The ferromagnetic (FM) transition temperature \( T_C \) of a two-band Double-Exchange (DE) model for colossal magnetoresistance (CMR) materials is studied using dynamical mean-field theory (DMFT), in wide ranges of coupling constants, hopping parameters, and carrier densities. The results are shown to be in excellent agreement with Monte Carlo simulations. When the bands overlap, the value of \( T_C \) is found to be much larger than in the one-band case, for all values of the chemical potential within the energy overlap interval. A nonzero interband hopping produces an additional substantial increase of \( T_C \), showing the importance of these nondiagonal terms, and the concomitant use of multiband models, to boost up the critical temperatures in DE-based theories.

The study of the CMR rare-earth perovskites has recently attracted considerable attention due to the rich magnetic and structural transitions they display. The CMR effect, namely an extremely large drop in resistivity caused by a magnetic field, occurs at the transition between a low-temperature FM-metallic ground state and a high-temperature paramagnetic-insulating phase, i.e., near \( T_C \). A basic aspect of CMR physics is that the mobile carriers (Mn \( t_2g \)-symmetric electrons) are strongly coupled ferromagnetically to localized spins (Mn \( t_2g \)-symmetric electrons). The core spin alignment influences on the electron motion leading to ferromagnetism. The basic model used to describe CMR materials is the DE model, formulated with one localized spin per site coupled to mobile carriers via a Hund’s coupling \( J \) much larger than the hopping amplitudes. While DE ideas explain qualitatively the existence of ferromagnetism, much of the CMR physics is still under debate. This is in part caused by the absence of fully reliable many-body techniques to study the complicated DE models needed to describe these compounds. Only MC and static mean-field approximations have been applied to the realistic multiband problem, the DMFT treatment being notoriously absent. Despite a considerable effort carried out within DMFT in the context of one-band models, the realistic case of two active bands has received much less attention since its analysis is far more difficult.

In this paper, the DMFT method is applied for the first time to the analysis of \( T_C \) of a two-band model for CMR materials. Its results are contrasted against MC simulations and found to be in good agreement. Besides the relevance of this combined DMFT+MC contribution, which is highly nontrivial technically as shown below, we also unveil here the key relevance of the interband hopping amplitudes to boost the value of the critical FM temperature. This effect was also not discussed in previous literature, and may lead to creative procedures to further increase \( T_C \) in real materials. The DMFT approach is general, with two \( s=1/2 \) active bands, arbitrary couplings, hoppings, and carrier densities \( p \).

The two-band model is based on the DE Hamiltonian:

\[
H = - \sum_{\underline{i}',\jmath,\alpha} (t_{\underline{i}'\jmath}\, c_{\underline{i}',\jmath,\alpha}^\dagger c_{\underline{i}\jmath,\alpha} + H.c.) - 2 \sum_{\underline{i},\underline{j},\alpha} J_{\underline{i}} S_{\underline{i}} \cdot S_{\underline{j}},
\]

where \( \underline{i}, \underline{j} = (1, 2) \) are the \( e_g \)-band indexes, \( i, j \) label the sites, \( c_{\underline{i},i,\alpha} \) destroys an electron at site \( i \) in the band \( l \), \( s_{\underline{i},i,\beta} = c_{\underline{i},i,\beta,\alpha} (\sigma_{\beta,\alpha}/2) c_{\underline{i},i,\alpha} \) is the spin-operator of the mobile carrier at band \( l \) (\( \sigma \) = Pauli vector), \( \alpha \) and \( \beta \) are spin indexes, \( J_{\underline{i}} \) is the coupling between the core spin and the conduction electrons of band \( l \), and \( S_{\underline{i}} \) is the localized spin of the magnetic ion at site \( i \). For \( l = \underline{i}' \) we refer to \( t_{\underline{i}} \) as the band hopping \( (\equiv t_{\underline{i}}) \). For \( l \neq \underline{i}' \), the \( t_{\underline{i}} \) is referred to as the interband hopping \( (t_{\underline{i}'\jmath} = t_{\underline{i}'\jmath}) \). The two active bands couple through the simultaneous scattering of carriers with the same core spin, as well as through the exchange of carriers via the nondiagonal hopping. While the first coupling clearly causes an increase in \( T_C \) when the bands overlap within the same energy interval, namely when \( J_{\underline{i}} \) are closed, the electron exchange among bands is also shown to induce higher \( T_C \) even when the \( J_{\underline{i}} \)'s are very different.

Note that the addition of other important terms, such as the antiferromagnetic exchange \( J_{\underline{AF}} \) between core spins and/or the cooperative Jahn-Teller phonons, will need a sophisticated “cluster” DMFT where at least some short-distance effects are considered. For this reason, this first study using the DMFT method on a two-band model focuses on the simplest case where only the FM phase is relevant. The study of the competition with other phases is left for future investigations. The model is studied below using DMFT and MC techniques.

**DMFT results:** Within DMFT, the self-energy is local; \( \Sigma(p, \omega_n) \rightarrow \Sigma_i(\omega_n) \) (\( \omega_n = (2n + 1)\pi T \) are the Mat-
subar frequencies). Since $\Sigma$ is momentum independent, the information about the hopping of carriers on and off lattice sites is carried by the bare Green's function $G_0(i\omega_n)$. With the effective action $S_{\text{eff}}(m)$ defined by $G_0$ quadratic in the Grassmann variables, the full Green's function $G$ can be solved by integration: 
\[
\langle G(i\omega_n) \rangle = \langle [G_0^{-1}(i\omega_n) + J S \mathbf{m}\sigma]^{-1} \rangle.
\]

The average $\langle X(m) \rangle = \int d\Omega_n X(m) P(m)$ is over the orientations $\mathbf{m}$ of the local moment with the probability $P(m)$. In the FM phase near $T_c$, $P(m) \propto \exp(-3\beta M\mathbf{m})$, where $\beta = 1/T$, and $M = \langle m_z \rangle_m$ is the local-order parameter, nonzero only below $T_c$. If two bands are active, then one rewrites the average above for each band; $\langle G_l(i\omega_n) \rangle = \langle (G_0^{-1}_l(i\omega_n) + J S \mathbf{m}\sigma)_l \rangle^{-1}$, and solve the equations for the coupled Green's functions: $\langle G_0^{-1}_l(i\omega_n) \rangle = z_n - t_l^2 \langle G_l(i\omega_n) \rangle - t_{l'}^2 \langle G_{l'}(i\omega_n) \rangle$, ($l \neq l'$) on a Bethe lattice with a semicircular noninteracting Density-Of-States

DOS$_l(\omega) = (4t_l^2 - \omega^2)^{1/2}/2\pi t_l^2$, where $z_n = i\omega_n + \mu$ ($\mu$ = chemical potential). $t_{l'}^2$ carries the information about the second band $l'$ through $G_{l'}$. To find $T_C$, we parametrize $G_0^{-1}_l(i\omega_n) = [z_n + R_l(i\omega_n)]\mathbf{I} + Q_l(i\omega_n)\tilde{\sigma}_z$, and linearize $G_0^{-1}_l$ with $M$. Up to first order:

\[
R_l = -t_l^2 \frac{B_l}{B_l^2 - J_l^2} - t_{l'}^2 \frac{B_{l'}}{B_{l'}^2 - J_{l'}^2}, \tag{2}
\]

where above, if $l = 1$ (2), then $l' = 2$ (1). At $t_{l'} = 0$, Eq. (2) reduces to:

\[
\sum_{n=0}^{\infty} \sum_{l=1}^{2} \frac{-2t_l^2 J_{l}^2}{3(B_l^2 - J_l^2)^2 - 3t_l^2 (B_l^2 - J_l^2)^2} = 1, \tag{5}
\]

where $B_l$ satisfies: $B_l^3 = z_n B_l^2 + (t_l^2 - J_l^2) B_l + z_n J_l^2 = 0$. We tested Eqs. (2), (5) in several cases: (1) at $t_{l'} = 0$ and $J_0 = 0$ we recovered the one-band model results reported in Ref. [2]; (2) at $t_2 = t_2$, $J_2 = 0$, and $J_1 \rightarrow \infty$, the results of Ref. [3] are reproduced. Details on the calculations above will be published elsewhere. From Eq. (2), the $T_C$ contained in the Matsubara frequencies was extracted numerically. Eq. (5) predicts an increase in $T_C$ only for the values of $\mu$ within the energy overlap interval.

In Fig. (a), the DOS$_l(\omega)$ at $J_1/t_1 = 25$ and $J_2/t_2 = 15$ is shown for several $t_{l'}$. Our $J_1/t_1$ are much larger than the value $(J_1/t_1)_{\text{min}} \approx 1.4$ that corresponds to the electron and hole bands formation, and than the value $J/t = 8$ considered in the one-band model large enough to capture properly the FM features of CMRs [4]. Hence, the electron bands are centered at $\omega_1 = -25$ and $\omega_2 = -15$, respectively (the hole bands, centered at $\omega_1^+ = 25$ and $\omega_2^+ = 15$ due to the electron-hole symmetry, are not shown here for simplicity). For clarity, we plotted DOS$_l(\omega)$ with a reversed sign. Since $|J_1/t_1 - J_2/t_2| \gg 1$, the bands occupy different energy intervals. As a consequence, each band gives its own contribution to $T_C$ (Fig. (b)). At $t_{l'} = 0$ the bands are fully decoupled, and the values of $T_C$ match the results of the one-band model for all $p$'s. However, if $t_{l'} \neq 0$, then the carriers are allowed to hop between the bands and, thus, they can belong simultaneously to both bands. This leads to an increase in the effective number of interacting electrons of each active band. As shown in Fig. (a), due to the transfer of electrons among bands, in DOS$_l(\omega)$ a new region occupied by the interacting electrons builds up within the interval of energies occupied by the DOS$_l(\omega)$. At $t_{l'} = t_1$, the effective number of interacting electrons within each energy interval becomes twice as large. In consequence, the $T_C$ for all $p$ corresponding to $\mu$ within each energy interval, is almost twice larger than in the one-band case (Fig.
FIG. 1: (a) DMFT zero-temperature interacting DOS for $J_1=25$ and $J_2=15$ at different values of $t_{12}$; (b) $T_C$ vs. $p$ for the cases shown in (a). Since the Hund’s couplings are very different, the bands and critical temperatures retain the semicircular form; (c) Zero-temperature interacting DOS at $t_{12}=0.5$, for the couplings indicated; (d) $T_C$ vs. $p$ for the cases shown in (c). Even if the overlap of bands is narrow, the exchange of electrons is strong enough to induce a robust $T_C$ at $p=1$ (black curve). In all frames $t_1=t_2=1$.

(b)). By contrary, when the $J_i$’s are similar the coupling of bands is strong enough to lead to a deviation from the semicircular form, especially when $t_{12} \sim |J_i-J_f|$ (Fig. 1(c)). If the bands partially overlap, a hump develops in $T_C$ at all values of $p$ corresponding to $\mu$ within the energy overlap interval (Fig. 1(d)).

In Fig. 2(a), the total interacting DOS $\mathrm{DOS}(\omega)$ at $t_1=1$, $t_2=1/3 \sim 0.33$ is shown, for different $t_{12}$ in the case when the bands fully overlap ($J_1/J_2=1$). The electron exchange effect does not only increase the effective number of interacting electrons in each band, but also extends the energy region occupied by the bands. However, the total number of interacting electrons does not change, the bands being fully filled for $p=2$. At $t_{12}=0$ (Eq. (5)) the increase in $T_C$ is due to the overlap of bands (green dashed curve in Fig. 2(b)). However, when $t_{12} \neq 0$ (see Eq. (1)) the exchange effect further boosts $T_C$ (Fig. 2(b)).

Monte Carlo results: The Hamiltonian (1) was also studied numerically using the MC methods widely applied to Mn-oxides [10] in the limit $J \to \infty$ [4]. Hence, the $e_g$-spins are perfectly aligned with the $t_{2g}$ spin. The technique involves finding the eigenvalues of the Hamiltonian matrix at each MC step corresponding to a newly updated set of localized spins. Although this substantially limits the size of the clusters being simulated, the results for small lattices are numerically exact and they allow for a direct comparison with DMFT. We have simulated lattices of sizes $8 \times 8$ in 2D and $4 \times 4 \times 4$ in 3D. The core spins are treated classically, while the treatment of the fermionic sector is exact. In all simulations $2 \times 10^4$ MC steps were used, the first $10^4$ been discarded in order to account properly for the thermalization of the random starting configuration. In finite dimensions, the hopping carries a direction index “$a$”, that is $t_{i,ij}^a$. In 2D (3D), $t_{i,ij}^a= - \sqrt{3} t_{i,ij}^x = - \sqrt{3} t_{i,ij}^{x,y} = 3 t_{i,ij}^z = 3 t_{i,ij}^{z,y} = 3 t_{i,ij}^{z,y} = 1$, $(t_x^a, t_y^a, t_z^a) = (0, t_{1,ij}^a = 1/3)$, in the $x$, $y$- (and $z$-) directions, respectively [11]. The indexes $l$ and $l'$ stand for the two active, $x^2-y^2$ and $3z^2-r^2$, orbitals. $t_3=1$ sets the energy unit. To find $T_C$ we investigate the long-range spin-spin correlations:

$$S(x) = \frac{1}{N} \sum_i \langle \hat{S}_i \cdot \hat{S}_{i+x} \rangle = \frac{1}{N} \sum_i \frac{\mathrm{Tr}(\hat{S}_i \hat{S}_{i+x} e^{-\beta H})}{\mathrm{Tr}(e^{-\beta H})},$$

where $N$ is the total number of sites. $T_C$ is the temperature for which $S \to 0$ upon heating, at the maximum distance $x_{max}$ in the clusters considered.

In Fig. 3 the results in 2D and 3D are displayed side-by-side for comparison. In panel (a), the spin-spin correlations at $x=x_{max}$ is shown for an $8 \times 8$ lattice, corresponding to different electron densities $p=N_e/2N$, where $N_e$ is the total number of electrons. The same in (d), but on a $4^3$ lattice. Moreover, we investigated $T_C$ vs. $p$ at $t_1=1$, $t_2=1/3$, and different $t_{12}$. The results are in Fig. 3(b) for 2D and in Fig. 3(e) for 3D. The $T_C$ is maximum at $p=1$ and vanishes in the limits $p \to 0$ and $p \to 2$, with an overall semicircular form in the phase diagram, as seen in the frames (c) and (f). The one-band phase diagram (denoted 1b) is also shown. Hence, as seen in (c) and (f), $t_{12}$ has a substantial effect in rising the $T_C$, which is in qualitative, and even in quantitative [12], agreement with DMFT. As $t_{12}$ increases from 0 to 1, the increase in
and the magnetization is turned on. The ideas developed here can be used to search for multiorbital FM materials with even higher $T_C$ than currently known, once the interband hopping is tuned up. Our study can be extended to Diluted Magnetic Semiconductors, with similar results expected [13]. We acknowledge conversations with R.S. Fishman, J. Moreno, G. Alvarez, A. Moreo, and T. Carsten. This research was supported by grant NSF-DMR-0443144.

$T_C$ can be as high as 100% in 2D and 60% in 3D.

The finite-size effects are checked using different boundary conditions as well as simulating clusters of up to 12×12 in 2D and 5×5×5 in 3D. The results are in Fig. 4, where the spin-spin correlations at $x = x_{\text{max}}$ (a) and the magnetization $|M|$ vs. $T$ curves (b) are shown. The size effects are small, showing that our MC method detects the $T_C$ accurately.

**Conclusion**: We carried out the first study of a multiband DE model applied to CMR using a powerful combination of DMFT and MC techniques. When two active bands are considered, the $T_C$ is maximized at $p=1$. DMFT shows that the interband hopping leads to an increase in $T_C$ at all $p$’s, even if the electron bands do not occupy the same energy interval. This is due to the electron exchange between the bands, which increases the effective number of interacting electrons within each band. Both DMFT and MC indicate that, if the bands fully overlap, besides the increase of $T_C$ due to the energy overlap, a further boost occurs when the interband hopping is turned on. The ideas developed here can be used to search for multiorbital FM materials with even higher $T_C$ than currently known, once the interband hopping is tuned up.

$T_C$ can be as high as 100% in 2D and 60% in 3D.

The finite-size effects are checked using different boundary conditions as well as simulating clusters of up to 12×12 in 2D and 5×5×5 in 3D. The results are in Fig. 4, where the spin-spin correlations at $x = x_{\text{max}}$ (a) and the magnetization $|M|$ vs. $T$ curves (b) are shown. The size effects are small, showing that our MC method detects the $T_C$ accurately.

**Conclusion**: We carried out the first study of a multiband DE model applied to CMR using a powerful combination of DMFT and MC techniques. When two active bands are considered, the $T_C$ is maximized at $p=1$. DMFT shows that the interband hopping leads to an increase in $T_C$ at all $p$’s, even if the electron bands do not occupy the same energy interval. This is due to the electron exchange between the bands, which increases the effective number of interacting electrons within each band. Both DMFT and MC indicate that, if the bands fully overlap, besides the increase of $T_C$ due to the energy overlap, a further boost occurs when the interband hopping is turned on. The ideas developed here can be used to search for multiorbital FM materials with even higher $T_C$ than currently known, once the interband hopping is tuned up. Our study can be extended to Diluted Magnetic Semiconductors, with similar results expected [13].
