Summary.—Local free cell (eosinophils and macrophages) and extracellular (acid mucopolysaccharides) reactions were studied by histochemical techniques in 72 primary lung cancers (Group A), 17 pulmonary metastases and 5 lung tumours of unknown origin (Group B). Strong cellular reactions were more frequent in Group A than in Group B, whereas extracellular reactions were more frequent in Group B than in Group A. In both groups the degrees of eosinophilic infiltration and accumulation of acid mucopolysaccharides tended to be negatively correlated. In contrast, macrophages and eosinophils showed a positive correlation in the primary cancers, but none in the other tumours.

The extracellular material had physical and chemical properties (solubility, affinity to stains and degradability by enzymes) of the sulphated acid mucopolysaccharides. From its distribution it appeared to be derived from fibroblasts and/or tumour cells.

In some experimental tumour systems the host develops an immune reaction against a neoplastic transplant, mediated in part by infiltrating cells in contact with the tumour cells. Important effectors of this defence reaction appear to be macrophages (Evans, 1972; Eccles & Alexander, 1974). On the other hand, the concept of “stromal reaction”, an ill-defined term coined by Russell (1908) has emerged from time to time for various observations in human tumour pathology: for “inflammatory infiltrates” in breast cancer (Berg, 1959) and carcinoma of the oesophagus (Takahashi, 1961) “elastosis” in breast carcinoma (Shivas & Douglas, 1972) “lymphocytic infiltrations” in gastric carcinoma (Black et al., 1956), neuroblastoma (Lauder & Aherne, 1972) and ovarian cancer (Barber et al., 1975), macrophages in melanomas (Roubin et al., 1975) and plasma cells and antibody in lung cancer (Ioachim et al., 1976). We now add another triad of pieces to the puzzle: eosinophils, macrophages and acid mucopolysaccharides in primary and secondary human lung cancers. Initially we were stimulated by the experimental “macrophage wave” but decided to focus on macrophages and eosinophils in the hope of gaining additional insight into the mechanisms of the host response. In the end the spectrum was widened by the inclusion of extracellular acid mucopolysaccharides. The choice of this parameter grew from accidental observations of odd strands of poorly structured metachromatic material between tumour cell groups and individual cells. No connection between the 3 parameters was implied at the beginning. A comparison between the results in 72 primary lung cancers, 17 pulmonary meta-

stases and 5 tumours of unknown origin is presented.

MATERIALS AND METHODS

Handling of tumour specimens.—The tumours were processed immediately after they had been removed. Small pieces were cut from the margin of the neoplasm together with a rim of lung tissue, packed air tight, frozen and stored at −20°C. Care was taken to choose the material from intact, non-necrotic parts. At weekly intervals 4-6 tumours were worked up together by histochemical procedures and examined by the same person (E.M.).

Staining techniques.—The frozen tissues were cut at 8 μm in the cryostat and the sections dried at 4°C before incubation for histochemical reactions. For identification of the cell types studied, an appropriate enzyme-staining technique was used.

Eosinophils were demonstrated by the benzidine method (van Duijn, 1955) with addition of L-DOPA (Müller, 1977) for peroxidase (E.C. 1.11.1.7) whilst macrophages were identified with the α-naphthyl-acetate method (Pearse, 1972) for non-specific esterases (E.C. 3.1.1.1).

For demonstration of non-specific metachromasia of mucopolysaccharides, toluidine blue and Giemsa-May-Grünwald staining were used.

For differential staining of acid glycosaminoglycans the alcian blue (Scott & Dorling, 1965) and the acridine orange-CTAC (Saunders, 1964) methods were used, each with the proper critical electrolyte concentrations.

RESULTS

The histochemical observations were recorded without knowledge of operative or other clinical data, and before the histological diagnosis was known. Initially the tumours were studied for infiltrating cells only, either eosinophils or macrophages or both. However, it became evident after 39 tumours had been examined, that "metachromasia" observed with toluidine blue staining might also be worth systematic evaluation, because it was so conspicuous in some, but absent in other cases. Therefore, metachromasia was added as a third parameter in the subsequent 92 tumours examined and herein presented. The incomplete results of the first 39 tumours were omitted.

Eosinophils

These cells, which contain peroxidase in abundance, were easy to identify by the brown-black reaction deposit of the enzyme developed histochemically. As Fig. 1 shows, the cells were spread singly or in clusters in the scarce stroma of tumours with a compact structure. On the other hand, in tumours growing more invasively into the parenchyma of the lung, the eosinophils were more irregularly scattered and mostly localized in the interalveolar septa. In addition, the blood vessels nearby sometimes contained numerous eosinophils. Occasionally the adjacent parenchyma of the lung showed small groups of lymphocytes arranged in pseudofollicles, sometimes surrounded by eosinophils.

Macrophages

As Fig. 3 shows, these cells were identified by the reaction deposit for non-specific esterases. Not every macrophage showed equally strong enzyme activity; all shades of intensities being observed (Fig. 4). The macrophages were distributed in densely packed clusters within septa and alveoli throughout the parenchyma of the lung. They were, however, never detected within the venules surrounding the tumour.

Metachromasia

Some tumours, when stained with alcian blue or toluidine blue, were interwoven with intensely metachromatic strands (Fig. 5) containing few cellular elements (Fig. 7). At higher magnification much metachromatic material could often be detected also between the tumour cells themselves (Fig. 7). Alcian blue staining with the addition of different concentrations of magnesium chloride, allowed partial characterization of the mucopolysaccharides in the strands. At low concentrations of MgCl₂ (0.1–0.3m) the ground

Fig. 2.—Irregular distribution of eosinophils in an invasively growing lung tumour. Most of the reactive cells seem to be localized in the interalveolar septa. Peroxidase incubation and toluidine blue counterstaining.

Fig. 3.—Dense clusters of macrophages within the pulmonary alveoli and septa after incubation for non-specific esterases. The tissue of the invasively growing tumour (right corner) and the lung parenchyma are unstained.

Fig. 4.—Higher magnification of a macrophage cluster in the same lung tumour incubated for non-specific esterases. Note the varying enzyme intensities of the cells. No counterstaining.
while the tumour cells lost the stain (Fig. 6). From these results the metachromatic material could be chondroitin sulphate, heparin or keratin sulphate, but not hyaluronic acid. Confirming results were obtained with the acridine orange—CTAC-method.

Enzymic digestion studies showed the material to be resistant to hyaluronidase, neuraminidase, collagenase and trypsin; however, it could be washed out after digestion with pepsin. Therefore it appeared to be firmly bound to a protein backbone. Preliminary preparative extraction and electrophoresis (unpublished) showed that the metachromatic material had an electrophoretic mobility of its own, contained a small fraction of hyaluronidase-digestible, but a major nondigestible fraction. This fraction was also resistant to neuraminidase. Its electrophoretic mobility was distinct from extracted acid mucopolysaccharides of normal lung, trachea, cartilage, bronchial mucosa and peritracheal connective tissue used as controls, and from the markers commercial animal hyaluronic acid, chondroitin sulphates A and C and heparin. From these properties the material seemed to belong to the group of chondroitin sulphates B.

**Grading of cellular and extracellular reactions**

The following grading scales for the 3 parameters were used in the preliminary studies: (0), (+), (++) and (+++). In the definitive studies presented in this report, the degrees (++) and (+++) were no longer differentiated. They were mentally combined and are designated (+++) in the figures, meaning “strong reactivity” as opposed to “weak reactivity (+)” and “no reactivity (0)”. In Figs. 8–10 the reactions were correlated separately for the primary lung cancers and all the other tumours taken together. Shaded areas were used to point out the main parameter under consideration and its major relationship to one other parameter. Fig. 8 shows the correlations
between macrophages and eosinophils. Numerous macrophages were observed in 45/70 primary lung cancers (A); in 30/45 they were accompanied by numerous eosinophils, in 11/45 by few, and in only 4/45 were there no eosinophils. No correlation between the 2 cell types was evident however in the other tumours (B). In contrast, an inverse correlation of a similar degree was found between metachromasia and eosinophils (Fig. 9). No metachromasia was found in 38/72 primary tumours (A); this was associated with strong eosinophilia in 24/38, few eosinophils in 12/38 and none in 2/38 cases. There was also an inverse correlation...
between the 2 parameters in the other
tumours (B). Likewise, the correlation
between metachromasia and macrophages,
as demonstrated in Fig. 10, tended to be
negative in the primary lung cancers (A),
but was not clear-cut for the other group
(B).

DISCUSSION

The identification of reactive cell types
in human tumours is often neglected,
mainly because the relevant enzymes are
destroyed by fixation, the usual staining
is inadequate for this purpose and sur-
geons are more interested in histology than
in immunology. The results presented
show that more than half of the primary
lung cancers induced a strong infiltration
by free cells, usually both macrophages
and eosinophils, and only about a third
showed strong metachromasia; on the
other hand, locally strong eosinophilia
was found in only 5/22 other tumours, but
strong metachromasia in 10 of them. Thus,
the 2 tumour groups showed opposite
tendencies for the cellular and extracellu-
lar parameters, and within the same
group, the 2 parameters seemed to be
inversely correlated. However, strong
metachromasia, present in 20 primary
tumours, was not incompatible with strong
cellular reactivity; about half of these
tumours showed strong intensity for both
free cells and metachromasia. Of the other
tumours, 2/22 showed this type of reaction.
These observations indicate that patterns
of local response can be discerned in
malignant lung tumours; that cellular and
extracellular reactions may be correlated;
and that there are differences between
primary cancers (53 squamous-cell types,
9 undifferentiated tumours excluding oat-
cell types, 7 adenocarcinomas and 3
alveolar-cell carcinomas; for further
details see Kolb & Müller, 1979) and meta-
static tumours or tumours of unknown
origin (11 different histologies, including
6 hypernephromas and 5 teratomas).
From the frequent pattern in primary
tumours "strong cellular reactivity, no
metachromasia" and the less frequent, but
not to be ignored combination "strong
cellular reaction, strong metachromasia",
we suggest that the cellular and extra-
cellular responses do not depend directly
upon each other, but that the former
expresses host responsiveness, while the
latter expresses a complex interaction of
tumour cells and fibroblasts, with tumour cells perhaps inducing an abnormal fibroblast reaction (Dixon & Moore, 1953; Shivas & Douglas, 1972; Howard et al., 1976) possibly by producing acid mucopolysaccharides themselves (Takeuchi et al., 1976; Sampaio et al., 1977; Glimelius et al., 1978). However, strong metachromasia, frequently seen in metastatic tumours, might inhibit cellular responses. The possible significance of these observations will be evaluated in the subsequent paper by correlating them with clinical data (Kolb & Müller, 1979).

This work was supported by a grant from the Hartmann Muller-Stiftung.
