Abstract

Objectives: The purpose of the present study was to evaluate the postoperative analgesic efficacy of fentanyl patches versus subcutaneous tramadol after canine ovariectomy, with and without unilateral mastectomy.

Materials and methods: A total of 40 female dogs were included in the present study, all of which were domesticated, healthy and 4–12 years of age. The animals were divided into four groups (n = 10 per group) based on the surgery and the analgesic protocol used: the TO group only underwent ovariectomy, and received postoperative tramadol; the TM group underwent both ovariectomy and mastectomy, and received postoperative tramadol; the FO group only underwent ovariectomy, and received fentanyl patches; and the FM group underwent both ovariectomy and mastectomy, and received fentanyl patches. Postoperative pain was evaluated every 4 h for 24 h using a numeric analogue scale (NAS) and a modified Glasgow Composite Measure Pain Scale Short Form (CMPS-SF).

Results: The results of the present study showed that patients in all four groups tolerated postoperative surgical stress well. Analysis of variance for repeated measures did not show significant differences in the NAS scores and in Glasgow CMPS-SF between groups in terms of pain scores or rescue analgesia.

Clinical significance: These results indicated that the analgesic effect of the fentanyl patch was similar to that of subcutaneous (SC) tramadol in female dogs after ovariectomy, with and without unilateral mastectomy, suggesting that the fentanyl patch may represent a valid supplementary tool for the control of postoperative pain in animals after surgery.

KEYWORDS
fentanyl patch, ovariectomy analgesia, tramadol, unilateral mastectomy

1 INTRODUCTION

Ovariectomy is one of the most performed elective surgical procedures in small animals (Rutteman et al., 2001). This surgery involves both somatic and visceral pathways and is sometimes performed concurrently with mastectomy, resulting in extensive tissue damage and severe postoperative pain (Mathews, 2000). Fentanyl is a potent mu opioid receptor agonist, with a wide margin of safety and minimal effects on the cardiovascular and respiratory systems in canines (Reed et al., 2011). The short duration of action has limited its use in the surgical setting to perioperative injections, rescue analgesia, or constant rate infusions (CRI) (Pekcan & Koc, 2010). Therefore, to improve and extend the analgesic effect of fentanyl, additional delivery technologies have been developed for use in humans, including the ‘fentanyl patch’. This is an open access article under the terms of the Creative Commons Attribution-NonCommercial-NoDerivs License, which permits use and distribution in any medium, provided the original work is properly cited, the use is non-commercial and no modifications or adaptations are made. © 2021 The Authors. patch," which has been utilised in an extra-label manner in veterinary medicine (Egger et al., 1998; Gilbert et al., 2003; Kyles et al., 1998, 1996). Fentanyl patches have a prolonged duration of action and also reduce the side effects of oral and parenteral administration (Kukanich & Clark, 2012). Previous studies regarding the use of fentanyl patches in dogs have reported higher pain scores in the immediate postoperative period (0–6 h) and lower scores starting 12–18 h after the application of the patch (Robinson et al., 1999), indicating the necessity of applying the patch at least 18 h before surgery in order to reach the ideal hematic concentration required for an appropriate analgesic effect during the immediate postoperative period. Fentanyl patches provide the sustained delivery of fentanyl, which can be useful for both the control of postoperative pain and as antinociception during painful surgeries, such as orthopaedic procedures (Lafuente et al., 2005). To the authors’ knowledge, the use of fentanyl patch during canine mastectomy has not been described. It is expected that by using this patch, a good analgesia could be maintained in postoperative period. In the present study, we selected tramadol as a positive control for the fentanyl patch because it is a widely used and well-known drug used for the management of acute pain in small animals, providing the same analgesic effect as morphine at equipotent doses, and because of its immunomodulatory properties (Mastrocrinque & Fantoni, 2003). Tramadol is a synthetic opioid with low mu opioid agonist affinity (6000 times less than morphine), and its efficacy is due to two different mechanisms, it interacts with mu opioid receptors and affects serotonin and norepinephrine reuptake (G. L. Costa et al., 2015, 2019; G. Costa et al., 2018, 2021). In fact, Teixeira (Monteiro et al., 2009) showed that the intramuscular (IM) administration of tramadol (3 mg/kg) at 8-h intervals appeared to be effective for the management of postoperative pain during the first 24 h in most of the dogs undergoing unilateral mastectomy with or without ovariohysterectomy (OHE). The aim of the present study was to compare the early postoperative analgesic efficacy of fentanyl patches versus tramadol after ovariecotmy in canines, with and without unilateral mastectomy.

2 MATERIALS AND METHODS

2.1 Study design

This study model is a randomised non-blinded clinical trial.

2.2 Inclusion and exclusion criteria

For the present study, 40 female dogs meeting the following requirements were recruited: aged 4–12 years, weighing 11–30 kg, no known previous systemic pathologies, and classified as a low anaesthetic risk [American Society of Anaesthesiology (ASA) class 2]. Of the 40 female dogs, 20 were selected for elective ovaricectomy, and 20 were selected for ovariecotomy performed concurrently with unilateral mastectomy due to mammary tumours, diagnosed on clinical examination and which were staged according to the tumour node metastasis (TNM) classification system (Teixeira et al., 2013). Informed consent was obtained from the pet owners prior to participation in the study. The day before surgery, patients underwent general preoperative examinations, as well as thoracic radiographs, abdominal ultrasound scans, and routine blood tests (complete blood count and metabolic panel). Dogs were included if they were healthy, as determined by history, physical examination, complete blood count, and serum chemistry. Dogs that presented with ulcerated nodules, and those with evidence of lung metastasis, were excluded from the study. Of the 40 female dogs, 20 (10 selected for ovariecotomy and 10 for ovariecotomy and unilateral mastectomy) received fentanyl patches, which were placed on the necks of dogs previously shaved and disinfected, 24 h before surgery to optimise the effects and to reach the highest plasma concentration (Freise et al., 2012) in the postoperative period. The patches were fixed with stitches and adhesive for 72 h (Bellei et al., 2011; Hofmeister & Egger, 2004) according to the protocol presented by Gilbert et al. (2003) as follows: < 10 kg = 25 mcg/h; 10–20 kg = 50 mcg/h; 20–30 kg = 75 mcg/h; and 30–40 kg = 100 mcg/h (Hellyer et al., 2006).

2.3 Study groups

The female dogs were randomly (StatView statistical software, JMP) assigned into four groups (n = 10 per group): the TO group only underwent ovariecotomy and received postoperative tramadol (Altadal, Formevet S.r.l., Milano, Italy at a dosage of 5 mg/kg); the TM group underwent both ovariecotomy and mastectomy and received postoperative tramadol (5 mg/kg); the FO group only underwent ovariecotomy and received fentanyl patches (Durogesic, Janssen, Milano, Italy); and the FM group underwent both ovariecotomy and mastectomy and received fentanyl patches. Food was withheld for 12 h prior to the surgery. The time period between patch application and surgery was chosen based on a study by Kukanich and Clark (2012), who observed that plasma fentanyl concentrations increased slowly during the first 24 h and remained in a steady-state period for the next 48 h.

2.4 Anaesthesia and surgical procedures

Patients in all four groups were pre-medicated 20 min before surgery with IM dexametomidine (Dexdomitor, Vetoquinol Italia SRL, Bertinoro, Italy) at a dosage of 3 µg/kg and IM methadone hydrochloride (Semfortan, Eurovet Animal Health BV, Bladel, The Netherlands) at a dosage of 0.25 mg/kg mixed in the same syringe. When the sedative effect was achieved, a 24G intravenous (IV) catheter was inserted into the cephalic vein to start standard maintenance fluid therapy using ringer lactate 5 ml/kg/h (Ringer Lattato, BBraun Milano Spa, Milano, Italy), and to allow for rapid drug administration, if necessary. This was followed by the administration of 100% oxygen via a face mask using a Mapleson F circuit. Anaesthesia was induced in all dogs by the administration of IV propofol (Vetofol,Esteve, Barcelona, Spain) at a dosage of 4 mg/kg (SD 1 mg/kg). When anaesthesia was achieved, the patients were intubated and connected to the anaesthesia machine.
using a Mapleson F respiratory circuit. Anaesthesia was maintained throughout the surgery by the administration of sevoflurane (EtSev 2.5%; SevoFlo, EcuPhar Italia S.r.l., Milano, Italy) through the respiratory circuit. Systemic analgesia was administered as a 1 µg/kg bolus of sufentanil citrate (50 µg/ml) followed by a maintenance dose constant-rate IV infusion of 1.5 µg/kg/h until the surgery was completed (G. L. Costa et al., 2019). The following vital parameters were monitored throughout the surgery: heart rate, electrocardiographic trace, pulse oximetry, end-tidal carbon dioxide concentration, end-tidal percentage of sevoflurane, non-invasive blood pressure, and body temperature (GE-Datex Ohmeda Carestation 620 Anaesthesia Cart, GE-Datex Ohmeda B 450 Monitor). The skin at the surgical site was shaved and aseptically prepared, and the animals were placed in the dorsal recumbency position. Throughout the procedure, heat dispersion was minimised by placing the patient on an air-heated mat (Bair Hugger model 505; 3 M Italia). All surgeries were performed by the same surgeon and the same surgical team, in full compliance with the indications of the righting reflex and the assumption of sternal decubitus position. During the postoperative period, immediately after the reappearance of the righting reflex and the assumption of sternal decubitus position, patients in the TO and TM groups received SC tramadol injections every 8 h. To assess pain in veterinary patients, we used the numerical analogue scale (NAS) and the Glasgow Composite Measure Pain Scale Short Form (CMPS-SF) (Hellyer et al., 2006; Reid et al., 2007). The NAS score was defined as the distance between the left end of the scale and the mark (Flecknell & Waterman-Pearson, 2000; Sarrau et al., 2007). The CMPS-SF was developed using a psychometric methodology, and takes into account postural attitudes and pain for the animal. The NAS score was defined as the distance between the left end of the scale and the mark (Flecknell & Waterman-Pearson, 2000; Sarrau et al., 2007). The CMPS-SF was developed using a psychometric methodology, and takes into account postural attitudes and facial expressions, vocalisations, mood, the response to manipulation and palpation of the painful area, physical activity and gait, and the subject’s behaviour towards the surrounding environment (Flecknell & Waterman-Pearson, 2000; Morton et al., 2005; Tranquili et al., 2007). These scales were considered the most appropriate assessments for the evaluations performed in the present study, the aim of which was to compare the analgesic efficacy of the fentanyl patch versus SC tramadol after ovarioectomy, with and without unilateral mastectomy. In all groups, the level of postoperative pain and discomfort was assessed using the NAS and Glasgow CMPS-SF scores every 4 h for 24 h (Reid et al., 2007) immediately after the end of the surgery. The patients with NAS and Glasgow CMPS-SF scores > 4 received rescue analgesia with IM methadone at a dosage of 0.2 mg/kg (Reid et al., 2007).

2.6 Data analysis

All data collected were entered into a database created with an Excel spreadsheet, and data analysis was performed using Stata MP16 software. Continuous variables were described as median and interquartile range (IQR) and as media on figures, and categorical variables as proportions. The skewness and kurtosis test was used to evaluate the normality of continuous variables, and a normalisation model was used for those not normally distributed. One-way analysis of variance (ANOVA) was used to compare continuous variables between groups, with Bonferroni correction to compare two groups at a time. The ANOVA for repeated measures test was used to compare continuous variables between groups and detection time. The Fisher’s exact test was used to compare proportions between groups. To assess the relation between the difference between t24 and t0 of NAS and CMPS-SF scores and age, weight and groups multivariate linear regression models were built; correlation coefficients were reported with the indication of 95% confidence interval (95% CI). For all tests, a two-sided p-value < 0.05 was considered statistically significant.

3 RESULTS

All surgical procedures lasted on average 25 min (SD 5 min) for the simple ovarioectomy and 50 min (SD 7 min) for the ovarioectomy performed concurrently with mastectomy. The population for the present study consisted of 40 female dogs: 10 (25.0%) in the FM group, 10 (25.0%) in the FO group, 10 (25.0%) in the TM group, and 10 (25.0%) in the TO group. The characteristics of the population by group are listed in Table 1.

Analysis of variance (ANOVA) for repeated measures did not show significant differences in the NAS scores (p = 0.279) between groups or between detection time and group (p = 0.867). However, significant differences were observed between detection times (p < 0.0001; Figure 1). Comparisons between individual groups are shown in Table 2.

ANOVA for repeated measures did not show any significant differences in the Glasgow CMPS-SF scores between groups (p = 0.103) or between detection time and group (p = 0.660). Significant differences, however, were observed in the comparison between detection times (p < 0.0001), as shown in Figure 1. Comparisons between individual groups are shown in Table 3.

The proportion of dogs undergoing rescue analgesia is described in Table 4; no statistically significant differences were found between groups (p > 0.05).

No statistically significant relations were found between the difference between t24 and t0 of NAS and CMPS-SF scores and determinants in analysis (p > 0.05; Table 5).

4 DISCUSSION

The results of the present study suggest that fentanyl patches may provide postoperative analgesic effects equivalent to those of tramadol

in dogs that have undergone ovariectomy, with and without unilateral mastectomy, for 24 h post-surgery. This means that the fentanyl patch is a useful alternative for postoperative pain management in dogs. In fact, the use of transdermal patches for analgesia may be considered a valid form of pain therapy in small animals; in particular, it contributes to the postoperative well-being of patients undergoing painful surg-
CMPS-SF scores in multivariate linear regression models
group and detection time

Although the fentanyl patch can be included in the anaesthesiology protocol, it cannot be used for pre-emptive analgesia during surgery, given the individual variables which influence its absorption and the transdermal administration of the drug (Rialland et al., 2012). Some studies have shown that the absorption of fentanyl is related to the patient’s body temperature or accidental ingestion of the patch (Pettifer & Hoggard, 2014; Schmiedt & Bjorling, 2007). In our study, fentanyl patches were well tolerated and did not cause any adverse effects, which was likely because the dogs were in a standardised postoperative hospital setting and were under close veterinary surveillance. No negative or other side effects were reported. The use of long-acting analgesics, such as the fentanyl patch, ensures satisfactory analgesic coverage that lasts for at least 24 h postoperatively (Cicirelli, Lacalandra, et al., 2021; Grubb & Lobprise, 2020), which guarantees adequate pain management.

Effective postoperative pain control can be achieved with multimodal analgesia using a combination of agents with different mechanisms of action (Cicirelli, Debidda, Maggio, Cairà, Lacalandra, et al., 2021; Cicirelli, Debidda, Maggio, Cairà, Mrenoshki, et al., 2021). Multimodal anaesthesia, which was utilised in the fentanyl groups, includes drugs administered both systemically and regionally, and is considered the most effective approach to provide pain relief (Cicirelli, Lacalandra, et al., 2021; Grubb & Lobprise, 2020). This type of anaesthesia includes single or combination drugs administered at varying dosages and routes, and for varying times; it is a less standardised approach, but is better suited to individual patients’ needs (Campagnol et al., 2012).

5 | CONCLUSIONS

These findings could be a starting point for further investigations in dogs that cannot take oral medications during the postoperative period. For future studies it will be important to increase the number of dogs enrolled to improve this topic. Moreover, considering the cost, availability, restrictions, and side effects associated with the fentanyl patch, this study is encouraging and could spark interest, leading to a possible association between routine postoperative analgesia and fentanyl patch.
