = \lambda_{j,n}.
\]
Since the last term is independent of the choice of \( i \), we have that all the \( 1^T A^j_n e_i \) are the same, as \( i \) varies. This means exactly that the column sums of \( A^j_n \) are all equal. Now the diagonal argument (as in (a)) can be applied.

(c) In the simultaneous case, we first ensure that the process in (a) is carried out, then apply the method of (b).

**Lemma 9.2** Let \( G \) be a simple dimension group with unique trace \( \tau \), and let \( H \) be a noncyclic rank one subgroup such that \( \tau(H) \neq 0 \) and \( G/H \) is torsion-free. Then we can write \( G = \cup G_n \) where \( G_n \subset G_{n+1} \) are simple dimension groups with unique trace (in the relative ordering), each of finite rank, and each containing \( H \).

*Remark.* Curiously, it is not true that every simple dimension group can be written as an increasing union of finite rank simple subgroups \([H5]\), and moreover, this can occur in rather drastic ways, e.g., with just two pure traces. It isn’t even true that every simple dimension group can be written as a direct limit of simple dimension groups each of whose pure trace spaces is finite.

*Proof.* Consider the subgroup of the reals, \( \tau(G) \); since this is countable, and \( \tau(H) \) is contained in it, we can find a countable set of elements \( \{r_n\} \) such that with \( J_n := \tau(H) + \sum_{i=1}^n r_i \mathbb{Z} \subset \mathbb{R} \), we have \( \tau(H) \leq J_n \leq J_{n+1} \) and \( \cup J_n = \tau(G) \). Select \( g_i \in G \) such that \( \tau(g_i) = r_i \).

Now \( \ker \tau \) is a countable torsion-free abelian group (and nothing else: every countable torsion-free abelian group can appear as a \( \ker \tau \)); we may thus write it as an increasing union of free abelian groups of finite rank (this is completely elementary: list the elements, then take increasing finite subsets), say \( \ker \tau = \cup T_n \), each \( T_n \) of finite rank.

Finally, set \( G_n = T_n + \sum_{1 \leq i \leq n} g_i \mathbb{Z} \). Then \( H \subset G_n \subset G_{n+1} \subset \ldots \). Since \( \tau(H) \subset \tau(G_n) \), the range of \( \tau|G_n \) is dense, and it is immediate that with the relative ordering inherited from \( G \), \( G_n \) is a simple dimension group with unique trace \( \tau \). Next let \( G_0 = \cup G_n \subset G \); we note that \( \ker \tau = \cup A_n \subset G_0 \), and \( \tau(G_0) = \tau(G) \) by construction. Hence \( G_0 = G \). Since each of \( T_n, H \), and \( \sum_{1 \leq i \leq n} g_i \mathbb{Z} \) is of finite rank, so is \( G_n \).

**Corollary 9.3** \([\text{Theorem 7.1(b)}]\) Let \( G \) be a (countable) simple dimension group with unique trace \( \tau \), and let \( H \) be a noncyclic rank one subgroup of \( G \) such that \( \tau(H) \neq 0 \) and \( G/H \) is torsion-free. Then there is an ERS realization of \( G \) with respect to \( H \).

*Proof.* By the preceding, we can write \( G = \cup G_n \) with \( H \subset G_n \), where each \( G \) is a simple dimension group with unique trace given by the restriction of \( \tau \). Since \( G/H \) is torsion-free and \( G_n/H \subset G/H \), we have \( G_n/H \) is torsion-free. Hence each \( G_n \) admits an ERS realization with respect to \( H \). The inclusion maps \( G_n \to G_{n+1} \) send \( H \) onto \( H \), and implement a realization of \( G \) as a direct limit of the \( G_n \)'s, hence 9.2 applies.

There are still questions about realizations that both ERS and ECS (simultaneously; that is, the matrices have their row sums equal, and their column sums equal). These will be addressed in
the next two sections.

10 ECRS and nearly split extensions

A realization is ECRS if it is simultaneously ECS and ERS. The trace induced by normalized multiples of the rows $1_{f(n)}$ is automatically rational-valued, and will be denoted $\tau$. If $G$ admits an ECRS realization wherein, viewed as an ERS realization, it is with respect to $H$, then we shall write, an ECRS realization with respect to $H$. It is routine to see that if $G$ admits an ECRS realization with respect to $H$ that is of size $s$ (so all the matrices have both $1_s$ and $1_s^T$ as their right and left Perron eigenvectors respectively), then $|\tau(G)/\tau(H)|$ divides $s$: the image of the trace on $G$ is $\cup(1/p_{j+1} \ldots p_2)Z$, while on the image of the subgroup $\cup[1_s,k]Z$, it is $\cup(s/p_{j+1} \ldots p_2)Z$, and the one by the other is a quotient of $Z/sZ$, hence has order dividing $s$.

This puts a fairly stringent condition on the matrix sizes required for bounded ECRS realizations. Of course, unbounded ECRS realizations can be obtained as direct limits (obtained from unions) of bounded ones (exactly as in the case of ERS realizations).

**Lemma 10.1** Suppose $t : G \to U \subseteq Q$ is obtained as the direct limit $G \simeq \lim C_n : Z^s \to Z^s$ where the map $t$ is obtained from a common left eigenvector $w$ of all the $C_n$ (with corresponding eigenvalue $c_{n+1}$), via $t[a,n] = wa/c_1 \ldots c_n$. Suppose in addition, the $C_n$ have a common right eigenvector $v$ and $vw \neq 0$. Then the extension $0 \to \ker t \to G \to U \to 0$ is nearly split.

**Proof.** We note that the eigenvalue of $v$ for $C_n$ must be the same as that of $w$, $c_{n+1}$, since $vw \neq 0$. Set $H = \cup[v,n]Z \subseteq G$. Then $\cup(c_2 \ldots c_n)^{-1}vwZ \subseteq H$, and this is obviously of finite index in $U = t(G) = \cup(c_1 \ldots c_n)^{-1}Z$. Thus $\ker t \oplus H$ is of finite index in $G$, so the extension is nearly split.

When freeness occurs, then the index of the image of $\ker t$ in $J/H$ is finite. In that case, $\ker t \oplus H$ has finite index in $J$, so that the extension $\ker t \to J \to U$ is nearly split. Thus we have the following.

**Lemma 10.2** For any simple dimension group of finite rank with unique trace, which is rational-valued, $t : G \to U \subseteq Q$ such that $\ker t$ is free, and admits a bounded ERS realization, the extension $\ker t \to G \to U$ is nearly split.

Although freeness of $J/H$ implies $J \to J/H$ splits yielding a group isomorphism $J \simeq Z^{s-1} \times H$, this does not imply that $J \to U$ splits. In the stationary and ECRS example, $G = \lim \begin{pmatrix} 1 & 2 \\ 1 & 1 \end{pmatrix} : Z^2 \to Z^2$, we have $\tau(G) := U = Z[1/3]$ and $\tau(H) = 2Z[1/3]$ (where $H = \cup_n[1_2,n]Z$), so the extension $0 \to Z \to G \to U \to 0$ does not split, although $G \simeq Z \oplus Z[1/3]$ (as abelian groups) and $t|H \neq 0$. As we will see in the next section, this is fairly typical.

Dropping the strong assumption that $\ker t$ or $J/H$ be free, a sufficient condition for the extension $J \to U$ to be nearly split, that is, $\ker t \oplus H$ be of finite index in $J$, is that the image of $\ker t$ be of finite index in $J/H$.

This places restrictions on realizations of dimension groups by commuting primitive matrices. For example, if $G$ is a simple dimension group with unique trace, and it is realized by commuting nonnegative matrices, we can telescope and kill off zero rows, and arrange that the matrices additionally be primitive. Hence they will have common left and common right Perron eigenvectors and the unique trace is determined from the left Perron eigenvector. Thus the corresponding extension $0 \to \ker t \to G \to \tau(G) \to 0$ given by the image of the trace must be nearly split.

If for example, $\ker \tau = Z^k$ and $\tau(G) = U$ has an interesting supernatural number (e.g., every prime has multiplicity at most one), then the set of isomorphism classes of nearly split extensions within the class of extensions of $Z^k$ by $U$ is negligible. So most extensions cannot be given by
commuting families of matrices. Certainly a realization of bounded matrix size that is both ERS and ECS qualifies for 10.1, as does a stationary dimension group.

In particular, Example 10.4 below is a simple dimension group with unique and rational-valued trace, of rank two, that cannot be realized by any sequence of (square) primitive matrices which have common right and common left eigenvectors; in particular, it cannot be realized by a bounded sequence of simultaneously ERS and ECS primitive matrices. It can be realized by a sequence of increasing size strictly positive rectangular matrices, \( M_n : \mathbb{Z}^{f(n)} \to \mathbb{Z}^{f(n+1)} \), where \( f(n) \to \infty \), and each \( M_n \) is both ERS and ECS, as we will see in the next section. It can be shown that for any such realization, \( f(n+1)/f(n) \) must be divisible by 3 for infinitely many \( n \).

There is a trivial case in which the extension must be nearly split.

**LEMMA 10.3** Suppose \( t : G \to U \) is a finite rank torsion-free group such that \( U = \mathbb{Z}[1/p] \) for some prime \( p \). If \( G \) contains a noncyclic rank one subgroup that is disjoint from \( \ker t \), then the extension \( 0 \to \ker t \to G \to U \to 0 \) is nearly split.

**Remark.** Stationary examples show that such extensions need not be split.

**Proof.** Obviously, \( t \) induces an embedding \( H \to t(G) \). The extension is nearly split because every noncyclic subgroup of \( \mathbb{Z}[1/p] \) is of finite index!

Let \( q \) be a prime; all noncyclic subgroups of \( U = \mathbb{Z}[1/p] \) are therefore of finite index. Hence, if in the situation of the lemma above, \( t(G) \) is isomorphic to \( \mathbb{Z}[1/p] \) (and \( H \) is not cyclic, which is part of the hypotheses), then the corresponding extension is nearly split (Lemma 10.3 below). Another situation arises when the realization is by commuting matrices, or more generally, when the implementing matrices have common left eigenvector and common right eigenvector. In the situation arising from positive matrices, these must be the Perron eigenvectors, hence correspond to the same eigenvalue (for each \( n \)).

**EXAMPLE 10.4** An example of a simple dimension group with unique, rational-valued trace, which is ERS-realizable, but for which the corresponding extension, \( 0 \to \ker t \to G \to t(G) = U \to 0 \), is not nearly split.

We construct a simple example for which the subgroup \( H \simeq \mathbb{Z}[1/3] \) and \( t(G) \simeq \mathbb{Z}[1/6] \). In this case, the extension \( \mathbb{Z} \to G \to \mathbb{Z}[1/6] \) is not nearly split, but the corresponding dimension group admits an ERS realization (of size three). It also admits an ECS realization, but cannot have a simultaneously ECS and ERS realization of bounded size (since that would imply common left and common right eigenvectors, which entails nearly splitting, see Lemma 10.1 below).

Construct an extension \( 0 \to \mathbb{Z} \to G_0 \to \mathbb{Z}[1/2] \to 0 \) for which there are no 2-divisible elements in \( G_0 \), equivalently, the extension is not nearly split (as 2 is a prime, we can get away with this). Let \( t_0 : G \to \mathbb{Z}[1/2] \) denote the map. We may regard \( G_0 \) as a subgroup of its divisible hull, which is of course \( \mathbb{Q}^2 \); \( t_0 \) extends uniquely to a group homomorphism \( T : \mathbb{Q}^2 \to \mathbb{Q} \). Pick an element of \( G \), \( u \in t_0^{-1}(1) \), and form \( G = G + u\mathbb{Z}[1/3] \) (inside \( \mathbb{Q}^2 \)). Then \( T \) restricts to a map, called \( t : G \to \mathbb{Q} \), with values in \( \mathbb{Z}[1/2] + \mathbb{Z}[1/3] = \mathbb{Z}[1/6] \).

Now we show that \( \ker t = \ker t_0 = \mathbb{Z} \), so that \( \mathbb{Z} \to G \to \mathbb{Z}[1/6] \) is the corresponding extension. Elements of \( G \) are of the form \( g = g_0 - um/3^k \) for \( g_0 \in G_0 \), \( m \) an integer, and \( k \) a nonnegative integer. If \( t(g) = 0 \), then \( t(g_0) = m/3^k \); there exist integers \( l \) and nonnegative \( j \) such that \( t(g_0) = l/2^j \). Hence \( 3^k \lvert l \rvert \). This forces \( 3^k \) to divide \( m \), so \( g \in G_0 \). Hence \( \ker t_0 = \ker t \).

Next, we show that \( G \) contains no 2-divisible elements. Select \( g = g_0 + um/3^k \) in \( G \) with \( g_0 \in G_0 \) as in the previous paragraph. If \( g \) were 2-divisible, for all positive integers \( l \), we could solve the equations

\[
g_0 + \frac{um}{3^k} = 2^l \left( g_l + u \frac{m_l}{3^k \lvert l \rvert} \right),
\]
where $g_l \in G_0$; we may assume that $m$ and $m_l$ are relatively prime to 3. Suppose for now that $k, k(l) > 0$. Fix $l$ and multiply by $3^k$. This yields $3^k g_0 + m u = 3^k 2^l g_l + 2^l 3^{k-l} m_l u$. Thus $2^l m_l 3^{k-l} u \in G_0$, so its value at $t_0$, $2^l m_l 3^{k-l} u \in \mathbb{Z}^{[1/2]}$. Thus if $k(l) > k$, we must have 3 dividing $m_l$, a contradiction. Thus $k \geq k(l)$.

This yields $3^k (g_0 - 2^l g_l) = u (m - 2^l 3^{k-l})$. Evaluating at $t_0$, we obtain $3^k t_0 (g_0 - 2^l g_l) = m - 2^l 3^{k-l}$. If $k > k(l)$, then 3 divides $m$ (as the values of $t_0$ lie in $\mathbb{Z}^{[1/2]}$, again a contradiction. Hence $k = k(l)$, so that $m - 2^l \equiv 0 \mod 3^k$. Since $m$ and $k$ are fixed, but the mod 3 equivalence classes of $2^l$ alternate between 1, 2, this is impossible.

Let us dispose of the remaining possibilities; first, if $k = 0$, we have the equations $g + mu = 2^l g_l + 2^l m_l 3^{k-l} u$, so $2^l m_l 3^{k-l} u \in G_0$; evaluating at $t_0$, we obtain $2^l m_l 3^{k-l} \in \mathbb{Z}^{[1/2]}$; since 3 does not divide $m_l$, we must have $k(l) = 0$ for all $l$. But then the element $g + mu = 2^l (g_l + m_l u)$ is 2-divisible within $G_0$, a contradiction.

Next, if $k(l) = 0$ for one value of $l > 0$, then $um 3^{-k} \in G_0$, which forces $k = 0$ (evaluate at $t_0$ again), and we are in the preceding case.

Thus $G$ contains no 2-divisible subgroup. Since any subgroup of finite index in $\mathbb{Z}^{[1/6]}$ must be 2-divisible, the extension cannot be nearly split. On the other hand, the subgroup $H = u \mathbb{Z}^{[1/3]}$ of $G$ is 3-divisible, so there is a group realization of the form described in the lemma, that is, common right eigenvector, and a corresponding ERS realization for the dimension group. But there cannot be a dimension group realization that is both ERS and ECS simultaneously when the matrix size is bounded.

In terms of the $B_n$, a necessary condition for $G \rightarrow \tau(G)$ to split is that if $d_n = |\det B_n|$, then $H$ is of finite index in $\cup(1/\prod_{i=1}^n d_i) \mathbb{Z} + t(H)$ (e.g., if $p_{n+1}$ are powers of the same prime $p$, this would force almost all the $d_n$ to be powers of $p$). But this is not sufficient.

### 11 ECRS

Suppose that $(G, H)$ is a simple dimension group with noncyclic rank one subgroup such that $G/H$ is torsion free, and in addition that $G$ admits a unique trace $\tau$. Moreover, assume that $\tau(G) := U$ is a subgroup of the rationals, and $\tau(H) \neq 0$. These conditions (except the uniqueness of the trace) are necessary for an ECRS realization of $G$ with respect to $H$.

The converse is not quite true. We will show that if $U$ is $p$-divisible for some prime $p$ (that is, at least one prime has infinite multiplicity in the supernatural number of $U$), then the converse is true. However, in case $U$ is not $p$-divisible for any prime $p$, then an ECRS realization exists with respect to $H$ exists if and only if $\text{rank} G \leq |\tau(G)/\tau(H)|$. In this formulation, we allow $\infty$ as a value, and this corresponds to unbounded realizations. In the cases that $\text{rank} G < \infty$, we have some control on the size of the realization.

In particular, if $\tau(G)$ has no primes with infinite multiplicity, and $\text{rank} G > 1$ (the case of $\text{rank} G = 1$ is trivial), then the split case, $G = U \oplus \ker \tau$ with the strict ordering from the projection onto $U$, does not admit an ECRS realization. In particular, if $\ker \tau$ is free of finite rank, by earlier results, then $G$ admits both an ECS realization and an ERS realization with respect to $H$, of the same size, but no ECRS realizations at all.

We begin with the case that $|\tau(G)/\tau(H)| < \infty$. This of course implies that $G \rightarrow U$ is nearly split. For now, we also assume $G/H$ is free and finite rank. Then we can write $G = H \oplus \mathbb{Z}^k$ (with $\tau(H) = n \tau(G)$ for some integer $n$), but we must recall that $\ker \tau$ is not the copy of $\mathbb{Z}^k$ that appears as a direct summand.

For a row or column $v$ consisting of integers, the content of $v$, denoted $c(v)$ is the greatest common divisor of the nonzero entries of $v$.

**Lemma 11.1** Let $\lambda, p_{n+1} > 1$ be positive integers such that for all $n$, $p_{n+1} \equiv 1 \mod \lambda$, and let $\rho \in \mathbb{Z}^k$ be a vector such that $(c(\rho), \lambda) = 1$; set $q_n = p_2 \cdots p_n$. For each $n$, define

27
\[ M_n = \begin{pmatrix} p_{n+1} & 0 \\ 0 & 1_h \end{pmatrix}, \quad \text{and } r^n = (\lambda/p_2 \cdot \ldots \cdot p_n, \rho) \text{ for } n > 1, \quad \text{and } r_1 = (\lambda, \rho) \in \mathbb{Z}^{1 \times (s+1)}; \]

with \( G = \lim M_n \) (as abelian groups) define \( t : G \to \mathbb{Q} \) by \( t[w, n] = r^n w \). Then there exist \( v_n = \rho(p_{n+1} - 1)/\lambda, y_n = \rho(q_n - 1)/\lambda \in \mathbb{Z}^{1 \times s} \) such that for all \( n \), the following transition matrices are

\[
\begin{array}{cccccc}
Z^{k+1} & \xrightarrow{M_1} & Z^{k+1} & \xrightarrow{M_2} & \cdots & \xrightarrow{M_n} & Z^{k+1} & \cdots \\
\downarrow \rho_{E_1} & & \downarrow \rho_{E_2} & & \cdots & & \downarrow \rho_{E_n} & \\
\downarrow \rho_{E_1} & & \downarrow \rho_{E_2} & & \cdots & & \downarrow \rho_{E_n} & \\
\end{array}
\]

and in addition, \( r^i M_i = r^{i-1} \) and \( r^1 \) is a common left eigenvector of all the matrices \( (p_{n+1} v_n) \), with corresponding eigenvalue \( p_{n+1} \).

Under the assumptions of the lemma, set \( v_0 = (1, 1, 0, \ldots, 0) \in \mathbb{Z}^k \). There exists \( E_0 \in \text{GL}(k, \mathbb{Z}) \) such that \( \rho E_0^{-1} = c(\rho)(1, 0, \ldots, 0) \). Then

\[
v_0 (1 - p_{n+1}) + \frac{p_{n+1} - 1}{\lambda} \rho E_0^{-1} = \frac{p_{n+1} - 1}{\lambda} (c(\rho) + \lambda, \lambda, 0, \ldots, 0).
\]

Now \( \gcd \{\lambda, c(\rho) + \lambda\} = \gcd \{\lambda, \lambda(c(\rho))\} = 1 \). There thus exists \( E_1 \in \text{GL}(k, \mathbb{Z}) \) such that \( (c(\rho) + \lambda, \lambda, 0, \ldots, 0) E_1^{-1} = (1, 1, \ldots, 1) \). Setting \( v = v_0 E_0^{-1} E_1 \) and \( E = E_1 E_0 \) then for all \( n \), \( v(1 - p_{n+1}) + \rho(c(\rho) + \lambda, \lambda, 0, \ldots, 0) E = \frac{p_{n+1} - 1}{\lambda} (1, 1, \ldots, 1) \).

Let \( u = (1, 1, \ldots, 1) \in \mathbb{Z}^k \). Now for any choice of integer \( p \) (such that \( \lambda \) divides \( p - 1 \)), we have

\[
\begin{pmatrix} 1 & v \\ 0 & E \end{pmatrix} \begin{pmatrix} p_{n+1} & 0 \\ 0 & I \end{pmatrix} \begin{pmatrix} 1 & v \\ 0 & E \end{pmatrix}^{-1} = \begin{pmatrix} p & pv E^{-1} + \frac{p_{n+1} - 1}{\lambda} (\rho + v) E^{-1} \\ 0 & E \end{pmatrix} = \begin{pmatrix} p & \frac{p_{n+1} - 1}{\lambda} u \\ 0 & I \end{pmatrix}.
\]

Hence, after conjugating every \( \begin{pmatrix} p_{n+1} & v_n \\ 0 & I \end{pmatrix} \) by the same matrix, we reduce to the case that the transition matrices are \( \begin{pmatrix} p_{n+1} & p_{n+1} - 1 \\ 0 & I \end{pmatrix} \), having \( (\lambda, \rho E^{-1}) \) as common eigenvector, and since it is
an eigenvector of the matrices, it follows that \( \rho E^{-1} = (1, 1, \ldots, 1) \in \mathbb{Z}^k \), and the trace on the group with homomorphism is given by the suitably normalized eigenvector, \((\lambda, 1, 1, \ldots, 1)/q_n\) at the \(n\)th level.

At this stage, we note that if \( \lambda = k + 1 \), there is a simple finishing argument. Add the first row of each matrix, that is, \( (p_n + 1, \frac{1}{\lambda} \sum_{j=1}^{k} a_{1j}) \) to all the other rows, and then subtract all the columns from the first. This amounts to conjugating every one of the matrices with same elementary matrix. The entries are suddenly strictly positive, and since the inner product of the left and right unimodular Perron eigenvectors is \( \lambda = k + 1 \), and they consist strictly positive of strictly positive integers, they must all be exactly one. (We will review this argument.)

We record the following elementary criterion.

**Lemma 11.2** Let \( A \) be a primitive integer matrix of size \( s \), whose Perron eigenvalue is an integer, and let \( V \) and \( W \) be the corresponding left and right Perron eigenvectors consisting of integers, such that \( c(V) = c(W) = 1 \). If \( VW = s \), then all row and column sums are equal.

**Proof.** The Perron eigenvectors consist of strictly positive real numbers, and since they are all integers, each is at least one; as they are of size \( s \), the only way \( VW \) is as small as \( s \) is if every entry of each is one. Hence the column and row sums are all equal.

In the case that \( \lambda > k \), our strategy is to embroider a block of \( \lambda - k - 1 \) zero rows and corresponding nonzero columns (or zero columns and nonzero rows) around each of our current matrices in such a way that the resulting matrices still have common left and common right eigenvectors corresponding to \( p_n \), and such that their unimodularized inner product (the \( VW \) of Lemma 11.2) is still \( \lambda \). Then we conjugate all the matrices (with the same matrix), so that as in the \( \lambda = k + 1 \) case outlined above, the resulting matrices are primitive.

The embroidered pieces actually vary in \( n \) (in order to guarantee that the eigenvectors do not vary in \( n \)), and must be carefully chosen.

If \( \lambda < k + 1 \), we run into a technical difficulty when we try this, and indeed, an easy result shows that it is impossible to proceed.

Suppose \( \lambda \geq k + 1 \); this bifurcates into \( \lambda - (k - 1) \leq k \) and \( \lambda - (k - 1) \geq k \) (for which the treatments are similar).

We first justify the process of embroidering; this is elementary, and completely derivative of symbolic dynamical techniques.

**Lemma 11.3** Let \( M_n := (A_n B_n) \) be block partitions of \( s \times s \) integer matrices (with \( A_n \) square of size \( a \) and \( D_n \) square of size \( s - a \)) of full rank, \( s \). Form the \( S \times S \) matrices

\[
M'_n = \begin{pmatrix} A_n & B_n & 0 \\ C_n & D_n & 0 \\ 0 & X_n & 0 \end{pmatrix}, \quad M''_n = \begin{pmatrix} A_n & B_n & Z_n \\ C_n & D_n & Y_n \\ 0 & 0 & 0 \end{pmatrix}
\]

where \( X_n = (S - s) \times s, Y_n = s \times (S - s) \), and \( Z_n = a \times (S - s) \) integer matrices. Then there are natural isomorphisms \( G' = \lim M'_n \rightarrow G = \lim M_n \) and \( G \rightarrow G'' = \lim M''_n \), induced by \( \mathbb{Z}^S \rightarrow \mathbb{Z}^s \) (projection onto first \( s \) coordinates) and the natural inclusion of \( \mathbb{Z}^s \) in \( \mathbb{Z}^S \). Moreover, if \( v = (\alpha, \beta) \) is a left eigenvector for \( M_n \) (with corresponding block decomposition), then \( v' = (\alpha, \beta, 0) \) is a left eigenvector for \( M'_n \).

**Proof.** Let \( V \) be the subgroup of \( \mathbb{Z}^S \) with zeros in the top \( s \) entries, and let \( \phi : \mathbb{Z}^S \rightarrow \mathbb{Z}^s \) be the projection onto the top \( s \) coordinates, so that \( VU = \ker \phi \). Then \( \phi M'_n = M_n \phi \), so \( \phi \) induces a group homomorphism between the limit groups, which is clearly onto. Since rank \( M_n = s \) and this
is full, it easily follows that rank $M'_n = s$, hence rank $G' \leq s$. As $G' \to G$ is onto, and the rank of the latter ($s$) is at least as large as that of the former, the map must be one to one.

Define $\psi : \mathbb{Z}^s \to \mathbb{Z}^S$ to be the inclusion (viewing $\mathbb{Z}^s$ as the subgroup whose bottom $S - s$ entries are zero. Then it is trivial that $M''_{n} \psi = \psi M_{n}$, so $\psi$ induces a map $G'' \to G$, which is obviously one to one. Since $M''_{n}(\mathbb{Z}^S) \subset \phi(\mathbb{Z}^S)$, the map is onto (in the direct limit).

The eigenvector property is trivial.

First consider the case $\lambda - k - 1 \leq k$ (and $\lambda \geq k + 1$). Relabel our current matrices

$$M_n = \begin{pmatrix} p_{n+1} & \frac{p_{n+1}-1}{\lambda} u \\ 0 & I \end{pmatrix};$$

this has left eigenvector $(\lambda, u)$ and right eigenvector $(1, 0, \ldots, 0)^T$ for $p_{n+1}$ (recall $u = (1, 1, 0, \ldots, 1)$). Here, $a = 1$ and $s = k + 1$. We set $X_n = (I_{\lambda-k-1} 0)$ (the big zero is the block of size $(\lambda - k - 1) \times (k - \lambda)$, so $X_n$ is $(\lambda - k - 1) \times (k - (\lambda - k - 1))$, so we have

$$M'_n = \begin{pmatrix} p_{n+1} & \frac{p_{n+1}-1}{\lambda} u & 0 & 0 & \ldots & 0 \\ 0 & 0 & 0 & \ldots & 0 & 0 \\ 0 & 0 & 0 & \ldots & 0 & 0 \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots \\ 0 & 0 & 0 & \ddots & \ddots & \ddots \\ 0 & 0 & 0 & \ddots & \ddots & \ddots \end{pmatrix}.$$

Now we perform the elementary column operations which simply add the first $\lambda - k - 1$ columns of the second block to their counterparts in the third (so the columns get shifted to the right by $k$). The inverse operation is to subtract the corresponding rows of the third block from their counterparts in the second. The two operations together amount to simultaneous conjugation by the same element of GL$(\lambda, \mathbb{Z})$, and lead to the following matrices,

$$\begin{pmatrix} p_{n+1} & \frac{p_{n+1}-1}{\lambda} (1, 1, \ldots, 1) \\ 0 & 0 & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & \ldots & \ldots & \ldots & \ldots \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots \\ 0 & 0 & \ldots & \ddots & \ddots & \ddots \\ 0 & 0 & \ldots & \ddots & \ddots & \ddots \end{pmatrix}.$$

Now we add the first row to each of the others, and correspondingly subtract all the columns from the first; again, these are implemented simultaneously in $n$ by a single product of elementary matrices, and results in all the entries being nonnegative, and moreover, all the matrices are primitive (since the first column and the first row are strictly positive), and with the same zero pattern (so products will still be primitive). Call these matrices $A_n$.

The content one left and right eigenvectors of $M'_n$ for $p_{n+1}$ are $V' = (\lambda, u, 0)$ and $W' = (1, 0, \ldots, 0)^T$, hence their inner product $V'W' = \lambda$. This is preserved by simultaneous conjugation; as each $A_n$ is primitive of size $\lambda$, it follows from 11.2 above that the left and right Perron eigenvectors of $A_n$ consist entirely of ones, hence the column and row sums are equal. The simultaneous conjugations obviously induce isomorphism of the groups with homomorphism induced by the common left eigenvector, so we have a realization of $G$ as lim $A_n$, which is ECRS.

In case $\lambda = k + 1$, we skip the embroidery ($X_n$), and just proceed via conjugations with elements of GL$(k + 1, \mathbb{Z})$. If $\lambda - k - 1 = k$, then there are no extra zero blocks, and the same process works. In this case, the realization is ultrasimplicial.

The process for $\lambda \geq k + 1$ and $\lambda - k - 1 \geq k$ (that is, $\lambda \geq 2k + 1$) is almost the same. We embroider the matrix with $\lambda - k - 1$ columns of zeros at the right (as we did before) and the same
number of rows at the bottom, and with $X_n$ being $\begin{pmatrix} 1_k \\ 0 \end{pmatrix}$. Then we add the corresponding columns to the third block and subtract the rows from the second analogously with what we did before, and we can again just perform the last operation, adding the first row to all the others and subtracting the columns from the first.

So far, we have the following.

**PROPOSITION 11.4** Let $G$ be a simple dimension group of finite rank containing a rank one noncyclic subgroup $H$ such that $G/H$ is free and $H \cap G^{++} \neq \emptyset$, and suppose $G$ has a unique trace $\tau$, and $\tau(G)$ is a rank one subgroup of $Q$ whose supernatural number contains no primes of infinite multiplicity. Then $G$ admits an ECRS realization of size $\lambda := |\tau(G)/\tau(H)|$ with respect to $H$ if $\lambda \geq \operatorname{rank} G$.

**Proof.** If rank $G = 1$, then there is almost nothing to do. Otherwise, $\lambda > 1$. For subgroups $V \subset U$ of $Q$, $|U/V| < \infty$ implies there exists $m$ such that $V = mU$, and if $U$ has no primes of infinite multiplicity, then $|U/mU| = m$. Set $U = \tau(G)$, and discard from the supernatural number all the primes (including multiples) that divide $\lambda$; the resulting subgroup $U_0$ is isomorphic to $U$, and correspondingly, $U_0/mU_0$ is isomorphic to $U/mU$. Consider the set of primes (together with their multiplicities) dividing $U_0$; since they are all relatively prime to $\lambda$, we may telescope them to obtain sequence of positive integers representing $U_0$, $\{p_n\}_{n=1}^{\infty}$, such that $p_{n+1} \equiv 1 \pmod{\lambda}$.

Since $G/H$ is free, the extension $\ker \tau \rightarrow G \rightarrow U$ is nearly split. Hence we can write $G = H \oplus \mathbb{Z}^{k}$, and the trace, given by the row $r_1$ at the first level, is of the form described in the top row of the statement of Lemma 11.1. The bottom row of the statement yields a representation of $G$ as a direct limit of abelian groups, with group homomorphism induced by the common left eigenvector, $[w, n] \mapsto r^1 w/q_n$.

The comment subsequent to the lemma allows us to assume that the realizing matrices are all in the form $\begin{pmatrix} p_{n+1} & \cdots & p_n \\ 0 & \cdots & 1 \end{pmatrix}$, having common left eigenvector $(\lambda, 1, 1, \ldots, 1)$. Now the embroidery process, together with 11.3, and subsequent simultaneous conjugation, gives an isomorphism of groups with group homomorphism to the direct limit of primitive matrices with equal row and column sums, as described above.

Now we show that if $U$ has no primes of infinite multiplicity, then $|t(G)/t(H)| \geq \operatorname{rank} G$ is a necessary condition for $G$ to have a bounded ECRS realization.

**LEMMA 11.5** Let $U$ be a noncyclic subgroup of rank one with no primes of infinite multiplicity. If $l$ is an integer exceeding 1, then $U/lU \simeq \mathbb{Z}/l\mathbb{Z}$.

**Proof.** First, if $j > 1$, then $U \neq jU$, otherwise $xj$ is a group automorphism of $U$, hence $x1/j$ is also an automorphism, and it easily follows that if $p$ is a prime dividing $j$, it must have infinite multiplicity in $U$. If follows that if $j$ properly divides $l$, then $jU \neq lU$. As every subgroup of finite index in $U$ is of the form $nU$ for some integer $n$, there is an obvious bijection between the intermediate subgroups $lU \subset U_0 \subset U$ and those of $l\mathbb{Z} \subset \mathbb{Z}_0 \subset \mathbb{Z}$, thus the map $\mathbb{Z} \rightarrow U \rightarrow U/lU$ has kernel $l\mathbb{Z}$, and is obviously onto.

Suppose $G$, with unique trace, has a realization as $\lim A_n : \mathbb{Z}^s \rightarrow \mathbb{Z}^r$ which is ECRS, where $H$ is identified with $\cup [1, n] \mathbb{Z}$. Then the trace is given by the normalized constant row, and we see immediately that $\tau(H) = st(G)$. Hence if $\tau(G)$ has no primes with infinite multiplicity, we have $|\tau(G)/\tau(H)| = s \geq \operatorname{rank} G$. However, $\tau(G)/\tau(H)$ is an invariant of $(G, H)$, as $G$ has unique trace.

**COROLLARY 11.6** Suppose $G$ is a finite rank simple dimension group with unique trace $\tau$, such that $\tau(G)$ is a rank one noncyclic subgroup of $\mathbb{R}$ with no prime divisors of infinite multiplicity. If $G$ admits an ECRS representation with respect to $H$, then $\tau(G)/\tau(H)$ is finite and must be at least as large as rank $G$. 

31
Proof. Finiteness comes from the extension $G \rightarrow \tau(G)$ being nearly split (10.1). The rest is from the comment just above.

THEOREM 11.7 Suppose that $G$ is a finite rank simple dimension group with unique trace $\tau$, having rational values, and $H$ is a rank one noncyclic subgroup such that $G/H$ is free and $\tau(G)$ is not $p$-divisible for any prime $p$. Then $G$ admits an ECRS realization (with respect to $H$) if and only if $|\tau(G)/\tau(H)| \geq \text{rank } G$.

For example, if $G = U \oplus \mathbb{Z}^k$ where $U$ is an infinite multiplicity-free noncyclic subgroup of $\mathbb{Q}$, and we impose the strict ordering induced by the projection onto $U$, then the extension is split, and obviously $|\tau(G)/\tau(H)| = 1$; so $G$ admits an ECRS realization (there is only one choice for $H$, namely $U$) if and only if $k = 0$, and the latter is uninteresting. If instead, we impose as trace $\tau(u,v) = lu + v_1 (ru+ \text{the first entry of } v)$, then $\tau(G) = U$, but $\tau(U) = U$, so that $|\tau(G)/\tau(H)| = l$, then $G$ admits an ECRS realization if and only if $l \geq k + 1 = \text{rank } G$.

Now we assume $G$ simple dimension group with unique trace $\tau$, $\tau(G)$ is rank one [and being dense, is noncyclic] $H$ is a noncyclic rank one subgroup of $G$ such that $G/H$ is torsion-free, and $\tau(H) \neq 0$. We permit rank $G$ and $\tau(G)/\tau(H)$ to be infinite.

THEOREM 11.8 Suppose that $G$ is a simple dimension group with unique trace $\tau$, the value group of $\tau$ is $\tau(G) = U \subseteq \mathbb{Q}$, and $U$ has no primes of infinite multiplicity. Assume that $H$ is a rank one noncyclic subgroup of $G$ such that $\tau(H) \neq 0$ and $G/H$ is torsion-free. Then $G$ admits an ECRS realization with respect to $H$ if either of the conditions below hold.

(a) $|\tau(G)/\tau(H)| = \infty$, regardless of rank $G$ (which can be infinite); in this case the realization must be unbounded.

(b) $\infty > |\tau(G)/\tau(H)| \geq |\text{rank } G|$, and in this case, the realization is bounded.

Proof. First we note that if $U \cap U = \emptyset$ are noncyclic rank one subgroups of $\mathbb{Q}$, then there exists an infinite increasing chain of subgroups, $U_0 \subseteq U_1 \subseteq U_2 \subseteq \cdots \subseteq U$ such that $U = \cup U_i$ and $|U/U_i| < \infty$. Applying this with $U_0 = \tau(H)$ and $U = \tau(G)$, set $G_i^n = \tau^{-1}(U_i)$. Moreover, $U_i/U_0$, being finite, is cyclic. Hence there exists $g_i \in G_i$ such that $\tau(G_i) = \tau(H) + \tau(g_i)\mathbb{Z}$.

Since ker $\tau$ is torsion free, we may find an increasing union of finitely generated subgroups $F_1 \subseteq F_2 \subseteq F_3 \subseteq \cdots$ such that ker $\tau = \cup F_i$; by interposing as many equalities as we like, and telescoping the $G_i$, we may assume $j + \text{rank } F_j < |\tau(G_j)/\tau(H)|$.

Set $G_j = F_j + H + \sum_{i \leq j} g_i\mathbb{Z}$; then $G_j \subseteq G_{j+1}$ and $G = \cup G_j$. Moreover, rank $G_j \leq \text{rank } F_j + 1 + j \leq |\tau(G_j)/\tau(H)|$. In addition, $G_j/H$ is finitely generated, and a subgroup of $G/H$, hence is torsion-free, hence is free. Since $H$ is dense in $G$, $G_j$ with the relative ordering is a simple dimension group with unique trace, the restriction of $\tau$. Thus ker $\tau \cap G_j \rightarrow G_j \rightarrow \tau(G_j)$ is nearly split, and the condition $|\tau(G_j)/\tau(H)| \geq \text{rank } G_j$ ensures that $G_j$ has a bounded ECRS realization with respect to $H$.

Since $G$ is obviously the direct limit of $G_j$, by 9.1(c), $G$ has an ECRS realization with respect to $H$. In case (a), it must be unbounded (since bounded ERS realizations yield $|\tau(G)/\tau(H)| < \infty$). In case (b), the realization is obtained from telescoping a uniformly bounded family of realizations (using the method of 9.1(c)), so is bounded (or see the observation in the next paragraph).

Now we have an elementary observation about unbounded ECRS realizations, when $\tau(G)$ has no infinite prime divisors. Suppose $G = \lim A_n : \mathbb{Z}^{|(n)|} \rightarrow \mathbb{Z}^{|(n+1)|}$ is an ECRS realization, with sup $f(n) = \infty$. The sequence of row vectors $(1^T \bar{f}(n)/p_2 \cdots p_n)$, where $1^T \bar{f}(n)A_n = 1^T \bar{f}(n+1)p_{n+1}$ (defining $p_{n+1}$, the constant column sum of $A_n$), induces a trace $\tau[y,n] = 1^T \bar{f}(n)y/p_2 \cdots p_n$. If we assume that $G$ is simple with unique trace; necessarily, this is $\tau$. Then $\tau(G)$ is $\cup \text{n}_1/p_2 \cdots p_n$. 32
With $H$ identified with $\cup_n \mathbb{1}_{f(n)} \cdot n \mathbb{Z}$, we see that $|\tau(G)/\tau(H)| \geq f(n)$ for all $n$ (this follows from no $p$-divisible subgroups for all primes $p$).

Combining everything in sight, we have the following complete characterization of ECRS realizations when $\tau(G)$ has no $p$-divisible elements for any prime $p$.

**THEOREM 11.9** Let $G$ be simple dimension group with unique trace, $\tau$. Suppose that $\tau(G)$ is a subgroup of $\mathbb{Q}$ whose supernatural number has no primes of infinite multiplicity. Let $H$ be a rank one noncyclic subgroup of $G$ such that $\tau(H) \neq 0$ and $G/H$ is torsion-free. Then $G$ admits an ECRS realization with respect to $H$ if and only if rank $G \leq |\tau(G)/\tau(H)|$; this includes the case that one or both of rank $G$ and $|\tau(G)/\tau(H)|$ are infinite. Finally, every ECRS realization is of size $|\tau(G)/\tau(H)|$ (that is, unbounded if and only if $\tau(G)/\tau(H)$ is infinite).

When $G$ is $p$-divisible for some prime, the situation is different; no restriction on $\tau(G)/\tau(H)$ is required.

Now we assume that $t(G)$ is divisible by $p^\infty$ and to begin with, we also assume $G/H$ is free and $\lambda := |t(G)/t(H)| < \infty$. If $p$ is any prime infinitely dividing $t(G)$, then it also divides $t(H)$; hence $\gcd(\lambda, p) = 1$ for any prime $p$ dividing $H$ (which is isomorphic to $t(H)$). If $\lambda = 1$, we are in the split case, for which there is an interesting argument, obtaining a realization by commuting matrices.

Set $G = U \oplus \mathbb{Z}^k$ with the projection onto $U$ as the unique trace—this is the split case—we show that $G$ admits a bounded ECRS realization (with respect to $H = U$, the only possible choice for $H$) under the assumption that $U$ is $p$-divisible for some prime $p$.

Find a power, $q = p^a > k - 1$. Then the matrix $M := \begin{pmatrix} q & 0 \\ 0 & -I_k \end{pmatrix}$ (note the appearance of the negative of the identity matrix) satisfies all the conditions of $[\text{BoH}, \text{xxx}]$. Hence there exists a primitive matrix $M'$ that is algebraically shift equivalent to $M$. By $[\text{M}, \text{xxx}]$, there exists a primitive matrix $A$ having equal row and column sums (so that $1^T$ and $1$ are respectively left and right Perron eigenvectors of $A$ for the eigenvalue $q$) shift equivalent to $M$. In particular, $A$ is algebraically shift equivalent to $M$.

If the supernatural number has only finitely many other primes of multiplicity at least one, then $U = \mathbb{Z}[1/p]$ and then $G$ admits a stationary realization with $A_n = A$ (the argument to show this will be included in what follows). Otherwise, we may telescope the other primes (including their multiplicities), so that $U_0 := \lim \times p_i : \mathbb{Z} \to \mathbb{Z}$ ($p_i$ are products of the other primes) is relatively prime to $p$ and $U = \mathbb{Z}[1/p] \otimes U_0$. Since $\gcd(p_i, p) = 1$, so $\gcd(p_i, p^a) = 1$, hence by a further telescoping, we may also assume that $p_i \equiv 1 \mod q = p^a$.

Now we use the following lemma to contort $A$.

**LEMMA 11.10** Let $m > 1$ be an integer, and suppose $l$ is a positive integer with $l \equiv 1 \mod m$. Then there exists $f \in \mathbb{Z}[x]^+$ (polynomials with nonnegative integer coefficients) such that $f(m) = l$ and $f(-1) \not\in \{1\}$.

**Proof.** We find $f_0 \in \mathbb{Z}[x]^+$ such that $f_0(m) = l$; then we modify it inductively until $|f(-1)| = 1$. Expand $l = \sum_{i=0}^t a_i m^i$ with $0 \leq a_i < m$ as an $m$-adic expansion. Then set $f_0 = \sum a_i x^i$. Obviously $f(m) = l$.

If $f_0(-1) > 1$, then $\sum a_i(-1)^i > 1$. If $a_0$ is the only even-indexed coefficient that is strictly greater than zero, then $f(m) \leq a_0 < m < l$, a contradiction. Hence there must exist $i = 2j$ such that $a_i > 0$. Replace $a_i$ by $a_i - 1$ and $a_{i-1}$ by $a_{i-1} + m$, to create $f_1$. Then $f_1(m) - f_0(m) = -m^i + m^i = 0$, so $f_1(m) = l$, and $f_1(-1) = f_0(-1) - m - 1$.

For any polynomial $g \in \mathbb{Z}[x]$, $g(m) \equiv g(-1) \mod m + 1$. Hence $l = f_0(m) - f_0(-1)$ is a multiple of $m + 1$; writing $l = km + 1$ (if $l \equiv 1 \mod m$, we have $km + 1 - f_0(-1) = s(m + 1)$, so
\[ f_0(-1) = 1 + km - s(m+1) \text{ and so } km \geq s(m+1). \] Also, \[ f_1(-1) = km - (s+1)(m+1) + 1. \] If this is negative, then \((s+1)m > km + 1 \geq s(m+1) + 1\), so \(m > s\). Also, \(s+1 > k \geq s + s/m\). This is impossible. Hence \(f_1(-1) \geq 1\). If it equals 1, we are done. If not, the process can be repeated, each time reducing the value at \(-1\) by \(m+1\), and it must eventually hit 1. A similar process works if \(l \equiv -1 \mod m\), except that the value at \(-1\) eventually hits \(-1\).

If \(f(-1) < -1\), the process is similar, but easier (we do not have to worry about large \(a_0\)). There must exist \(i = 2j + 1\) such that \(a_i > 0\); replace \(a_i\) by \(a_i - 1\) and \(a_{i-1}\) by \(a_{i-1} + 1\). The resulting \(f_1\) satisfies \(f_1(m) = l\) and \(f_1(-1) = f_0(-1) + m + 1\). A similar argument to that of the preceding allows us to conclude that \(f_1(-1) < 0\) (if \(l \equiv -1 \mod m\) or \(f_1(-1) \leq 1\), whence either it is \(\pm 1\), or strictly less than \(-1\), and the process can be iterated.

For each \(p_i \equiv 1 \mod q\), there exists \(f_i \in \mathbb{Z}[x]^+\) such that \(f_i(q) = p_i\) and \(f_i(-1) = 1\). Set \(A_n = A f_n(A)\); as \(f_n\) has only nonnegative coefficients, so does \(A_n\); since each \(A_n\) is a polynomial in \(A\), its large eigenvalue is \(q f_n(q) = q p_n\), they commute with each other, and have the same Perron eigenvectors, \(1^T\) and \(1\).

Suppose the matrix size of \(A\) is \(y\) (all we know is that \(y \geq k + 1\); otherwise, we have very little control over it).

Now form \(M_n = M f_n(M) = \begin{pmatrix} q p_n & 0 \\ 0 & 1 \end{pmatrix}\). Suppose the algebraic shift equivalence between \(M\) and \(A\) is given by \(X\) and \(Y\); that is, \(X M = A X\), \(M Y = Y A\), and \(X Y = A^t\), \(Y X = M^t\) (\(t\) is called the lag). Then for every nonzero power of \(A\), we have \(X M^t = A^t X\) and \(M^t Y = Y A^t\); hence for every polynomial \(g \in \mathbb{Z}[x]\) such that \(g(0) = 0\), we have \(X g(M) = g(A) X\) and \(g(M) Y = Y g(A)\). Hence the map \(X : \mathbb{Z}[x] \to \mathbb{Z}_y\) induces a group homomorphism \(G = \lim M_n \to G' = \lim A_n\) by \([z, m] \mapsto [X z, m]\), and similarly, \(Y\) induces a group homomorphism \(G' \to G\) via \([w, m] \mapsto [Y w, m]\). The products of the two group homomorphisms are given by \(\tilde{A}\) and \(\tilde{M}\) respectively, both of which are immediately seen to be group automorphisms of \(G'\) and \(G\) respectively. Hence the maps induced by \(X\) and \(Y\) are isomorphisms.

Moreover, they take the eigenspaces of nonzero eigenvalues for \(A\) to those of \(M\) (and vice versa), and in particular, they must send the common eigenvectors for \(q\), and thus send \((1, 0, \ldots)\) to \((1, 1, \ldots, 1)\) and the same with the transposes. They thus induce an isomorphism of the groups with group homomorphism. Moreover, it is easy (trivial) to see that \(G'\) has a unique trace (when given the direct limit ordering), so that the group isomorphism is an order isomorphism from \(G\) (with ordering induced by the common left eigenvector of \(M_n\) for \(q p_n\)) to \(G'\) (with direct limit ordering). It is trivial that \(G\) is simply the split extension.

The upshot is a special case.

**Lemma 11.11** Suppose \(G = U \oplus \mathbb{Z}^k\) where \(U\) is a rank one subgroup of \(Q\) that is \(p\)-divisible for some prime \(p\), and the unique trace on \(G\) is the projection onto \(U\) (the split case). Then with \(H = U\), there exists a bounded ECRS realization of \(G\) with respect to \(H\) by commuting matrices.

The matrices constructed in the other realizations need not commute. A similar argument can be made to work in some non-split cases with a prime having infinite multiplicity. We can of course extend this via the direct limit argument of 9.1(c).

So we may assume that \(\lambda > 1\).

If all primes infinitely divide \(H\), then \(H\) (and thus \(t(G)\)) are rational vector spaces, \(\lambda = 1\), the extension splits (indeed, there is only one extension). If \(H \simeq \mathbb{Z}[1/n]\) for some integer \(n\), then the system is stationary, and the result follows from [M]. If there are only finitely many primes with finite multiplicity, we reduce to the last case immediately.

Otherwise, there exist infinitely many primes each with finite and nonzero multiplicity, in
addition to at least one prime $p$ with infinite multiplicity. Throwing away all the primes that divide $\lambda$ amounts to throwing away a finite set of primes with only finite multiplicity, hence doesn’t change anything.

There exists a power of $p$, $q = p^a$ such that $q \equiv 1 \mod \lambda$. We may also arrange, by taking a multiple of $a$ if necessary, that $q\lambda > k^2 + k$. We may telescope the other primes with their powers, so obtain $t(G)$ as $\mathbb{Z}[p^{-1}] \otimes \lim p_i : \mathbb{Z} \to \mathbb{Z}$ where $\gcd(p_i, \lambda) = \gcd(q, p_i) = 1$. Now we can implement the same isomorphism as in 11.1, with $qp_{i+1}$ replacing $p_{i+1}$ (and $(qp_{i+1} - 1)/\lambda$ replacing $(p_{i+1} - 1)/\lambda$), where we set $y_i = 0$, $v_i = \rho \cdot (qp_{i+1} - 1)/\lambda$, and $y_n = \rho \cdot (qq_n - 1)/\lambda$. This yields a group isomorphism to the limit group obtained as $\lim \left( \begin{array}{c} qp_{i+1} u_i \\ 0 \end{array} \right)_k$, and the group homomorphism has been converted to left multiplication by the common eigenvector, $(\lambda, \rho)$.

As in the previous case, we can simultaneously conjugate all the current matrices by $\left( \begin{array}{cc} 1 & v \\ 0 & E \end{array} \right)$ where $v \in \mathbb{Z}^{1 \times k}$ and $E \in \text{GL}(k, \mathbb{Z})$. This replaces the upper right entry by $\lambda^{-1}(qp_{i+1} - 1)(\rho - \lambda v)$. We could have previously conjugated the matrices with $\left( \begin{array}{cc} 1 & 0 \\ 0 & J \end{array} \right)$ where $J \in \text{GL}(k, \mathbb{Z})$, and so have assumed that $\rho = c(\rho)(1, 0, \ldots, 0)$ (this applies to the left eigenvector as well). Now set $v = (0, 1, 0, \ldots, 0)$, so $\rho - \lambda v = (c(\rho), -\lambda)$; hence $c(\rho - \lambda v) = 1$. Thus there exists $E \in \text{GL}(k, \mathbb{Z})$ such that $(\rho - \lambda v) E^{-1} = (1, 1, 1, \ldots, 1) = 1^T_k$, which as before, we call $u$.

Hence we are in the situation wherein the matrices are of the form $\left( \begin{array}{ccc} qp_{i+1} & (qp_{i+1} - 1)u/\lambda \\ 0 & 1_k \end{array} \right)$, their common eigenvector is $(\lambda, u)$ (for the eigenvalue $qp_{i+1}$), and the group homomorphism is obtained by left multiplication by suitable multiples of the eigenvector.

Now we embroider $\lambda q - k - 1$ rows and columns around the matrix; the only nonzero entries of the newly embroidered part occur in the top row, where we put $p_{i+1}1^T$. This creates new matrices

$$B_n = \left( \begin{array}{ccc} qp_{i+1} & \frac{qp_{i+1} - 1}{\lambda} (1, 1, \ldots, 1)^T \\ 0 & I_k \\ 0 & 0 \end{array} \right) p_{n+1}(1, 1, \ldots, 1),$$

which are of size $q\lambda$. Miraculously, $B_n$ have a common left eigenvector, $(\lambda q, qu, \lambda 1^T)$, where the third block is of size $\lambda q - k - 1$ (it is not in general true that embroidery where the right side is not zero in this case, $Z_n$ in 11.3, will preserve the common left eigenvector property).

In order to perform the desired column and row operations, we need an estimate. From $q(k^2 - \lambda^2 - k + \lambda) - k^2/p_{i+1} + k + 1 \geq k$ (easy), we see that

$$\frac{qp_{i+1} - 1}{\lambda} \geq k + q/\lambda;$$

hence there exists a multiple of $k$, $t = sk$, such that $q/\lambda \leq t/k \leq (qp_{i+1} - 1)/\lambda$. Now to each $B_n$, subtract $s$ times each of the first $k$ columns from their counterpart in the second block. The inequalities we just used are equivalent to the resulting top row consists of positive entries, and the sum of all but the first is less that $qp_{i+1}$. The inverse operation is to subtract the bottom rows from their counterparts, but this has no effect. This amounts to a conjugacy (which of course yields an isomorphism with group homomorphism), and now we simply add the top row to each of the others, and all the columns but the first from the first column. As before, the result is a primitive matrix, of size $\lambda q$; the inner product (as is easy to see) is the same as the size, so the matrix has equal row and column sums.

This yields the following rather surprising result.

**PROPOSITION 11.12** Let $G$ be a simple dimension group of finite rank with unique trace $\tau$, such that $\tau(G)$ is $p$-divisible for at least one prime $p$. Suppose $H$ is a noncyclic rank
one subgroup such that $\tau(H) \neq 0$ and $G/H$ is free. Then there exists an ECRS realization of $G$ with respect to $H$.

And the direct limit argument, using 9.11 and 11.8, yields the definitive result.

THEOREM 11.13 Let $G$ be a simple dimension group with unique trace $\tau$, such that $\tau(G)$ is $p$-divisible for at least one prime $p$. Suppose $H$ is a rank one noncyclic subgroup of $G$ such that $\tau(H) \neq 0$ and $G/H$ is torsion-free. Then $G$ admits an ECRS realization with respect to $H$.

So we have a dichotomy: if $\tau(G)$ is not $p$-divisible for at least one prime $p$, then the condition $|\tau(G)/\tau(H)| \geq \text{rank } G$ is necessary and sufficient (allowing $\infty$ as possible values); but if $\tau(G)$ is $p$-divisible for no primes $p$, there is no such constraint.

Related to this is a result of George Elliott [E], showing that the rank two split extension dimension group $\mathbb{Z}^{[1/2]} \oplus \mathbb{Z}$ (with the strict ordering) cannot be realized as a limit of simplicial groups of rank two (that is, any direct limit realization requires almost all the free abelian groups to be of rank at least three). In the latter, it was shown that this dimension group can be realized as a limit of rank three simplicial groups, and is stationary (via a size three primitive matrix algebraically shift equivalent to $\text{diag}(2,1)$). This is in fact what led me to think about using semigroups to obtain realization of the transfer matrices.

This paper was motivated by a question of Christian Skau: given the split extension $G = U \oplus \mathbb{Z}^k$, with $U \subseteq \mathbb{Q}$ and the projection onto $U$ yielding the ordering (so as to be a dimension group with unique trace), does it admit an ERS representation? (As we have seen, there is only one possible choice for the rank one noncyclic subgroup $H$ such that $G/H$ is torsion free, namely $U$ itself, so the choice of $H$ is unambiguous.) This appears as a special case, and the implementing matrices are the transposes of the matrices of the form $A$ appearing in section two (with parameters $p = p_{n+1}$, once we ensure that $p_{n+1} > (k+1)^2$). I would like to thank Christian for his repeated insistence on solving this problem.

Skau’s question was motivated by questions concerning Tplitz $\mathbb{Z}$-actions on Cantor sets (systems which admit factor maps onto odometers). A particular consequence of the results here is that among uniquely ergodic minimal actions of $\mathbb{Z}$ on Cantor sets, those that are strongly orbit equivalent to a Tplitz, and those that are orbit equivalent, are characterized.

It has been known for over a decade that dimension groups which are rational vector spaces admit ERS realizations with respect to any dimension one subspace containing an order unit (this appears in [GJ]). The recipe is to begin with any realization of the dimension group, find an increasing sequence $h_n \mathbb{Z} \subset h_{n+1} \mathbb{Z}$ whose union is $H$ where $h_n$ is an order unit, telescope the realization, so that a cofinal collection of the $h_n$ appear, each at the $n$th level, say by a strictly positive vector $v_n$, apply the obvious diagonal matrix $\Delta_n \in \text{GL}(f(n), \mathbb{Q})$ so that $\Delta_n v_n$ is a multiple of $1$, replace the $n$th matrix $A_n$ by $\Delta_{n+1} A_n \Delta_n^{-1}$, then multiply each by a positive integer to ensure that the entries are all nonnegative integers. Since the dimension group $G$ satisfies $G \otimes \mathbb{Q} \simeq G$, it follows immediately that the new improved direct limit yields $G$, and the elements of $H$ are implemented by constant vectors in the limit.

There is a substantial literature on realizing shift equivalence classes of integer matrices with nonnegative ones ([BoH] and the references there), corresponding to stationary direct limits (that is, $G$ is a limit with the same matrix repeated, an abelian group with real-valued homomorphism emanating from the largest eigenvalue and corresponding left eigenvector). Here we have a generally easier problem, since we are permitted to telescope matrices, something not allowed in the matrix realization problem. On the other hand, there are situations in dimension group realization questions (such as $\tau(G)$ being a subgroup of the rationals with no primes of infinite multiplicity).
which don’t arise in the matrix realization case.

There are of course more questions to be answered. The most interesting would be to determine conditions on general dimension groups to admit an ERS realization. The general result characterizing ECS realizations (6.1(b)) suggests some sort of dual or transpose of good, this time applied to (rank one) subgroups. Thierry Giordano suggested that this might have a connection to recent work of Glasner and Host (extending earlier results of Giordano, Putnam, and Skau) on realizing dynamically the inclusion $H \subset G$ (for not necessarily rank one subgroups $H$).
