Belimumab: A BAFF-specific Inhibitor for the Treatment of Systemic Lupus Erythematosus and Lupus Nephritis

Yoshiya Tanaka
The First Department of Internal Medicine, University of Occupational and Environmental Health, Kitakyushu, Japan

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease that affects multiple organs. In particular, the presence of renal involvement, known as lupus nephritis, is a major determinant of prognosis. Conventional treatments for SLE include hydroxychloroquine, glucocorticoid and immunosuppressive agents. However, the use of such non-specific drugs increases the risk of side effects, such as infections. Soluble B-cell-activating factor (BAFF), belonging to the tumour necrosis factor family, is produced by dendritic cells and induces class switching of B cells and differentiation into antibody-producing cells. International phase III studies demonstrated the efficacy and safety of belimumab (a monoclonal antibody against soluble BAFF) not only in patients with SLE, but also in those with active lupus nephritis. There were no significant differences between the belimumab and placebo groups in the incidence of adverse events, including serious events and events necessitating drug cessation. Thus, belimumab could become an alternative induction treatment for lupus nephritis. This article describes the pathogenesis of SLE and lupus nephritis, and reviews the results of recent phase III trials of belimumab and its promising role for the treatment of patients.
Belimumab: A BAFF-specific Inhibitor for the Treatment of Systemic Lupus Erythematosus and Lupus Nephritis

Figure 1: The role of B-cell-activating factor in systemic lupus erythematosus

Belimumab is a human immunoglobulin G1 (IgG1) monoclonal antibody that binds to soluble BAFF. In the phase III clinical trials of belimumab in subjects with SLE (BLISS), the primary endpoint was defined as the achievement of an SLE responder index 4 (SRI-4) response. SRI-4 consists of a 4-point improvement in overall disease activity, major organ disorders, and complications such as infections and cardiac diseases. Lupus nephritis treatment is selected based on the ISN/RPS histological classification. Hydroxychloroquine is recommended for all patients, while those with class III or IV lupus nephritis are treated with glucocorticoids and immunosuppressive agents (intravenous cyclophosphamide pulse therapy followed by high-dose glucocorticoids and immunosuppressive agents) and be discontinued as soon as possible whenever possible. Indications and initial doses of glucocorticoids and immunosuppressive agents are determined based on a comprehensive assessment of disease activity, major organ disorders, and complications such as infections and cardiac diseases. Lupus nephritis treatment is selected based on the ISN/RPS histological classification. Hydroxychloroquine is recommended for all patients, while those with class III or IV lupus nephritis are treated with glucocorticoids and immunosuppressive agents (intravenous cyclophosphamide pulse therapy followed by high-dose glucocorticoids and immunosuppressive agents) and be discontinued as soon as possible whenever possible.
of scores derived from the SLEDAI, British Isles Lupus Assessment Group (BILAG) index and Physician Global Assessment (PGA). SRI-4 response is defined as a ≥4-point reduction in SLEDAI, no new BILAG A or no more than one new BILAG B domain score, and no deterioration from baseline in the PGA by ≥0.3 points.

The BLISS-52 study (ClinicalTrials.gov Identifier: NCT00424476) (a phase III international study of belimumab) investigated 865 patients with SLE with moderate disease activity and a SLEDAI score of ≥6. The study reported that the proportion of patients achieving SRI-4 response at 52 weeks was significantly higher in the belimumab group (intravenous infusion of 10 mg/kg at 0, 2 and 4 weeks, and then every 4 weeks) than in the placebo group (58% versus 44%). Significant differences between the two groups were also found in the decrease in autoantibodies, increase in complement activation, number of patients with glucocorticoid dose ≤7.5 mg (prednisolone equivalent), and improvement in patient’s quality of life and fatigue. In addition, a baseline SLEDAI score ≥10, anti-dsDNA antibody positivity, and hypocomplementemia contributed to achieving SRI-4 response at 52 weeks. There were no significant differences in the incidence of adverse events, including serious adverse drug reactions and infections.

The BLISS-76 study investigated 819 patients and reported that the proportion of patients achieving SRI-4 response at 52 weeks was significantly higher in the belimumab 10 mg/kg group than in the placebo group (43% versus 34%). Based on these results, belimumab was the first approved biologic for SLE in 2011.

The BLISS-NEA (ClinicalTrials.gov Identifier: NCT01345253) phase III study was conducted in northeast Asia (Japan, Korea and China), and enrolled 705 patients with SLE on standard therapy with autoantibody positivity and a SLEDAI score of ≥8. The proportion of patients achieving SRI-4 response at 52 weeks was significantly higher in the belimumab group than in the placebo group (54% versus 40%). In 60 Japanese patients, the figures were 46% versus 25%, respectively. The prolongation of time to relapse and the reduction in glucocorticoid dose were also greater in the belimumab group than in the placebo group. However, there were no significant differences in safety between the belimumab and placebo groups. The analysis of SLEDAI scores showed a significant improvement in the musculoskeletal, renal and immunological items, a decrease in serum anti-dsDNA antibody titre, an increase in complement activity and a reduction in glucocorticoid dose in the belimumab group compared with the placebo group.

The BLISS-SC (ClinicalTrials.gov Identifier: NCT01484496) study investigated 836 patients with SLE and a SLEDAI score of ≥8, and reported that the proportion of patients achieving SRI-4 response at 52 weeks was significantly higher in the belimumab group (200 mg subcutaneous injection once weekly) than in the placebo group (61% versus 48%). The safety profile was unremarkable.

No notable adverse events were observed in any of the clinical studies. However, a post-marketing surveillance study reported the occurrence of progressive multifocal leukoencephalopathy due to reactivation of John Cunningham virus, depression (0.4%), suicide ideation and suicide attempts, although the causal relationship with belimumab is unknown.

The long-term extension of randomized trials supports not only a favourable safety profile of belimumab, with a relatively low incidence of serious and opportunistic infections, but also an efficacy with significant reduction in severe flares, lower cumulative exposure to glucocorticoids, lower accrual of irreversible organ damage and improved health-related quality of life. In the BLISS-NEA study, improvement in the SLEDAI renal items (urinary cast, haematuria, proteinuria and pyuria) was observed by the 7-year follow-up. Another study also reported that the addition of belimumab to standard-of-care treatment was effective in reducing glucocorticoids, preventing relapse of disease activity and preventing the progression of organ damage in patients with SLE during maintenance therapy after obtaining remission or low disease activity. These findings may be important aspects in the treat-to-target context during maintenance therapy for SLE.

**Belimumab therapy in lupus nephritis**

From the BLISS-52 and BLISS-76 studies, a subanalysis of 267 patients with lupus nephritis was performed. The belimumab 10 mg/kg group showed improvement in urine protein and SLEDAI renal items, decrease in nephropathy relapse, and normalization of complement activity and dsDNA antibody titre at 52 weeks, compared with the placebo group. This tendency was prominent in patients with lupus nephritis with high anti-dsDNA antibody titres and low complement activity. When participants were limited to patients receiving MMF, the belimumab 10 mg/kg group showed a significant improvement at 52 weeks compared with the placebo group, both in urinary protein and complement activity, as well as in SLEDAI score, BILAG score and the proportion of patients achieving SRI-4 response. However, interpretation of the results should be done carefully because patients with acute, severe lupus nephritis were excluded from the trials and renal biopsies were not performed in most of patients.

The phase III BLISS-LN (ClinicalTrials.gov Identifier: NCT01639339) placebo-controlled trial included patients with SLE and lupus nephritis. Patients had antinuclear antibody positivity or anti-dsDNA antibody positivity, a urinary protein:creatinine ratio of ≤1.0 and ISN/RPS class III–V (including active phase). Patients initially received standard treatment, including high-dose glucocorticoid therapy and MMF or IV-CY for 60 days, and were consequently treated with belimumab 10 mg/kg or placebo. Patients who were refractory to both IV-CY and MMF, and those with an estimated glomerular filtration rate (eGFR) of <30 mL/min/1.73 m², were excluded from the analysis. The dose of glucocorticoids was reduced to 10 mg during the first 24 weeks of induction therapy, and maintenance therapy was continued for 104 weeks. Primary evaluation was performed at 104 weeks. The mean age of the patients was approximately 33 years. The mean disease duration of lupus nephritis was approximately 0.2 years and the mean SLEDAI-S2K score was approximately 12. Histological examination of the kidney resulted in at least 80% of patients being classified as having class III or IV lupus nephritis.

The primary endpoint was the primary efficacy renal response (PERR) at 104 weeks, which was defined as a urinary protein:creatinine ratio of ≤0.7, eGFR that was not less than 20% of the value before the renal flare or ≥60 mL/min/1.73 m², and no use of rescue therapy. At 104 weeks, significantly more patients in the belimumab group than in the placebo group had a PERR (43.0% versus 32.3%). The secondary endpoints were complete renal response rate (CRR) at 104 weeks, time to relapse or death, ordinal renal response rate and PERR at 52 weeks. CRR was defined as the percentage of patients who met the following three criteria: a urinary protein:creatinine ratio of ≤0.5, an eGFR that was not less than 10% of the value before the renal flare or ≥90 mL/min/1.73 m² and no use of rescue therapy. At 104 weeks, significantly more patients in the belimumab group than in the placebo group had a CRR (30.0% versus 19.7%). Significant differences were also found in
time to relapse or death at 104 weeks, urinary protein:creatinine ratio, urinary sediment, CRR based on the ordinal renal response rate by eGFR, and PERR at 52 weeks. In addition, the use of MMF at baseline, class III or IV lupus nephritis, and races other than Black contributed to PERR and CRR at 104 weeks. There were also significant differences in SLEDAI-2K scores (27.8% versus 18.4%), proportion of patients receiving prednisolone ≤7.5 mg or ≤5.0 mg and positive rate of anti-dsDNA antibody at 104 weeks. Furthermore, in a secondary analysis of the BLISS-LN study, belimumab could significantly attenuate the risk of lupus nephritis flare and eGFR decline, compared with standard of care and placebo, in patients with lupus nephritis.34 There were no significant differences between the belimumab and placebo groups in the incidence of adverse events, including serious events and events necessitating drug discontinuation.

Thus, the BLISS-LN study indicated that the addition of belimumab to standard-of-care treatment appeared to be effective in preserving long-term kidney function in patients with lupus nephritis. However, there are several limitations to this study, and questions remain. First, the study outcomes were set for nephritis, but SLE is often complicated with multiple organ manifestations, and mean SLEDAI-2K scores were 12.5. The effects of belimumab on other organs and changes in composite disease activity such as SRI-4 and the ACR-50 criteria were not examined. Second, in the BLISS-SLE and BLISS-76 studies, SLEDAI score ≥10, anti-dsDNA antibody positivity and hypocomplementemia at baseline contributed to the achievement of the SRI-4 response at 52 weeks.23,24 Determining baseline factors that are predictive of responsiveness to belimumab in lupus nephritis would be useful if it is approved for the disease. Third, the prevalence and severity of lupus nephritis are known to be more severe in Black and Asian patients than in Caucasian patients, but the number of enrolled patients with different ethnicity was limited in the trial, warranting further study to demonstrate and clarify racial differences.23,24 Fourth, the concomitant immunosuppressants were limited to cyclophosphamide or MMF. However, azathioprine and calcineurin inhibitors such as tacrolimus are often used for lupus nephritis; therefore further study will be needed. Finally, the effectiveness of combination therapy of rituximab and belimumab in lupus nephritis requires further investigation. The upregulation of serum BAFF levels after rituximab therapy is often observed and is known to promote expansion of autoreactive B cells, which results in lower frequencies of clinical responses to rituximab.25

In the CALIBRATE study (ClinicalTrials.gov Identifier: NCT02269034), sequential administration of rituximab and belimumab was performed in patients with lupus nephritis.45 Although the trial did not find any significant clinical benefit of the addition of belimumab to standard-of-care treatment, more sustained B-cell depletion, diminished maturation of transitional to naïve B cells and enhanced negative selection of autoreactive B cells were observed.45 Larger studies investigating the addition of belimumab to standard-of-care treatment are warranted.

**Conclusions**

The most common cause of death in patients with SLE, including lupus nephritis, is infection, which is mainly due to immunocompromised conditions caused by treatments such as glucocorticoids and immunosuppressive agents. A treat-to-target approach for SLE has been proposed. Clinical studies have started to evaluate the clinical outcomes, including glucocorticoid dose reduction and cessation, and an interventional study without using glucocorticoids is also ongoing. Genome-wide association studies in SLE have shown that the identified disease susceptibility genes are associated not only with B-cell signalling but also with the innate immune system, including intracellular signalling in dendritic cells.46 An international phase III study showed that belimumab, a monoclonal antibody against soluble BAFF, was effective in patients with SLE and those with lupus nephritis; therefore, future indications may include earlier use of belimumab for SLE and lupus nephritis.23,25,26 In addition, anifrolumab, an anti-interferon-α receptor monoclonal antibody, has been approved in the USA and Japan.46,47 Both BAFF and interferon-α are produced by dendritic cells, which induce differentiation of B cells. ‘Bridging cytokines’ that connect the innate and acquired immune systems have been receiving attention for the development of new molecular-targeted drugs and are expected to contribute to the establishment of new therapeutic approaches.48
